Contents

1	Overview	20
1.1	Document Overview	20
1.2	General Modeling Overview	20
1.3	Simulation Manager	20
1.4	Warmup Convergence	22
2	Integrated Solution Manager	25
2.1	Basis for the Zone and Air System Integration	26
2.1.1	Zone Sensible Heat Capacity Multiplier	29
2.2	Summary of Predictor-Corrector Procedure	30
2.3	Air System Control	30
2.4	Moisture Predictor-Corrector	35
2.4.1	Moisture Prediction	36
2.4.2	Moisture Correction	38
2.4.3	Which moisture buffering model is best?	40
2.5	Carbon Dioxide Predictor-Corrector	41
2.5.1	Carbon Dioxide Prediction	43
2.5.2	Carbon Dioxide Correction	44
2.6	Generic Contaminant Predictor-Corrector	45
2.6.1	Generic Contaminant Prediction	46
2.6.2	Generic Contaminant Correction	48
2.7	Zone Air Mass Flow Conservation	49
2.7.1	Overview	49
2.7.2	Return Air Flow Rate Calculations	49
2.7.3	Zone Mixing Flow Rate Calculations	52
2.7.4	Infiltration Flow Rate Adjustments	54
2.8	Summary of Time Marching Solution	55
2.8.1	Summary of Timestep Model Formulation	55
2.8.2	Zone Update Method	55
2.8.3	Variable Timestep	57
2.8.4	Simultaneous Solution of Plant/System Water Loop	58
2.8.5	References	59
3	Surface Heat Balance Manager / Processes	60
3.1	Conduction Through The Walls	60
3.1.1	Conduction Transfer Function Module	60

3.1.2	Calculation of Conduction Transfer Functions	61
3.1.3	Conduction Transfer Function (CTF) Calculations in EnergyPlus	65
3.1.4	Conduction Transfer Function (CTF) Calculations Special Case: R-Value Only Layers	67
3.1.5	References	69
3.2	Conduction Finite Difference Solution Algorithm	70
3.2.1	Basic Finite Difference Solution Approach	70
3.2.2	Finite Difference Node Arrangement in Surfaces	74
3.2.3	Conduction Finite Difference Variable Thermal Conductivity	75
3.2.4	Conduction Finite Difference Source Sink Layers	75
3.2.5	Conduction Finite Difference Heat Flux Outputs	75
3.2.6	References	76
3.3	Combined Heat and Moisture Transfer (HAMT) Model	76
3.3.1	Overview	76
3.3.2	HAMT Nomenclature	77
3.3.3	HAMT Model Description	78
3.3.4	References	82
3.4	Effective Moisture Penetration Depth (EMPD) Model	82
3.4.1	Overview	82
3.4.2	EMPD Model Description	82
3.4.3	EMPD Nomenclature	85
3.4.4	References	86
3.5	Outside Surface Heat Balance	86
3.5.1	External Shortwave Radiation	88
3.5.2	External Longwave Radiation	88
3.5.3	References	90
3.5.4	Atmospheric Variation	90
3.5.5	Outdoor/Exterior Convection	93
3.5.6	Exterior/External Conduction	103
3.5.7	Additional Heat Balance Source	103
3.5.8	References	103
3.6	Inside Heat Balance	104
3.6.1	Internal Long-Wave Radiation Exchange	104
3.6.2	Internal Short-Wave Radiation	108
3.6.3	Interior Conduction	109
3.6.4	Interior Convection	109
3.6.5	Additional Heat Balance Source	128
3.7	Adiabatic Boundary Conditions	129
3.8	Infrared Radiation Transfer Material	129
3.8.1	Radiation Exchange Basics	130
3.8.2	IRT Radiation Exchange in EnergyPlus	134
3.8.3	Radiation Transfer Surface Details	134
3.8.4	Behavior Checks	135
3.9	Transparent Insulation Material (TIM)	137
3.9.1	Introduction	137
3.9.2	Comparison of Opaque and Transparent Insulation	138

3.9.3	Types of Transparent Insulation Materials	139
3.9.4	TIM- Basic Mathematical Model	140
3.9.5	Sample Test Run Cases: – Comparison	142
3.9.6	References	143
3.10	Surface Heat Balances With Moveable Insulation	144
3.10.1	Inside Heat Balance with Interior Moveable Insulation	144
3.10.2	Outside Heat Balance Cases for Exterior Moveable Insulation	146
3.10.3	Heat Balance Cases	147
3.10.4	C++ Algorithm Examples	150
3.10.5	C++ Variable Descriptions	151
3.10.6	References	153
3.11	Ground Heat Transfer Calculations using Foundation:Kiva	153
3.11.1	Approach	153
3.11.2	Two-dimensional Approximation	153
3.11.3	Numerical Calculations	154
3.11.4	Boundary Conditions	154
3.11.5	Multiple Kiva Instances	157
3.11.6	Core Zone Slabs	162
3.11.7	Warm-Up	162
3.11.8	Validation	163
3.11.9	References	163
3.12	Ground Heat Transfer Calculations using C and F Factor Constructions	164
3.13	Ground Heat Transfer Calculations using Site:GroundDomain:Slab	167
3.14	Ground Heat Transfer Calculations using Site:GroundDomain:Basement	169
3.15	Undisturbed Ground Temperature Model: Finite Difference	171
3.16	Undisturbed Ground Temperature Model: Kusuda-Achenbach	173
3.17	Undisturbed Ground Temperature Model: Xing	173
4	Advanced Surface Concepts	175
4.1	Exterior Naturally Vented Cavity	175
4.1.1	Baffle Heat Balance	175
4.1.2	Cavity Heat Balance	178
4.1.3	Underlying Heat Transfer Surface	179
4.1.4	Solar and Shading Calculations	180
4.1.5	Local Wind Speed Calculations	180
4.1.6	Convection Coefficients	180
4.1.7	Radiation Coefficients	181
4.1.8	References	181
4.2	Green Roof Model (EcoRoof)	182
4.2.1	Overview	182
4.2.2	Green Roof Model Description	183
4.2.3	Linearization	188
4.2.4	Final Equations	189
4.2.5	Green Roof Nomenclature	189
4.2.6	References	191
4.3	Underwater Surface Boundary Condition	192

4.3.1	Overview	192
5	Climate, Sky and Solar/Shading Calculations	193
5.1	Climate Calculations	193
5.1.1	EnergyPlus Design Day Temperature Calculations	194
5.1.2	Sky Radiation Modeling	195
5.1.3	EnergyPlus Sky Temperature Calculation	196
5.1.4	EnergyPlus Design Day Solar Radiation Calculations	196
5.1.5	Perez Direct/Diffuse Splitting Model	199
5.1.6	Weather File Solar Interpolation	199
5.1.7	Variable Location and Orientation	200
5.1.8	References	200
5.2	Design Week Specification	200
5.3	Sky Radiance Model	200
5.3.1	Sky Diffuse Solar Radiation on a Tilted Surface	203
5.3.2	Shadowing of Sky Diffuse Solar Radiation	204
5.3.3	Shadowing of Sky Long-Wave Radiation	206
5.4	Shading Module	206
5.4.1	Shading and Sunlit Area Calculations	206
5.4.2	Solar Position	207
5.4.3	Surface Geometry	207
5.4.4	Shadow Projection	211
5.4.5	Polygon Clipping	211
5.4.6	Pixel Counting	221
5.4.7	Solar Gains	221
5.4.8	Solar Distribution	222
5.4.9	Details of the Interior Solar Distribution Calculation	223
5.4.10	Ground Reflectances	229
5.4.11	Ground Reflectances (Snow)	229
5.4.12	References	230
6	Solar Radiation Reflected from Exterior Surfaces	231
6.1	Diffuse Reflection of Beam Solar and Sky Solar Radiation	233
6.1.1	Receiving points	233
6.1.2	Rays	234
6.1.3	Sky Solar Radiation Diffusely Reflected from Obstructions	234
6.1.4	Sky Solar Radiation Diffusely Reflected from the Ground	236
6.1.5	Beam Solar Radiation Diffusely Reflected from Obstructions	237
6.1.6	Beam Solar Radiation Diffusely Reflected from the Ground	237
6.1.7	Beam Solar Radiation Specularly Reflected from Obstructions	238
7	Daylighting and Window Calculations	240
7.1	Daylighting Calculations	240
7.2	Daylight Factor Calculation	241
7.2.1	Overview	246
7.2.2	Interior Illuminance Components	246

7.2.3	Daylight Factors	246
7.2.4	Sky Luminance Distributions	247
7.2.5	Direct Normal Solar Illuminance	250
7.2.6	Exterior Horizontal Illuminance	250
7.2.7	Direct Component of Interior Daylight Illuminance	250
7.2.8	Internally-Reflected Component of Interior Daylight Illuminance	252
7.2.9	Transmitted Flux from Sky and Ground	253
7.2.10	Transmitted Flux from Direct Sun	254
7.2.11	Luminance of Shaded Window	255
7.2.12	Daylight Discomfort Glare	255
7.3	Time-Step Daylighting Calculation	257
7.3.1	Overview	257
7.3.2	Time-Step Sky Luminance	259
7.3.3	Interior Illuminance	260
7.3.4	Glare Index	262
7.3.5	Lighting Control System Simulation	262
7.3.6	References	265
7.4	DElight Daylighting Calculations	265
7.4.1	DElight Daylight Factor Calculation Differences from SplitFlux Methods	266
7.4.2	DElight Time-Step Interior Daylighting Calculation Differences from Split-Flux Methods	269
7.4.3	References	269
7.5	Complex Fenestration Daylighting Calculations	269
7.5.1	Internal Average Reflected Illuminance From Window	270
7.5.2	Luminance from Exterior Elements	273
7.5.3	Luminous Flux and Direct Illuminance at Interior Side of the Window	273
7.5.4	Handling Exterior Obstructions	273
7.6	Daylighting Devices	275
7.6.1	Tubular Daylighting Devices	275
7.6.2	Daylighting Shelves	284
7.6.3	Window Light Well	288
7.7	Window Calculation Module	290
7.7.1	Optical Properties of Glazing	290
7.7.2	Glass Layer Properties	294
7.7.3	Glass Optical Properties Conversion	294
7.7.4	Simple Window Model	294
7.7.5	Glazing System Properties	300
7.7.6	Calculation of Angular Properties	302
7.7.7	Calculation of Hemispherical Values	306
7.7.8	Optical Properties of Window Shading Devices	307
7.7.9	Thermochromic Windows	310
7.7.10	Screen Properties and Calculations	331
7.7.11	Complex Fenestration Calculation Module	342
7.8	Window Heat Balance Calculation	368
7.8.1	The Glazing Heat Balance Equations	369
7.8.2	Room-Side Convection	371

7.8.3	Solving the Glazing Heat Balance Equations	373
7.8.4	Edge-Of-Glass Effects	373
7.8.5	Apportioning of Absorbed Short-Wave Radiation in Shading Device Layers .	377
7.8.6	Window Frame and Divider Calculation	377
7.8.7	Beam Solar Reflection from Window Reveal Surfaces	384
7.8.8	Shading Device Thermal Model	392
7.8.9	Heat Balance Equations for Shading Device and Adjacent Glass	393
7.8.10	Solving for Gap Airflow and Temperature	395
7.8.11	Improved Airflow Equations for Window Screens and Horizontal Louvered Blind Systems	400
7.8.12	Heat Balance Equations for Between-Glass Shading Device	403
7.8.13	Airflow Windows	406
7.8.14	Evacuated Glazing Unit (EGU)	410
7.8.15	Thermal Performance of Deflected Insulated Glazing Unit (IGU)	415
7.8.16	Equivalent Layer Fenestration Model	426
8	Air Heat Balance Manager / Processes	440
8.1	Convection from Surfaces	440
8.2	Convection from Internal Sources	440
8.3	Infiltration/Ventilation	440
8.3.1	Infiltration	440
8.3.2	Infiltration Design Flow Rate	441
8.3.3	Infiltration by Effective Leakage Area	442
8.3.4	Infiltration by Flow Coefficient	442
8.3.5	Ventilation	443
8.3.6	Ventilation Design Flow Rate	443
8.3.7	Ventilation by Wind and Stack with Open Area	444
8.3.8	Zone Air Balance Outdoor Airflow (ZoneAirBalance:OutdoorAir)	445
8.3.9	Reference	446
8.4	Air Exchange	446
8.4.1	Temperature Difference Controlled Air Exchange	447
8.4.2	Density Difference Controlled Air Exchange	448
8.4.3	References	450
8.5	Calculation of Zone Air Temperature	450
9	Building System Simulation System Manager / Processes	451
9.1	Air Loops	451
9.1.1	Definition of Air Loop	451
9.1.2	Simulation Method	451
9.1.3	Component Models	452
9.1.4	Iteration Scheme	452
9.1.5	Determination of Air Mass Flow Rates	452
9.2	Air Loop Simulation	452
9.3	Primary Air System Simulation	454
9.3.1	Input data	455
9.3.2	Initialization Calculations	456

9.3.3	Central air system simulation	458
9.4	Outdoor Air System	458
9.4.1	Simulation	459
9.5	Outdoor Air Mixer	459
9.5.1	Simulation	459
9.6	Zone Equipment Simulation	459
9.6.1	Input data	460
9.6.2	Initialization Calculations	461
9.6.3	Simulation	461
9.6.4	Zone Equipment Load Distribution	463
9.7	Air Path Components	464
9.7.1	Overview	464
9.7.2	Zone Supply Air Path	464
9.7.3	Zone Splitter	464
9.7.4	Zone Supply Plenum	464
9.7.5	Zone Return Air Path	465
9.7.6	Zone Mixer	465
9.7.7	Zone Return Plenum	465
9.8	Plant Load Profile	466
9.8.1	Calculation Model	466
9.9	Plant/Condenser Loops	467
9.9.1	Integration of System and Plant	467
9.9.2	Current Primary System Modeling Methodology	467
9.9.3	Plant Manager	469
9.9.4	Plant Flow Resolver	471
9.9.5	Summary of Load Distribution Schemes	479
9.9.6	Summary of Plant Loop Demand Calculation Schemes	483
9.9.7	Plant and Condenser Equipment Operation Schemes	485
9.9.8	Plant Operation Schemes	485
9.9.9	Condenser Operation Schemes	485
9.9.10	Primary-Secondary Loop Systems	487
9.9.11	Heat Recovery Loop Systems	489
9.9.12	Plant Pressure Drop Simulation	492
9.10	Steam Systems and Component Models	496
9.10.1	Steam Loop Assumptions	497
9.10.2	Steam To Air Heat Exchanger	502
9.10.3	Condensate Pump	508
9.10.4	Steam Pipe	510
10	Loop, Equipment Sizing and other Design Data	512
10.1	Sizing Manager	512
10.2	HVAC Sizing Simulation Manager	514
10.3	Zone Design Loads and Air Flow Rates	515
10.3.1	Overview	515
10.3.2	Zone Design Data Arrays	515
10.3.3	Zone Design Load Calculation	517

10.3.4	Updating and Adjusting the Zone Results	519
10.3.5	Air Terminal Unit Sizing	521
10.3.6	Zone HVAC Scalable Sizing	522
10.4	System Design Loads and Air Flow Rates	522
10.4.1	Overview	522
10.4.2	System Design Data Arrays	523
10.4.3	System Design Flow Rate and Load Summation and Adjustment	525
10.4.4	System Sizing Adjustments for Air Terminal Operation	530
10.4.5	Central Heating Maximum System Air Flow Ratio Sizing	531
10.4.6	System Design Outdoor Air Flow Rate	532
10.4.7	Scalable System HVAC Sizing	532
10.5	Plant and Condenser Loop Sizing	533
10.5.1	Maximum Loop Flow Rate	533
10.5.2	Loop Volume	533
10.6	Coincident Plant Sizing using HVAC Sizing Simulation	533
10.7	Component Sizing	535
10.7.1	Introduction	535
10.7.2	Fan Sizing	535
10.7.3	Design Fan Heat	535
10.7.4	Coil:Cooling:Water	536
10.7.5	Coil:Cooling:Water:DetailedGeometry Sizing	543
10.7.6	CoilSystem:Cooling:Water	545
10.7.7	Coil:Cooling:WaterToAirHeatPump:EquationFit Sizing	545
10.7.8	Coil:Cooling:WaterToAirHeatPump:VariableSpeedEquationFit Sizing	547
10.7.9	Coil:Heating:WaterToAirHeatPump:EquationFit Sizing	549
10.7.10	Coil:Heating:WaterToAirHeatPump:VariableSpeedEquationFit Sizing	549
10.7.11	Coil:Heating:Water Sizing	550
10.7.12	Coil:Heating:Steam Sizing	552
10.7.13	Sizing of Gas and Electric Heating Coils	554
10.7.14	DX Coil Sizing	555
10.7.15	DX MultiSpeed Coil Sizing	559
10.7.16	Coil:Cooling:DX:VariableSpeed Sizing	560
10.7.17	Coil:Heating:DX:VariableSpeed Sizing	561
10.7.18	Pump Sizing	561
10.7.19	Electric Chiller Sizing	562
10.7.20	Water to Water Heat Pump Sizing	563
10.7.21	Boiler Sizing	564
10.7.22	Plant Heat Exchanger Sizing	564
10.7.23	Humidifier Sizing	565
10.7.24	Cooling Tower Sizing	567
10.7.25	Fluid Cooler Sizing	570
10.7.26	Evaporative Fluid Cooler Sizing	572
10.7.27	Fan Coil Unit Sizing	575
10.7.28	Window Air Conditioner Sizing	576
10.7.29	Unit Ventilator Sizing	577
10.7.30	Packaged Terminal Heat Pump Sizing	577

10.7.31 MultiSpeed Heat Pump Sizing	578
10.7.32 Single Duct Terminal Units	579
10.7.33 Indirect Evaporative Cooler Sizing	581
10.7.34 Secondary DX Coils Sizing	581
10.7.35 Desiccant Dehumidifier Sizing	581
10.7.36 Evaporative Cooler Sizing	582
10.7.37 Heat Recovery Sizing	583
10.7.38 Low Temperature Radiant System Sizing	584
10.7.39 Unitary System Sizing	585
10.8 Zone Outdoor Air Design Data	586
10.8.1 Design Outdoor Air Calculation	587

Chapter 1

Overview

1.1 Document Overview

This document is organized to give you the best possible look into the EnergyPlus calculations. First, the concepts of modeling in EnergyPlus are presented. These include descriptions of the zone heat balance process, air loop/plant loop processes as well as other important processes for the building simulation.

Discussions during the modeling process may reference specific “object names” as found in the Input/Output Reference document.

The remainder of the document focuses on individual models.

1.2 General Modeling Overview

The EnergyPlus program is a collection of many program modules that work together to calculate the energy required for heating and cooling a building using a variety of systems and energy sources. It does this by simulating the building and associated energy systems when they are exposed to different environmental and operating conditions. The core of the simulation is a model of the building that is based on fundamental heat balance principles. Since it is relatively meaningless to state: “based on fundamental heat balance principles”, the model will be described in greater detail in later sections of this document in concert with the C++ code which is used to describe the model. It turns out that the model itself is relatively simple compared with the data organization and control that is needed to simulate the great many combinations of system types, primary energy plant arrangements, schedules, and environments. The next section shows this overall organization in schematic form. Later sections will expand on the details within the blocks of the schematic.

1.3 Simulation Manager

The simulation manager of EnergyPlus is contained in a single module. The main subroutine is shown below. Flow within the entire program is managed using a series of flags. These paired flags, in order (from the highest to the lowest) are:

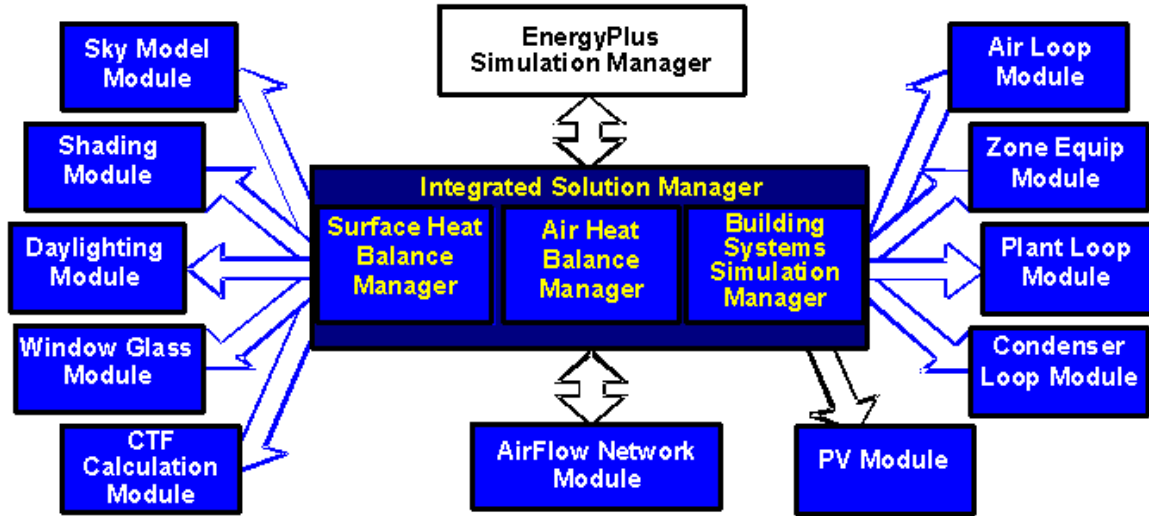

Figure 1.1: EnergyPlus Program Schematic

Table 1.1: Simulation Flags

BeginSimulationFlag	EndSimulationFlag
BeginEnvironmentFlag	EndEnvironmentFlag (one to many days)
BeginDayFlag	EndDayFlag
BeginHourFlag	EndHourFlag
BeginTimeStepFlag	EndTimeStepFlag

There is also a **WarmupFlag** to signal that the program is in warmup state. The operation of these flags can be seen in the following subroutine. This code is actually simplified, old EnergyPlus FORTRAN code but it concisely demonstrates the use of these flags in the code. The advantage of using the flag system is that any subroutine throughout the code can determine the exact state of the simulation by checking the status of the flags.

```

SUBROUTINE ManageSimulation      ! Main driver routine for this module
BeginSimFlag = .TRUE.
EndSimFlag = .FALSE.
CALL OpenOutputFiles
CALL GetProjectData
CALL GetEnvironmentInfo          ! Get the number and type of Environments
DO Envrn = 1, NumOfEnvrn        ! Begin environment loop ...
  BeginEnvrnFlag = .TRUE.
  EndEnvrnFlag = .FALSE.
  WarmupFlag = .TRUE.
  DayOfSim = 0
  DO WHILE ((DayOfSim.LT.NumOfDayInEnvrn).OR.(WarmupFlag)) ! Begin day loop ...
    DayOfSim = DayOfSim + 1
    BeginDayFlag = .TRUE.
    EndDayFlag = .FALSE.
    DO HourOfDay = 1, 24      ! Begin hour loop ...
      BeginHourFlag = .TRUE.
      EndHourFlag = .FALSE.
      DO TimeStep = 1, NumOfTimeStepInHour ! Begin time step (TINC) loop ...
        BeginTimeStepFlag = .TRUE.
        EndTimeStepFlag = .FALSE.
        ! Set the End_Flag variables to true if necessary. Note that each flag builds on
        ! the previous level. EndDayFlag cannot be .true. unless EndHourFlag is also .true.,
        ! etc.
        ! Note that the EndEnvrnFlag and the EndSimFlag cannot be set during warmup.
        ! Note also that BeginTimeStepFlag, EndTimeStepFlag, and the
        ! SubTimeStepFlag can/will be set/reset in the HVAC Manager

```

```

END DO                      ! ... End environment loop.
CALL CloseOutputFiles
RETURN
END SUBROUTINE ManageSimulation

```

1.4 Warmup Convergence

At the beginning of each new environment (design day or runperiod) zone and surface temperatures are initialized to 23C, and zone humidity ratios are initialized to the outdoor humidity ratio. The first day of the environment is repeated until the loads/temperature convergence tolerance values specified in the Building object are satisfied or until it reaches “maximum number of warmup days”.

Since everything in EnergyPlus is based on the foundation of the loads simulation, it stands to reason that any inaccuracies in the loads calculation will result in inaccuracies of similar or larger magnitude in the HVAC calculations. In the presumably limited cases where convergence was not truly achieved before the actual simulation began, it is unknown how much error would be introduced into the results. While simulations that last longer (annual vs. design day) will hopefully have any initial condition problems balanced by the sheer number of days in the simulation, shorter simulations—particularly those used for sizing—could result in relatively large errors. The simulation results could be unreliable and inaccurate when steady periodic conditions are not achieved. Therefore, it is important to properly determine when there is enough temperature and flux history terms to start an EnergyPlus simulation since this has a potential economic and energy impact on buildings that use EnergyPlus in design.

EnergyPlus determines warmup convergence in the following manner as shown in the Figure 1.2 below. The process of the convergence checks begins by tracking four parameters such including the maximum zone air temperature, the minimum zone air temperature, the maximum heating load, and the maximum cooling load for individual zone. It is note that these convergence checks are only in effective in simulations with at least one zone since the criteria is solely based on the maximum and minimum values obtained from an individual zone. Differences in these parameters between two consecutive days are then compared with the convergence tolerance values at the end of the day during the warmup period. For example, the maximum and minimum air temperature and the percentage difference of zone load for each zone at 9:00AM during the second to last warmup is compared to the values at 9:00AM last warmup day as follows:

$$T_{\max,prev} - T_{\max} < T_{tol} \quad (1.1)$$

$$T_{\min,prev} - T_{\min} < T_{tol} \quad (1.2)$$

$$\frac{q_h - q_{h,prev}}{q_h} < q_{tol} \quad (1.3)$$

$$\frac{q_c - q_{c,prev}}{q_c} < q_{tol} \quad (1.4)$$

where $T_{\max,prev}$ is the maximum zone temperature of previous day, T_{\max} is the maximum zone temperature of current day, T_{tol} is the value of temperature tolerance, $q_{h,prev}$ is the maximum heating load of previous day, q_h , is the maximum heating load of current day, q_{tol} is the value

of load tolerance, $q_{c,prev}$ is the maximum cooling load of previous day, and q_c , is the maximum cooling load of current day.

Note that a minimum load of 100W is used to establish a fraction for the maximum loads when they are less than the minimum. This is done to avoid a false negative indication for the percentage load difference that may appear when zonal loads are very small. The convergence checks are repeated until passed for all zones. EnergyPlus assumes that the warmup period has been reached steady-periodic when these four parameters are within tolerance. Finally, temperature and load differences between the last two warmup days for individual zone at each time step in the last warmup day are reported so that users can easily track whether or not the warmup period has converged. The input parameters and output related to the warmup period are discussed in the Input-Output Reference.

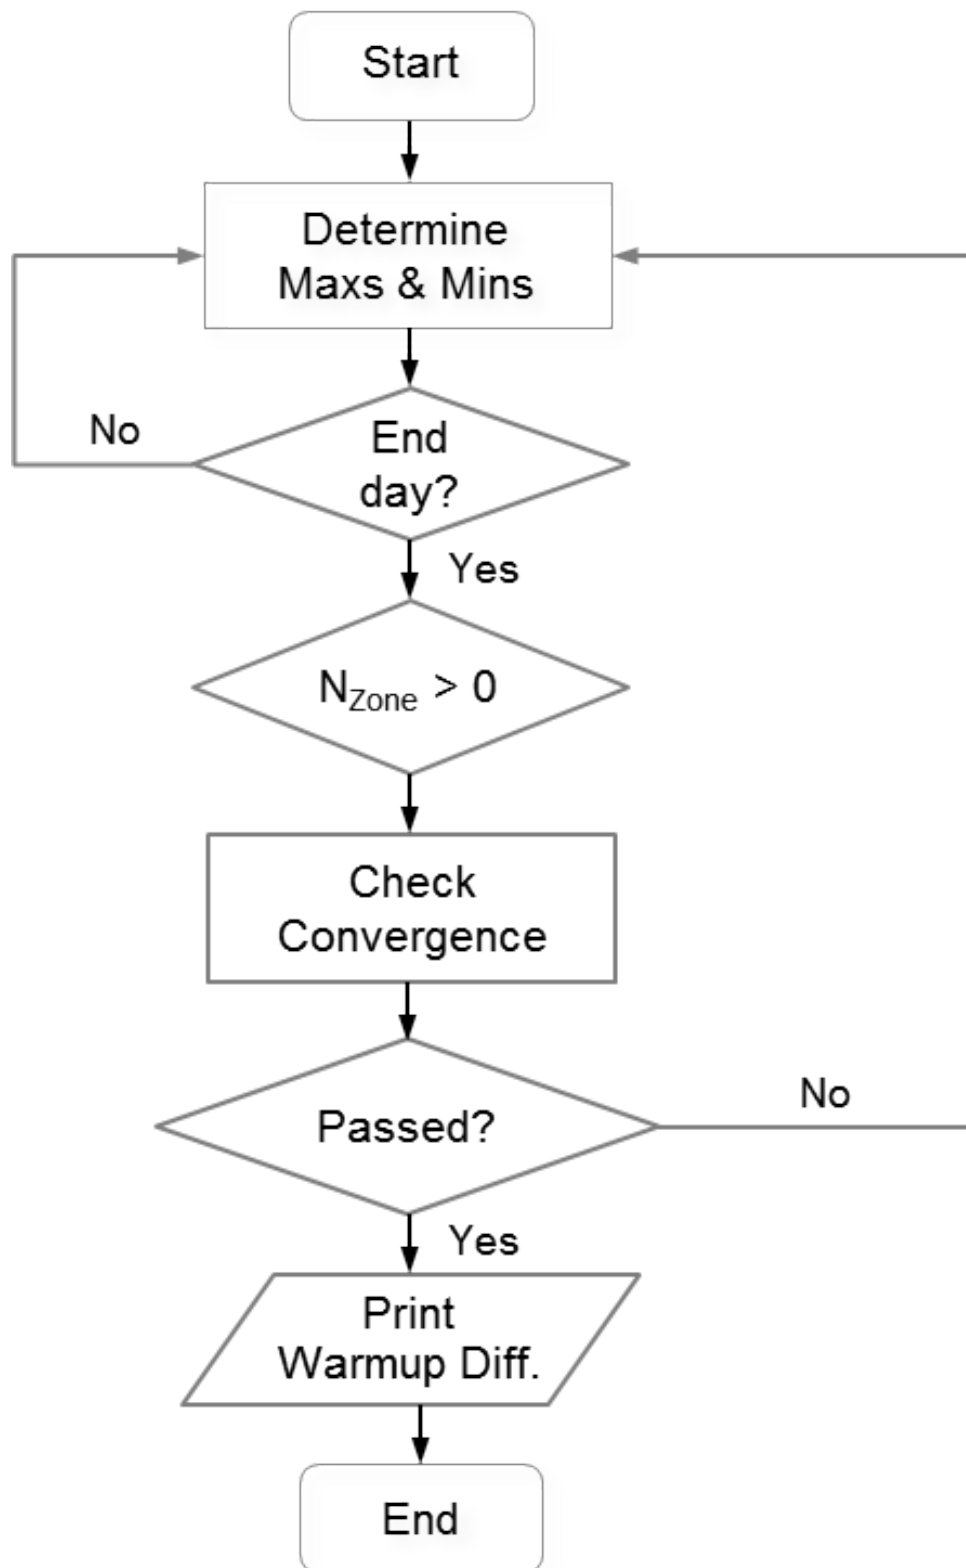

Figure 1.2: Flows of Warmup Convergence Checks

Chapter 2

Integrated Solution Manager

EnergyPlus is an integrated simulation. This means that all three of the major parts, building, system, and plant, must be solved simultaneously. In programs with sequential simulation, such as BLAST or DOE-2, the building zones, air handling systems, and central plant equipment are simulated sequentially with no feedback from one to the other. The sequential solution begins with a zone heat balance that updates the zone conditions and determines the heating/cooling loads at all time steps. This information is fed to the air handling simulation to determine the system response; but that response does not affect zone conditions. Similarly, the system information is passed to the plant simulation without feedback. This simulation technique works well when the system response is a well-defined function of the air temperature of the conditioned space. For a cooling situation, a typical supply and demand situation is shown schematically in the Figure 2.1. Here, the operating point is at the intersection of the supply and demand curves.

Figure 2.1: Sequential Simulation Supply/Demand Relationship.

However, in most situations the system capacity is dependent on outside conditions and/or other parameters of the conditioned space. The simple supply and demand situation above becomes a more complex relationship and the system curve is not fixed. The solution should move up and down the demand curve. This doesn't happen in sequential simulation methods and the lack of feedback from the system to the building can lead to nonphysical results. For example, if the system provides too much cooling to a conditioned space the excess is reported by the program as “overcooling”. Other categories of unmatched loads exist and are similarly reported by the program.

While this kind of reporting enables the affected system or plant components to be properly sized, the system designer would, in most cases, prefer to see the actual change in zone temperature. The same mismatches can occur between the system and plant simulations when they are simulated sequentially.

To obtain a simulation that is physically realistic, the elements have to be linked in a simultaneous solution scheme. The entire integrated program can be represented as a series of functional elements connected by fluid loops as shown in Figure 2.2. In EnergyPlus all the elements are integrated and controlled by the Integrated Solution Manager. The loops are divided into supply and demand sides, and the solution scheme generally relies on successive substitution iteration to reconcile supply and demand using the Gauss-Seidell philosophy of continuous updating.

Figure 2.2: Schematic of Simultaneous Solution Scheme

In the sections which follow, the various individual functions of the integrated solution will be described.

2.1 Basis for the Zone and Air System Integration

The basis for the zone and air system integration is to formulate energy and moisture balances for the zone air and solve the resulting ordinary differential equations using a predictor-corrector approach. The formulation of the solution scheme starts with a heat balance on the zone air.

$$C_z \frac{dT_z}{dt} = \sum_{i=1}^{N_{sl}} \dot{Q}_i + \sum_{i=1}^{N_{surfaces}} h_i A_i (T_{si} - T_z) + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p (T_{zi} - T_z) + \dot{m}_{inf} C_p (T_{\infty} - T_z) + \dot{Q}_{sys} \quad (2.1)$$

where:

$\sum_{i=1}^{N_{sl}} \dot{Q}_i$ = sum of the convective internal loads

$\sum_{i=1}^{N_{surfaces}} h_i A_i (T_{si} - T_z)$ = convective heat transfer from the zone surfaces

$\dot{m}_{\text{inf}} C_p (T_{\infty} - T_z)$ = heat transfer due to infiltration of outside air
 $\sum_{i=1}^{N_{\text{zones}}} \dot{m}_i C_p (T_{zi} - T_z)$ = heat transfer due to interzone air mixing
 \dot{Q}_{sys} = air systems output
 $C_z \frac{dT_z}{dt}$ = energy stored in zone air
 $C_z = \rho_{\text{air}} C_p C_T$
 ρ_{air} = zone air density
 C_p = zone air specific heat
 C_T = sensible heat capacity multiplier (Detailed description is provided below)
 If the air capacitance is neglected, the steady-state system output must be:

$$-\dot{Q}_{\text{sys}} = \sum_{i=1}^{N_{\text{sl}}} \dot{Q}_i + \sum_{i=1}^{N_{\text{surfaces}}} h_i A_i (T_{si} - T_z) + \sum_{i=1}^{N_{\text{zones}}} \dot{m}_i C_p (T_{zi} - T_z) + \dot{m}_{\text{inf}} C_p (T_{\infty} - T_z) \quad (2.2)$$

Air systems provide hot or cold air to the zones to meet heating or cooling loads. The system energy provided to the zone, \dot{Q}_{sys} , can thus be formulated from the difference between the supply air enthalpy and the enthalpy of the air leaving the zone as shown in Equation 2.3:

$$\dot{Q}_{\text{sys}} = \dot{m}_{\text{sys}} C_p (T_{\text{sup}} - T_z) \quad (2.3)$$

This equation assumes that the zone supply air mass flow rate is exactly equal to the sum of the air flow rates leaving the zone through the system return air plenum and being exhausted directly from the zone. Both air streams exit the zone at the zone mean air temperature. The result of substituting Equation 2.3 for \dot{Q}_{sys} in the heat balance Equation 2.1 is shown in Equation 2.4:

$$C_z \frac{dT_z}{dt} = \sum_{i=1}^{N_{\text{sl}}} \dot{Q}_i + \sum_{i=1}^{N_{\text{surfaces}}} h_i A_i (T_{si} - T_z) + \sum_{i=1}^{N_{\text{zones}}} \dot{m}_i C_p (T_{zi} - T_z) + \dot{m}_{\text{inf}} C_p (T_{\infty} - T_z) + \dot{m}_{\text{sys}} C_p (T_{\text{sup}} - T_z) \quad (2.4)$$

The sum of zone loads and air system output now equals the change in energy stored in the zone. Typically, the capacitance C_z would be that of the zone air only. However, thermal masses assumed to be in equilibrium with the zone air could be included in this term.

EnergyPlus provides three different solution algorithms to solve the zone air energy and moisture balance equations. These are defined in the Algorithm field in the ZoneAirHeatBalanceAlgorithm object: 3rdOrderBackwardDifference, EulerMethod and AnalyticalSolution. The first two methods to solve Equation 2.4 use the finite difference approximation while the third uses an analytical solution. A short description is given below.

In order to calculate the derivative term with respect to time, a finite difference approximation may be used, such as:

$$\frac{dT}{dt} = (\delta t)^{-1} (T_z^t - T_z^{t-\delta t}) + O(\delta t) \quad (2.5)$$

The use of numerical integration in a long time simulation is a cause for some concern due to the potential build-up of truncation error over many time steps. In this case, the finite difference approximation is of low order that further aggravates the problem. However, the cyclic nature of building energy simulations should cause truncation errors to cancel over each daily cycle so that no net accumulation of error occurs, even over many days of simulation (Walton, 1990). The Euler

formula, Equation 2.5, was employed in Equation 2.4 to replace the derivative term. All the terms containing the zone mean air temperature were then grouped on the left hand side of the equation. Since the remaining terms are not known at the current time, they were lagged by one time step and collected on the right hand side. This manipulation resulted in Equation 2.6, the formula for updating the zone mean air temperature:

$$C_z \frac{T_z^t - T_z^{t-\delta t}}{dt} + T_z^t \left(\sum_{i=1}^{N_{surfaces}} h_i A_i + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p + \dot{m}_{inf} C_p + \dot{m}_{sys} C_p \right) = \sum_{i=1}^{N_{sl}} \dot{Q}_i^t + \dot{m}_{sys} C_p T_{supply}^t + \left(\sum_{i=1}^{N_{surfaces}} h_i A_i T_{si} + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p T_{zi} + \dot{m}_{inf} C_p T_{\infty} \right)^{t-\delta t} \quad (2.6)$$

One final rearrangement was to move the lagged temperature in the derivative approximation to the right side of the equation. The explicit appearance of the zone air temperature was thus eliminated from one side of the equation. An energy balance equation that includes the effects of zone capacitance was then obtained by dividing both sides by the coefficient of T_z :

$$T_z^t = \frac{\sum_{i=1}^{N_{sl}} \dot{Q}_i^t + \dot{m}_{sys} C_p T_{supply}^t + \left(C_z \frac{T_z}{\delta t} + \sum_{i=1}^{N_{surfaces}} h_i A_i T_{si} + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p T_{zi} + \dot{m}_{inf} C_p T_{\infty} \right)^{t-\delta t}}{\frac{C_z}{\delta t} + \left(\sum_{i=1}^{N_{surfaces}} h_i A_i + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p + \dot{m}_{inf} C_p + \dot{m}_{sys} C_p \right)} \quad (2.7)$$

Equation 2.7 could be used to estimate zone air temperatures and is defined as the EulerMethod, one of the three solution algorithms provided in the ZoneAirHeatBalanceAlgorithm object. However, it can severely limit the time step size under some conditions. To improve on this, higher order expressions for the first derivative, with corresponding higher-order truncation errors, were developed. The goal of this approach was to allow for the use of larger time steps in the simulation than would be possible using the first order Euler form, without experiencing instabilities. Approximations from second through fifth order were tried as reported by Taylor, et al. (1990) with the conclusion that the third order finite difference approximation, shown below, gave the best results:

$$\left. \frac{dT_z}{dt} \right|_t \approx (\delta t)^{-1} \left(\frac{11}{6} T_z^t - 3 T_z^{t-\delta t} + \frac{3}{2} T_z^{t-2\delta t} - \frac{1}{3} T_z^{t-3\delta t} \right) + O(\delta t^3) \quad (2.8)$$

When this form for the derivative is used, Equation 2.6 changes to:

$$C_z (\delta t)^{-1} \left(\frac{11}{6} T_z^t - 3 T_z^{t-\delta t} + \frac{3}{2} T_z^{t-2\delta t} - \frac{1}{3} T_z^{t-3\delta t} \right) = \sum_{i=1}^{N_{sl}} \dot{Q}_i + \sum_{i=1}^{N_{surfaces}} h_i A_i (T_{si} - T_z) + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p (T_{zi} - T_z) + \dot{m}_{inf} C_p (T_{\infty} - T_z) + \dot{m}_{sys} C_p (T_{sup} - T_z) \quad (2.9)$$

and the zone temperature update equation becomes:

$$T_z^t = \frac{\sum_{i=1}^{N_{sl}} \dot{Q}_i + \sum_{i=1}^{N_{surfaces}} h_i A_i T_{si} + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p T_{zi} + \dot{m}_{inf} C_p T_{\infty} + \dot{m}_{sys} C_p T_{supply} - \left(\frac{C_z}{\delta t}\right) \left(-3T_z^{t-\delta t} + \frac{3}{2}T_z^{t-2\delta t} - \frac{1}{3}T_z^{t-3\delta t}\right)}{\left(\frac{11}{6}\right)\frac{C_z}{\delta t} + \sum_{i=1}^{N_{surfaces}} h_i A_i + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p + \dot{m}_{inf} C_p + \dot{m}_{sys} C_p} \quad (2.10)$$

This is the form historically used in EnergyPlus and is the current default referred to as 3rdOrderBackwardDifference in the ZoneAirHeatBalanceAlgorithm object. This algorithm requires zone air temperatures at three previous time steps and uses constant temperature coefficients. The assumption is that three previous time steps lengths are the same.

The AnalyticalSolution algorithm is an integration approach. While the 3rd order finite difference approximation provides stability without requiring a prohibitively small time step, the method still has truncation errors and requires a fixed time step length for the previous three simulation time steps. Therefore, different time step lengths for the previous three simulation time steps may make the temperature coefficients invalid.

The AnalyticalSolution algorithm provides a possible way to obtain solutions without truncation errors and independent of time step length. In addition, the algorithm only requires the zone air temperature for one previous time step, instead of three previous time steps as required by the 3rdOrderBackwardDifference algorithm. The integrated (analytical) solution for Equation 2.10 may be expressed as follows:

$$T_z^t = \left(T_z^{t-\delta t} - \frac{\sum_{i=1}^{N_{sl}} \dot{Q}_i + \sum_{i=1}^{N_{surfaces}} h_i A_i T_{si} + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p T_{zi} + \dot{m}_{inf} C_p T_{\infty} + \dot{m}_{sys} C_p T_{sup}}{\sum_{i=1}^{N_{surfaces}} h_i A_i + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p + \dot{m}_{inf} C_p + \dot{m}_{sys} C_p} \right) * \exp \left(- \frac{\sum_{i=1}^{N_{surfaces}} h_i A_i + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p + \dot{m}_{inf} C_p + \dot{m}_{sys} C_p}{C_z} \delta t \right) + \frac{\sum_{i=1}^{N_{sl}} \dot{Q}_i + \sum_{i=1}^{N_{surfaces}} h_i A_i T_{si} + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p T_{zi} + \dot{m}_{inf} C_p T_{\infty} + \dot{m}_{sys} C_p T_{sup}}{\sum_{i=1}^{N_{surfaces}} h_i A_i + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p + \dot{m}_{inf} C_p + \dot{m}_{sys} C_p} \quad (2.11)$$

Since the load on the zone drives the entire process, that load is used as a starting point to give a demand to the air system. Then a simulation of the air system provides the actual supply capability and the zone temperature is adjusted if necessary. This process in EnergyPlus is referred to as a Predictor/Corrector process. It is summarized below.

Code Reference: the **ZoneTempPredictorCorrector** module performs the calculations.

2.1.1 Zone Sensible Heat Capacity Multiplier

If the Zone Sensible Heat Capacity Multiplier = 1.0, this represents just the sensible heat capacitance of the air volume in the specified zone. If the value is not defined, it is set to 1.0. This multiplier can be greater than 1.0 if the zone air sensible heat capacity needs to be increased for stability of the simulation. This multiplier increases the capacitance of the air volume by increasing the zone volume that is used in the zone predictor-corrector algorithm in the simulation. This can be done for numerical reasons, such as to increase the stability by decreasing the zone air temperature

deviations at the time step level. Or it can be increased to try and account for the additional capacitance in the air loop not specified in the zone, i.e. dampers, diffusers, duct work, etc., to see the effect on the dynamics of the simulation. See the Input/Output Reference for additional information (Object: ZoneCapacitanceMultiplier:ResearchSpecial).

In the source code below we see how the ZoneVolCapMultpSens increases the zone volume used for the air ratio at the time step in the air system. This multiplier is constant throughout the simulation.

```

AIRRAT(ZoneNum) = Zone(ZoneNum)%Volume\***ZoneVolCapMultpSens**\* &
    PsyRhoAirFnPbTdbW(OutBaroPress,MAT(ZoneNum),ZoneAirHumRat(ZoneNum))\* &
    PsyCpAirFnW(ZoneAirHumRat(ZoneNum))/(TimeStepSys\*SecInHour)

```

2.2 Summary of Predictor-Corrector Procedure

The predictor-corrector scheme can be summarized as follows:

- Using Equation 2.2, an estimate is made of the air system energy required to balance the equation with the zone air temperature equal to the setpoint temperature.
- With that quantity as a demand, the air system is simulated to determine its actual supply capability at the time of the simulation. This will include a plant simulation if necessary.
- The actual air system capability is used in Equation 2.10 to calculate the resulting zone temperature.

2.3 Air System Control

Previously, the formulation of a new heat balance equation with an unsteady zone capacitance term was discussed Equation 2.3. In this equation the updated zone temperature was calculated by removing its explicit dependence from the right hand side and lagging, by one time step, the unknown terms on that side. However, the right hand side still contains implicit dependencies on the zone temperature through the air system control logic; the need for heating or cooling in the zones, is based on zone temperature. In real buildings the control system consists of one or more sensing units in the zone, such as a wall thermostat that samples the air temperature and sends signals to a control unit. The controller looks at the difference between the actual zone temperature and the desired temperature to ascertain if heating or cooling is required and then sends appropriate signals to the air system components to drive the zone temperature closer to the desired value.

Although many control systems use only the zone air temperature to control the air system, most modern energy management systems consider many other variables, such as outside environment conditions. Simulating such controllers would seem to be relatively straightforward in a simulation especially since some of the more complex control problems, such as managing duct pressures and flow rates, are not always modeled. However, real controllers have an advantage because they can sample zone conditions, and thus update air system response, on a time scale much shorter than any characteristic time of the air system or zone. Thus the feedback between zone and air system usually results in steady or, at worst, slowly oscillating zone conditions and air system operation unless the air system is grossly oversized. On the other hand, the numerical model is only able to sample zone conditions at discrete time intervals. In the interest of minimizing computation time, these intervals need to be as long as possible. Frequently, they are of the order of, or longer than,

the characteristic times of the air system and zones, except in the case of small air system capacity in relation to zone capacitance. This situation has the potential for unstable feedback between the zone and air system, resulting in an oscillatory or diverging solution.

Prior to implementing the new heat balance method (3rdOrderBackwardDifference) in IBLAST, several air system control strategies were considered. The primary objective was selection of a control method that would be numerically stable over a reasonable range of conditions, realistic from the standpoint of looking and operating like an actual air system controller, and flexible enough to be applied to all current and projected systems. The method actually implemented in IBLAST, and later EnergyPlus, took advantage of the computational model's "knowledge" of how much energy enters or leaves the zone as a function of zone air temperature i.e., the zone load. The real controller, on the other hand, does not have this information. The net zone load is given by Equation 2.12:

$$\dot{Q}_{load} = \sum_{i=1}^{N_{sl}} \dot{Q}_i + \sum_{i=1}^{N_{surfaces}} h_i A_i (T_{si} - T_z) + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p (T_{zi} - T_z) + \dot{m}_{inf} C_p (T_{\infty} - T_z) \quad (2.12)$$

This is Equation 2.2 without the term due to the air system. In addition, T_z is now the *desired* zone temperature as defined by the control system setpoints that must be specified for each zone. An assumption was made that if the air system has sufficient capacity (based on the desired zone air temperature) to meet the zone conditioning requirements (i.e. $\dot{Q}_{sys} = \dot{Q}_{load}$) at the desired zone air temperature then those requirements will be met. On the other hand, if the air system cannot provide enough conditioning to the zone to maintain the desired temperature, then the air system provides its maximum output to the zone and the zone air temperature is allowed to "float." Equation 2.12 was used to calculate the air system output required to maintain the desired zone air temperature; the actual zone temperature update was accomplished using Equation 2.7. This method was called *predictive system energy balance*. It has many characteristics of a predictor-corrector method since the air system response is first approximated based on a predicted zone temperature and then the actual change in zone temperature is determined from that air system response. The predictive air system energy balance method required that the system controls on air mass flow rate, supply air temperature, etc., be formulated as a function of the zone air temperature. However, this was not a serious drawback. The first example considered was a single zone draw through air system. Typically, such systems have a cooling coil and heating coil in series, and constant air volume flow rate. Single zone draw through systems run at maximum capacity when turned on; so the only way to regulate net air system output and keep the zone air temperature within the desired range is to turn the air system on and off. A simplified schematic of this system type is shown in Figure 2.3. Simplified Single Zone Draw Through Air System.

The amount of heating or cooling provided by the air system in relation to the desired zone air temperature is given by:

$$\dot{Q}_{sys} = \dot{m}_{sys} C_p \eta (T_{sup} - T_{z,desired}) \quad (2.13)$$

where η is the fraction of the time step that the air system is turned on and varies between 0 and 1. The supply air temperature is also implicitly limited by the effectiveness of the coils and the operating parameters of the central plant components. These interactions are discussed later.

A far more complex, though again simplified, air system is the variable air volume (VAV) system, shown in Figure 2.4. Simplified Variable Volume Air System. In VAV systems, the supply air

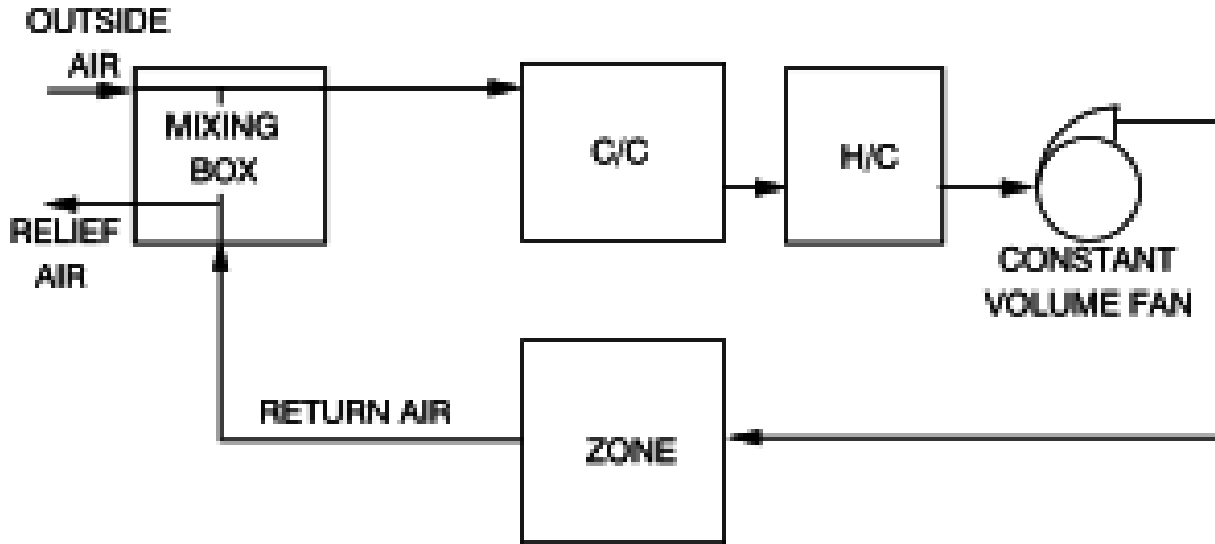

Figure 2.3: Simplified Single Zone Draw Through Air System

temperature, as well as the supply air volume, are continuous functions of zone air temperature. As shown in Figure 2.5. Idealized Variable Volume System Operation., when the zone air temperature is between T_{cl} and T_{cu} , cooling is required and the air system varies the supply air flow rate while maintaining a constant supply air temperature. When the zone air temperature is between T_{hl} and T_{hu} , heating is required and air is supplied at a constant minimum flow rate while the supply air temperature is varied.

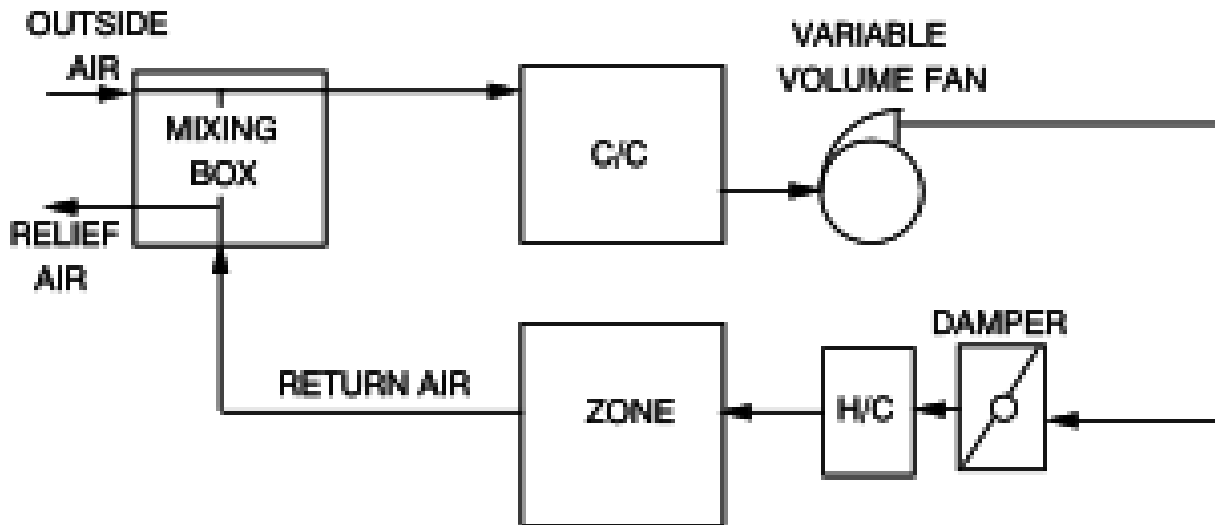

Figure 2.4: Simplified Variable Volume Air System.

The next figure (Idealized variable volume system operation) shows idealized behavior of a VAV system; in practice, the air flow rate and temperature are not exact linear functions of zone air temperature.

As long as a VAV system has sufficient capacity, the zone air temperatures can be expected to vary within the limits defining the range of operation of the air damper, when cooling, or the throttling range of the reheat coil, when the air system is heating. This means that the desired

Figure 2.5: Idealized Variable Volume System Operation.

zone air temperature, used to predict the air system response, is variable and must be calculated in order to determine the air system output. For the purposes of this calculation, the following definitions were found useful:

$$\dot{Q}_0 = \sum_{i=1}^{N_{sl}} \dot{Q}_i + \sum_{i=1}^{N_{surfaces}} h_i A_i T_{si} + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p T_{zi} + \dot{m}_{inf} C_p T_{\infty} \quad (2.14)$$

$$\dot{Q}_{slope} = \sum_{i=1}^{N_{surfaces}} h_i A_i + \sum_{i=1}^{N_{zones}} \dot{m}_i C_p + \dot{m}_{inf} C_p \quad (2.15)$$

Equations 2.14 and 2.15 are derived, respectively, from the numerator and denominator of Equation 2.10 but with the system related terms omitted. Also excluded from these expressions are the effects of zone capacitance.

When a zone requires cooling, the VAV system is designed to provide air to that zone at a constant supply air temperature. The amount of cooling is matched to the load by dampers in the supply air duct that vary the air volume flow rate of being supplied to the zone. Assuming that the volume flow rate varies linearly with zone air temperature, the volume flow rate of supply air normalized to the maximum flow rate, or supply air fraction, is given by:

$$\eta_c = \eta_{c,min} + (1 - \eta_{c,min}) \left(\frac{T_z - T_{c,lower}}{T_{c,upper} - T_{c,lower}} \right); \eta_{c,min} \leq \eta_c \leq 1.0 \quad (2.16)$$

Normally, the minimum supply air fraction $\eta_{c,min}$ must be greater than zero to ensure a supply of fresh air sufficient to eliminate contaminants from the zone.

Conversely, when heating is required in a zone, the VAV system becomes a constant volume flow rate system with a variable supply air temperature. The dampers are set to provide air to

the zone at the minimum supply air fraction. Throttling the hot water supply to the reheat coil, which effectively alters the coil's heating capacity, modulates the supply air temperature. Again, assuming the heat energy output varies linearly with zone air temperature and normalizing with respect to the maximum coil output gives the following result:

$$\eta_h = \left(\frac{T_{h,upper} - T_z}{T_{h,upper} - T_{h,lower}} \right); 0 \leq \eta_h \leq 1.0 \quad (2.17)$$

Observe that when η_h is equal to zero, the zone is supplied with air at the cooling coil outlet temperature at the minimum air fraction. Because the control strategies of the VAV system are different whether the air system is heating or cooling, two equations are necessary to describe the air system output in terms of η_h and η_c . These expressions are as shown in Equations 2.18 and 2.19:

$$\dot{Q}_{sys,h} = \eta_h \dot{Q}_{h/c,max} + C_p \rho \dot{V}_{min} (T_{c/c} - T_{z,pred,heat}) \quad (2.18)$$

$$\dot{Q}_{sys,c} = C_p \rho \left(\eta_c \dot{V}_{max} \right) (T_{c/c} - T_{z,pred,cool}) \quad (2.19)$$

Equation 2.18 is valid for zone air temperatures below $T_{h,upper}$, while Equation 2.19 is valid for all temperatures above this value. Equating the system output to the zone load, as given by Equation 2.12, the definitions of η_c and η_h were then used to develop expressions for the predicted zone air temperature in the cases of heating and cooling:

$$T_{z,pred,heat} = \frac{\dot{Q}_{h/c,max} T_{h,upper}}{T_{h,upper} - T_{h,lower}} + \dot{Q}_0 + \frac{C_p \rho \dot{V}_{min} T_{c/c}}{\frac{\dot{Q}_{h/c,max}}{T_{h,upper} - T_{h,lower}} + C_p \rho \dot{V}_{min} + \dot{Q}_{slope}} \quad (2.20)$$

$$T_{z,pred,cool} = \frac{B_1 + \sqrt{B_1^2 + B_2}}{2} \quad (2.21)$$

where,

$$B_1 = T_{c/c} + T_{c,lower} - \frac{\eta_{c,min} - C_2}{C_1} \quad (2.22)$$

$$B_2 = 4 \left(\frac{C_3}{C_1} + T_{c/c} \left(\frac{\eta_{c,min}}{C_1} - T_{c,lower} \right) \right) \quad (2.23)$$

and,

$$C_1 = \frac{1 - \eta_{c,min}}{T_{c,upper} - T_{c,lower}} \quad (2.24)$$

$$C_2 = \frac{\dot{Q}_{slope}}{C_p \rho \dot{V}_{max}} \quad (2.25)$$

$$C_3 = \frac{\dot{Q}_0}{C_p \rho \dot{V}_{max}} \quad (2.26)$$

Once the predicted zone air temperature has been calculated from Equations 2.20 and 2.21, the air system response may be determined. When a zone requires cooling, the system supply air temperature is constant at the cooling coil outlet temperature and the volume flow rate is given by:

$$\dot{V}_{supply} = \eta_c \dot{V}_{max} \quad (2.27)$$

where the supply air fraction η_c is computed from Equation 2.16. When heating is required by the zone, the air system provides air at the minimum volume flow rate and at a temperature given by:

$$T_{supply} = T_{c/c} + \frac{\eta_h \dot{Q}_{h/c,max}}{C_p \rho \dot{V}_{min}} \quad (2.28)$$

The reheat coil capacity fraction η_h is determined by using Equation 2.17. Once Equation 2.27 or 2.28 has been used, the supply air flow rate and temperature are known. These values are then used in Equation 2.7 to calculate the updated zone air temperature. The equations describing VAV system operation may be solved without iteration if the cooling coil outlet temperature is constant, i.e. if the coil has infinite capacity, and if the reheat coil capacity varies linearly with zone air temperature. This is not the case, either in practice or in simulations, when realistic coil models are used. Therefore, an iteration scheme was developed that solved these equations simultaneously with the coil performance models.

2.4 Moisture Predictor-Corrector

The transient air mass balance equation for the change in the zone humidity ratio = sum of internal scheduled latent loads + infiltration + system + multizone airflows + convection to the zone surfaces may be expressed as follows:

$$\begin{aligned} \rho_{air} V_z C_W \frac{dW_z}{dt} = & \sum_{i=1}^{N_{sl}} k g_{mass_{sched\ load}} + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} (W_{surfs_i} - W_z^t) + \sum_{i=1}^{N_{zones}} \dot{m}_i (W_{zi} - W_z^t) \\ & + \dot{m}_{inf} (W_{\infty} - W_z^t) + \dot{m}_{sys} (W_{sup} - W_z^t) \end{aligned} \quad (2.29)$$

where

C_W = humidity capacity multiplier (See the InputOutput Reference for additional information on the object ZoneCapacitanceMultiplier:ResearchSpecial)

In the same manner as described above for zone air temperature (ref. Basis for the Zone and Air System Integration), the solution algorithms provided in the ZoneAirHeatBalanceAlgorithm object are also applied to zone air moisture calculations.

In order to calculate the derivative term with respect to time, the first order backward finite difference method, defined as the EulerMethod in the ZoneAirHeatBalanceAlgorithm object, may be used:

$$\frac{dW}{dt} = (\delta t)^{-1} (W_z^t - W_z^{t-\delta t}) + O(\delta t) \quad (2.30)$$

The zone air humidity ratio update at the current time step using the EulerMethod may be expressed as follows:

$$\begin{aligned} \rho_{air} V C_W (\delta t)^{-1} (W_z^t - W_z^{t-\delta t}) &= \sum_{i=1}^{N_{sl}} k g_{mass_{sched\ load}} + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} (W_{surfs_i} - W_z^t) \\ &+ \sum_{i=1}^{N_{zones}} \dot{m}_i (W_{zi} - W_z^t) + \dot{m}_{inf} (W_{\infty} - W_z^t) + \dot{m}_{sys} (W_{sup} - W_z^t) \end{aligned} \quad (2.31)$$

To preserve the stability of the calculation of the zone humidity ratio, the third order differential approximation, derived by a Taylor Series and used in the calculation of the next time step's zone air temperature, is also applied to the zone air humidity ratio calculations. This algorithm is the default choice and is defined as 3rdOrderBackwardDifference in the ZoneAirHeatBalanceAlgorithm object.

The third order derivative derived from a Taylor Series expansion is defined as:

$$\left. \frac{dW_z}{dt} \right|_t \approx \frac{\left(\frac{11}{6} W_z^t - 3 W_z^{t-\delta t} + \frac{3}{2} W_z^{t-2\delta t} - \frac{1}{3} W_z^{t-3\delta t} \right)}{\delta t} + O(\delta t^3). \quad (2.32)$$

The coefficients of the approximated derivative are very close to the coefficients of the analogous Adams-Bashforth algorithm. Then the approximated derivative is substituted into the mass balance and the terms with the humidity ratio at past time steps are all put on the right hand side of the equation. This third order derivative zone humidity ratio update increases the number of previous time steps that are used in calculating the new zone humidity ratio, and decreases the dependence on the most recent. The higher order derivative approximations have the potential to allow the use of larger time steps by smoothing transitions through sudden changes in zone operating conditions.

$$\begin{aligned} \frac{\rho_{air} V_z C_W}{\delta t} \left(\frac{11}{6} \right) W_z^t + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} W_z^t + \sum_{i=1}^{N_{zones}} \dot{m}_i W_z^t + \dot{m}_{inf} W_z^t + \dot{m}_{sys} W_z^t &= \sum_{i=1}^{N_{sl}} k g_{mass_{sched\ load}} \\ &+ \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} W_{surfs_i} + \sum_{i=1}^{N_{zones}} \dot{m}_i W_{zi} + \dot{m}_{inf} W_{\infty} + \dot{m}_{sys} W_{sup} \\ &- \frac{\rho_{air} V_z C_W}{\delta t} \left(-3 W_z^{t-\delta t} + \frac{3}{2} W_z^{t-2\delta t} - \frac{1}{2} W_z^{t-3\delta t} \right) \end{aligned} \quad (2.33)$$

This gives us the basic air mass balance equation that will be solved two different ways, one way for the predict step and one way for the correct step.

Since the third choice of solution algorithms uses an integration approach, defined as AnalyticalSolution in the ZoneAirHeatBalanceAlgorithm object, it does not require any approximations and has no truncation errors. The solutions in both prediction and correction are provided below in detail.

2.4.1 Moisture Prediction

For the moisture prediction case, the equation is solved for the anticipated system response as shown below.

$$\begin{aligned} \text{PredictedSystemLoad} &= m_{sys} * (W_z^t - W_{sup}) \\ \text{MassFlow} * \text{HumRat} &= \frac{\text{kg}_{air}}{\text{sec}} \frac{\text{kg}_{water}}{\text{kg}_{air}} = \frac{\text{kg}_{water}}{\text{sec}} \end{aligned} \quad (2.34)$$

Since the program provides three solution algorithms, the moisture prediction from each solution algorithm is given below.

2.4.1.1 EulerMethod

For this solution algorithm, the air mass balance for the predicted air system load or response is:

$$\begin{aligned} \text{PredictedSystemLoad}[kg_{Water}/\text{sec}] = & \rho_{air} V_z C_W (\delta t)^{-1} \left(W_{\text{setpoint}}^t - W_z^{t-\delta t} \right) \\ & - \left[\sum_{i=1}^{N_{sl}} kg_{mass_{schedload}} + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} \left(W_{surf_i} - W_{\text{setpoint}}^t \right) + \sum_{i=1}^{N_{zones}} \dot{m}_i \left(W_{zi} - W_{\text{setpoint}}^t \right) + \dot{m}_{inf} \left(W_{\infty} - W_{\text{setpoint}}^t \right) \right] \end{aligned} \quad (2.35)$$

2.4.1.2 ThirdOrderBackwardDifference

For this solution algorithm, the air mass balance for the predicted system load or response is given below:

$$\begin{aligned} \text{PredictedSystemLoad}[kg_{Water}/\text{sec}] = & \left(\frac{\rho_{air} V_z C_W}{\delta t} \left(\frac{11}{6} \right) + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} + \sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} \right) W_z^t - \\ & \left[\sum_{i=1}^{N_{sl}} kg_{mass_{schedload}} + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} W_{surf_i} + \sum_{i=1}^{N_{zones}} \dot{m}_i W_{zi} + \dot{m}_{inf} W_{\infty} + \frac{\rho_{air} V_z C_W}{\delta t} \left(3W_z^{t-\delta t} - \frac{3}{2}W_z^{t-2\delta t} + \frac{1}{3}W_z^{t-3\delta t} \right) \right] \end{aligned} \quad (2.36)$$

Then, using the following substitutions, the air mass balance equation becomes:

$$A = \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} + \sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} \quad (2.37)$$

$$B = \sum_{i=1}^{N_{sl}} kg_{mass_{schedload}} + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} W_{surf_i} + \sum_{i=1}^{N_{zones}} \dot{m}_i W_{zi} + \dot{m}_{inf} W_{\infty} \quad (2.38)$$

$$C = \frac{\rho_{air} V_z C_W}{\delta t} \quad (2.39)$$

$$\begin{aligned} \text{PredictedSystemLoad} [kg_{Water}/\text{sec}] = & \left[\frac{11}{6} * C + A \right] * W_{SetPoint} - \\ & \left[B + C * \left(3W_z^{t-\delta t} - \frac{3}{2}W_z^{t-2\delta t} + \frac{1}{3}W_z^{t-3\delta t} \right) \right] \end{aligned} \quad (2.40)$$

2.4.1.3 AnalyticalSolution

For this solution algorithm, the air mass balance for the predicted air system load or response is given below:

$$\begin{aligned}
\text{PredictedSystemLoad } [kg_{water}/\text{sec}] = & \left[\sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} + \sum_{i=1}^{N_{zones}} \dot{m}_i W_{zi} + \dot{m}_{inf} \right] * \\
& \left[W_{\text{setpoint}}^t - W_z^{t-\delta t} * \exp \left(- \frac{\sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} + \sum_{i=1}^{N_{zones}} \dot{m}_i W_{zi} + \dot{m}_{inf}}{\rho_{air} V_z C_W} \delta t \right) \right] * \\
& \left[1 - \exp \left(- \frac{\sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} + \sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf}}{\rho_{air} V_z C_W} \delta t \right) \right]^{-1} - \\
& \left(\sum_{i=1}^{N_{sl}} kg_{mass_{sched\ load}} + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} W_{surf_{si}} + \sum_{i=1}^{N_{zones}} \dot{m}_i W_{zi} + \dot{m}_{inf} W_{\infty} \right)
\end{aligned} \tag{2.41}$$

At the prediction point in the simulation, the system air mass flows are not known; therefore, the system response is approximated. The predicted air system moisture load is then used in the system simulation to achieve the best results possible. The system simulation components that have moisture control will try to meet this predicted moisture load. For example, humidifiers will look for positive moisture loads and add moisture at the specified rate to achieve the relative humidity setpoint. Likewise, dehumidification processes will try to remove moisture at the specified negative predicted moisture load to meet the relative humidity setpoint.

After the system simulation is completed the actual response from the air system is used in the moisture correction of step, which is shown next.

2.4.2 Moisture Correction

For the correct step, the expanded air mass balance equation is solved for the final zone humidity ratio at the current time step. When the air system is operating, the mass flow for the system outlet includes the infiltration mass flow rate, therefore the infiltration mass flow rate is not included as a separate term in the air mass balance equation. But when the air system is off, the infiltration mass flow in is then exhausted out of the zone directly.

In the same manner as described above for predicting the moisture load to be met by the air system, the zone air moisture correction calculation will be described individually for the three solution algorithms.

2.4.2.1 EulerMethod

$$W_z^t = \frac{\sum_{i=1}^{N_{sl}} kg_{mass_{schedload}} + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} W_{surf_{si}} + \sum_{i=1}^{N_{zones}} \dot{m}_i W_{zi} + \dot{m}_{inf} W_{\infty} + \dot{m}_{sys} W_{sup} + \rho_{air} V_z C_W \frac{W_z^{t-\delta t}}{\delta t}}{\frac{\rho_{air} V_z C_W}{\delta t} + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} + \sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys}} \tag{2.42}$$

2.4.2.2 ThirdOrderBackwardDifference

$$W_z^t = \frac{\sum_{i=1}^{N_{sl}} kg_{mass_{sched load}} + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} W_{surf_{si}} + \sum_{i=1}^{N_{zones}} \dot{m}_i W_{zi} + \dot{m}_{inf} W_{\infty} + \dot{m}_{sys} W_{sup} + \frac{\rho_{air} V_z C_W}{\delta t} (3W_z^{t-\delta t} - \frac{3}{2}W_z^{t-2\delta t} + \frac{1}{3}W_z^{t-3\delta t})}{\frac{\rho_{air} V_z C_W}{\delta t} (\frac{11}{6}) + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} + \sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys}} \quad (2.43)$$

Using the same A, B, and C parameters from the prediction step modified with actual zone mass flows with the air system ON and OFF result in:

If (ZoneSupplyAirMassFlowRate > 0.0) **Then**

$$A = \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} + \sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys} \quad (2.44)$$

$$B = \sum_{i=1}^{N_{sl}} kg_{mass_{sched load}} + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} W_{surf_{si}} + \sum_{i=1}^{N_{zones}} \dot{m}_i W_{zi} + \dot{m}_{inf} W_{\infty} + \dot{m}_{sys} W_{sup} \quad (2.45)$$

$$C = \frac{\rho_{air} V_z C_W}{\delta t} \quad (2.46)$$

Else If (ZoneSupplyAirMassFlowRate <= 0.0) **Then**

$$A = \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} + \sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{Exhaust} \quad (2.47)$$

$$B = \sum_{i=1}^{N_{sl}} kg_{mass_{sched load}} + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} W_{surf_{si}} + \sum_{i=1}^{N_{zones}} \dot{m}_i W_{zi} + \dot{m}_{inf} W_{\infty} + \dot{m}_{Exhaust} W_{\infty} \quad (2.48)$$

$$C = \frac{\rho_{air} V_z C_W}{\delta t} \quad (2.49)$$

End If

Inserting in the parameters A, B and C above in the air mass balance equation, it simplifies to:

$$W_z^t = \left[\frac{B + C * (3W_z^{t-\delta t} - \frac{3}{2}W_z^{t-2\delta t} + \frac{1}{3}W_z^{t-3\delta t})}{(\frac{11}{6}) * C + A} \right] \quad (2.50)$$

2.4.2.3 AnalyticalSolution

$$\begin{aligned}
 W_z^t = & \left[W_z^{t-\delta t} - \frac{\sum_{i=1}^{N_{sl}} kg_{mass_{sched\ load}} + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} W_{surf_i} + \sum_{i=1}^{N_{zones}} \dot{m}_i W_{zi} + \dot{m}_{inf} W_{\infty} + \dot{m}_{sys} W_{sup}}{\sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} + \sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys}} \right] * \\
 & \exp \left(- \frac{\sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} + \sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys}}{\rho_{air} V_z C_W} \delta t \right) + \\
 & \frac{\sum_{i=1}^{N_{sl}} kg_{mass_{sched\ load}} + \sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} W_{surf_i} + \sum_{i=1}^{N_{zones}} \dot{m}_i W_{zi} + \dot{m}_{inf} W_{\infty} + \dot{m}_{sys} W_{sup}}{\sum_{i=1}^{N_{surfaces}} A_i h_{mi} \rho_{air_z} + \sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys}}
 \end{aligned} \tag{2.51}$$

The above solutions are implemented in the Correct Zone Air Humidity Ratio step in EnergyPlus. This moisture update equation is used for the Conduction Transfer Function (CTF) heat balance algorithm, in addition to the effective moisture penetration depth (EMPD) with conduction transfer function heat balance algorithm. The equations are identical except that the convection to the zone surfaces is non-zero for the moisture penetration depth case. This moisture update allows both methods to be updated in the same way, with the only difference being the additional moisture capacitance of the zone surfaces for the Effective Moisture Penetration Depth (EMPD) solution approach.

When the HAMT (Combined Heat And Moisture Finite Element) defined in the HeatBalanceAlgorithm object is applied, the moisture update equations are also the same as the equations used in the effective moisture penetration depth (EMPD) with conduction transfer function solution algorithm.

2.4.3 Which moisture buffering model is best?

The 'correct' moisture buffering model depends on the questions being answered by the building energy simulation. Previous research (Woods et al., 2013a) has shown that using the effective capacitance model to account for moisture buffering of materials will provide a good estimate of energy use when humidity is not being actively controlled. See the InputOutput Reference for additional information on the object ZoneCapacitanceMultiplier:ResearchSpecial. This model has some limitations (Woods et al., 2013b):

- it will not accurately predict indoor humidity (or thermal comfort),
- it will not accurately predict energy use when humidity is being actively controlled, and
- it will not provide insight into the moisture content and potential moisture problems associated with a specific wall construction.

The effective moisture penetration depth (EMPD) model will address the first two concerns above: it can accurately predict indoor humidity, and can accurately predict energy use associated with controlling humidity. The EMPD model requires more user input than the effective capacitance model, specifically some of the moisture properties of the materials in the building. For more information, see the Effective Moisture Penetration Depth Model section in this document.

Like the EMPD model, the combined heat, air, and moisture transfer (HAMT) model addresses the first two issues discussed above for the effective capacitance model. It also addresses the third, by providing temperature and moisture profiles through composite building walls, and helping to identify surfaces with high surface humidity. The HAMT model requires a few more user inputs on moisture properties of materials than the EMPD model, and this model also increases the required simulation time by an order of magnitude. For more information on this model, see the Combined Heat and Moisture Transfer (HAMT) Model section in this document.

Note that the EMPD and HAMT models above ensure accurate *calculations* of the effect of moisture buffering, but it will only be accurate relative to reality when given appropriate inputs for the material properties.

Woods, J., J. Winkler, D. Christensen, *Moisture modeling: Effective moisture penetration depth versus effective capacitance*, in Thermal Performance of the Exterior Envelopes of Whole Buildings XII International Conference. 2013a: Clearwater, FL.

2.5 Carbon Dioxide Predictor-Corrector

The transient air mass balance equation for the change in zone air carbon dioxide concentration may be expressed as follows:

$$\rho_{air} V_z C_{CO2} \frac{dC_z^t}{dt} = \sum_{i=1}^{N_{sl}} k g_{mass_{sched\ load}} * 1.0^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i (C_{zi} - C_z^t) + \dot{m}_{inf} (C_{\infty} - C_z^t) + \dot{m}_{sys} (C_{sup} - C_z^t) \quad (2.52)$$

where:

$\sum_{i=1}^{N_{sl}} k g_{mass_{sched\ load}}$ = sum of scheduled internal carbon dioxide loads. The zone air density is used

to convert the volumetric rate of carbon dioxide generation from user input into mass generation rate [kg/s]. The coefficient of 10^6 is used to make the units of carbon dioxide as ppm.

$\sum_{i=1}^{N_{zones}} \dot{m}_i (C_{zi} - C_z^t)$ = carbon dioxide transfer due to interzone air mixing [ppm-kg/s]

C_{zi} = carbon dioxide concentration in the zone air being transferred into this zone [ppm]

$\dot{m}_{inf} (C_{\infty} - C_z^t)$ = carbon dioxide transfer due to infiltration and ventilation of outdoor air [ppm-kg/s]

C_{∞} = carbon dioxide concentration in outdoor air [ppm]

$\dot{m}_{sys} (C_{sup} - C_z^t)$ = carbon dioxide transfer due to system supply [ppm-kg/s]

C_{sup} = carbon dioxide concentration in the system supply airstream [ppm]

\dot{m}_{sys} = air system supply mass flow rate [kg/s]

$\rho_{air} V_z \frac{dC_z^t}{dt}$ = carbon dioxide storage term in zone air [kg/s]

C_z^t = zone air carbon dioxide concentration at the current time step [ppm]

ρ_{air} = zone air density [kg/m³]

V_z = zone volume [m³]

C_{CO2} = carbon dioxide capacity multiplier [dimensionless] (See the InputOutput Reference for additional information on the object ZoneCapacitanceMultiplier:ResearchSpecial)

In the same manner as described above for zone air temperature (ref. Basis for the Zone and Air System Integration), the solution algorithms provided in the ZoneAirHeatBalanceAlgorithm object are also applied to the zone air carbon dioxide calculations.

In order to calculate the derivative term with respect to time, the first order backward finite difference method, defined as the EulerMethod in the ZoneAirHeatBalanceAlgorithm object, may be used:

$$\frac{dC_z^t}{dt} = (\delta t)^{-1}(C_z^t - C_z^{t-\delta t}) + O(\delta t) \quad (2.53)$$

The zone air carbon dioxide concentration update at the current time step using the Euler-Method may be expressed as follows:

$$\begin{aligned} \rho_{air} V_Z C_{CO2} (\delta t)^{-1} (C_z^t - C_z^{t-\delta t}) &= \sum_{i=1}^{N_{sl}} kg_{mass_{sched\ load}} * 10^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i (C_{zi} - C_z^t) \\ &+ \dot{m}_{inf} (C_{\infty} - C_z^t) + \dot{m}_{sys} (C_{sup} - C_z^t) \end{aligned} \quad (2.54)$$

To preserve the stability of the calculation of the zone carbon dioxide concentration, the third order differential approximation, derived by a Taylor Series and used in the calculation of the next time step's zone air temperature, is also applied to the zone air carbon dioxide calculations. This algorithm is the default choice and is defined as ThirdOrderBackwardDifference in the ZoneAirHeatBalanceAlgorithm object.

The third order derivative derived from a Taylor Series expansion is defined as:

$$\frac{dC_z^t}{dt} \approx \frac{\frac{11}{6}C_z^t - 3C_z^{t-\delta t} + \frac{3}{2}C_z^{t-2\delta t} - \frac{1}{3}C_z^{t-3\delta t}}{\delta t} + O(\delta t^3) \quad (2.55)$$

The coefficients of the approximated derivative are very close to the coefficients of the analogous Adams-Bashforth algorithm. Then the approximated derivative is substituted into the mass balance and the terms with the carbon dioxide concentration at past time steps are all put on the right-hand side of the equation. This third order derivative zone carbon dioxide update increases the number of previous time steps that are used in calculating the new zone carbon dioxide concentration, and decreases the dependence on the most recent. The higher order derivative approximations have the potential to allow the use of larger time steps by smoothing transitions through sudden changes in zone operating conditions.

$$\begin{aligned} \frac{\rho_{air} V_Z C_{CO2}}{\delta t} \left(\frac{11}{6} \right) C_z^t + \sum_{i=1}^{N_{zones}} \dot{m}_i C_z^t + \dot{m}_{inf} C_z^t + \dot{m}_{sys} C_z^t &= \sum_{i=1}^{N_{sl}} kg_{mass_{sched\ load}} * 10^6 \\ + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{zi} + \dot{m}_{inf} C_{\infty} + \dot{m}_{sys} C_{sup} &- \frac{\rho_{air} V_Z C_{CO2}}{\delta t} \left(-3C_z^{t-\delta t} + \frac{3}{2}C_z^{t-2\delta t} - \frac{1}{3}C_z^{t-3\delta t} \right) \end{aligned} \quad (2.56)$$

This gives us the basic air mass balance equation that will be solved two different ways, one way for the predict step and one way for the correct step.

Since the third choice of solution algorithms uses an integration approach, defined as AnalyticalSolution in the ZoneAirHeatBalanceAlgorithm object, it does not require any approximations and has no truncation errors. The solutions in both prediction and correction are provided below in detail.

2.5.1 Carbon Dioxide Prediction

For the carbon dioxide concentration prediction case, the equation is solved for the anticipated system response as shown below.

$$\text{PredictedSystemLoad} = \dot{m}_{sys} (C_{\text{sup}} - C_z^t) \quad (2.57)$$

Since the program provides three solution algorithms, the carbon dioxide prediction from each solution algorithm is given below.

2.5.1.1 EulerMethod

For this solution algorithm, the air mass balance for the predicted air system load or response is:

$$\begin{aligned} \text{PredictedSystemLoad [kg/sec]} &= \rho_{air} V_Z C_{CO2} (\delta t)^{-1} (C_{\text{setpoint}}^t - C_z^{t-\delta t}) \\ &- \left[\sum_{i=1}^{N_{sl}} kg_{mass_{sched\ load}} * 10^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i (C_{zi} - C_{\text{setpoint}}^t) + \dot{m}_{\text{inf}} (C_{\infty} - C_{\text{setpoint}}^t) \right] \end{aligned} \quad (2.58)$$

2.5.1.2 ThirdOrderBackwardDifference

For this solution algorithm, the air mass balance for the predicted system load or response is given below:

$$\begin{aligned} \text{PredictedSystemLoad [kg/sec]} &= \left[\frac{\rho_{air} V_Z C_{CO2}}{\delta t} \left(\frac{11}{6} \right) + \sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{\text{inf}} \right] * C_{\text{setpoint}}^t \\ &- \left[\sum_{i=1}^{N_{sl}} kg_{mass_{sched\ load}} * 10^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{zi} + \dot{m}_{\text{inf}} C_{\infty} + \frac{\rho_{air} V_Z C_{CO2}}{\delta t} \left(3C_z^{t-\delta t} - \frac{3}{2}C_z^{t-2\delta t} + \frac{1}{3}C_z^{t-3\delta t} \right) \right] \end{aligned} \quad (2.59)$$

2.5.1.3 AnalyticalSolution

For this solution algorithm, the air mass balance for the predicted air system load or response is given below:

$$\begin{aligned} \text{PredictedSystemLoad[kg/sec]} &= \left[\sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{\text{inf}} \right] * \left[C_{\text{setpoint}}^t - C_z^{t-\delta t} * \exp \left(- \frac{\sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{\text{inf}}}{\rho_{air} V_Z C_{CO2}} \delta t \right) \right] * \\ &\left[1 - \exp \left(- \frac{\sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{\text{inf}}}{\rho_{air} V_Z C_{CO2}} \delta t \right) \right]^{-1} - \left(\sum_{i=1}^{N_{sl}} kg_{mass_{sched\ load}} * 10^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{zi} + \dot{m}_{\text{inf}} C_{\infty} \right) \end{aligned} \quad (2.60)$$

At the prediction point in the simulation, the system air mass flows are not known; therefore, the system response is approximated. The predicted air system carbon dioxide load is then used in the system simulation to achieve the best results possible. If a central HVAC system provides the

outdoor flow rate from a Controller:MechanicalVentilation object, the outdoor airflow rate may be approximated as:

$$\text{PredictedSystemLoad} = \dot{m}_{sys} (C_{\text{sup}} - C_z^t) \approx \dot{m}_{OA,z} (C_{\infty} - C_{\text{setpoint}}^t) \quad (2.61)$$

where:

$\dot{m}_{OA,z}$ = supply outdoor airflow rate into the controlled zone [kg/s]

The above approximation is based on the assumption that the carbon dioxide concentration at the outdoor air (OA) mixer inlet is equal to the zone air outlet concentration level, and the carbon dioxide level at the zone supply air inlet is equal to the level at the outlet node of the OA mixer.

After the system simulation is completed the actual response from the air system is used in the carbon dioxide correction step, which is shown next.

2.5.2 Carbon Dioxide Correction

For the correct step, the expanded air mass balance equation is solved for the final zone carbon dioxide concentration at the current time step. In the same manner as described above for predicting the carbon dioxide load to be met by the air system, the zone air carbon dioxide correction calculation will be described individually for the three solution algorithms.

2.5.2.1 EulerMethod

$$C_z^t = \frac{\sum_{i=1}^{N_{sl}} kg_{mass_{sched\ load}} * 10^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{zi} + \dot{m}_{inf} C_{\infty} + \dot{m}_{sys} C_{\text{sup}} + \rho_{air} V_Z C_{CO2} \frac{C_z^{t-\delta t}}{\delta t}}{\frac{\rho_{air} V_Z C_{CO2}}{\delta t} + \sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys}} \quad (2.62)$$

2.5.2.2 ThirdOrderBackwardDifference

$$C_z^t = \frac{\sum_{i=1}^{N_{sl}} kg_{mass_{sched\ load}} * 10^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{zi} + \dot{m}_{inf} C_{\infty} + \dot{m}_{sys} C_{\text{sup}} + \frac{\rho_{air} V_Z C_{CO2}}{\delta t} (3C_z^{t-\delta t} - \frac{3}{2}C_z^{t-2\delta t} + \frac{1}{3}C_z^{t-3\delta t})}{\frac{\rho_{air} V_Z C_{CO2}}{\delta t} (\frac{11}{6}) + \sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys}} \quad (2.63)$$

2.5.2.3 AnalyticalSolution

$$C_z^t = \left[C_z^{t-\delta t} - \frac{\sum_{i=1}^{N_{sl}} kg_{mass_{sched\ load}} * 10^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{zi} + \dot{m}_{inf} C_{\infty} + \dot{m}_{sys} C_{\text{sup}}}{\sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys}} \right] * \exp \left(- \frac{\sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys}}{\rho_{air} V_Z C_{CO2}} \delta t \right) + \frac{\sum_{i=1}^{N_{sl}} kg_{mass_{sched\ load}} * 10^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{zi} + \dot{m}_{inf} C_{\infty} + \dot{m}_{sys} C_{\text{sup}}}{\sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys}} \quad (2.64)$$

The above solutions are implemented in the Correct Zone Air Carbon Dioxide step in the Zone Contaminant Predictor Corrector module of EnergyPlus.

2.6 Generic Contaminant Predictor-Corrector

The transient air mass balance equation for the change in zone air generic contaminant concentration may be expressed as follows:

$$\rho_{air} V_z M_{for} \frac{dC_{f,z}^t}{dt} = \sum_{i=1}^{N_{source}} \rho_{air} G_{f,i} * 10^6 - \rho_{air} \sum_{i=1}^{N_{sink}} R_{f,i} C_{f,z} + \sum_{i=1}^{N_{zones}} \dot{m}_i (C_{f,z,i} - C_{f,z}^t) + \dot{m}_{inf} (C_{f,\infty} - C_{f,z}^t) + \dot{m}_{sys} (C_{f,sup} - C_{f,z}^t) + \sum_j h_j \rho A_j \left(\frac{C_{s,j}}{k_j} - C_{f,z} \right) + S_f(C_{f,z}^{t-\delta t}) \quad (2.65)$$

where:

$\sum_{i=1}^{N_{source}} \rho_{air} G_{f,i}$ = Sum of internal generic contaminant loads from sources in a zone or interior surfaces.

The zone air density is used to convert the volumetric rate of generic contaminant generation from user input into mass generation rate [kg/s]. The coefficient of 10^6 is used to make the units of generic contaminant as ppm.

$\rho_{air} \sum_{i=1}^{N_{sink}} R_{f,i} C_{f,z}$ = Sum of removal rate from sinks in a zone or interior surfaces [ppm-kg/s]

$\sum_{i=1}^{N_{zones}} \dot{m}_i (C_{f,z,i} - C_{f,z}^t)$ = Generic contaminant transfer due to interzone air mixing [ppm-kg/s]

$C_{f,z,i}$ = Generic contaminant concentration in the zone air being transferred into this zone [ppm]

$\dot{m}_{inf} (C_{f,\infty} - C_{f,z}^t)$ = Generic contaminant transfer due to infiltration and ventilation of outdoor air [ppm-kg/s]

$C_{f,\infty}$ = Generic contaminant concentration in outdoor air [ppm]

$\dot{m}_{sys} (C_{f,sup} - C_{f,z}^t)$ = Generic contaminant transfer due to system supply [ppm-kg/s]

$C_{f,sup}$ = Generic contaminant concentration in the system supply airstream [ppm]

\dot{m}_{sys} = Air system supply mass flow rate [kg/s]

$\rho_{air} V_z \frac{dC_{f,z}^t}{dt}$ = Generic contaminant storage term in zone air [ppm-kg/s]

$C_{f,z}^t$ = Zone air generic contaminant concentration at the current time step [ppm]

ρ_{air} = Zone air density [kg/m³]

V_z = Zone volume [m³]

$\sum_j h_j \rho A_j \left(\frac{C_{s,j}}{k_j} - C_{f,z} \right)$ = Generic contaminant transport through diffusion between interior surfaces and zone air

faces and zone air

$S_f(C_{f,z}^{t-\delta t})$ = Generic contaminant generation or removal rate as a function of zone air generic contaminant level at the previous time step

Mfor = Generic contaminant capacity multiplier [dimensionless] (See the InputOutput Reference for additional information on the object ZoneCapacitanceMultiplier:ResearchSpecial)

In the same manner as described above for zone air temperature (ref. Basis for the Zone and Air System Integration), the solution algorithms provided in the ZoneAirHeatBalanceAlgorithm object are also applied to the zone air carbon dioxide calculations.

In order to calculate the derivative term with respect to time, the first order backward finite difference method, defined as the EulerMethod in the ZoneAirHeatBalanceAlgorithm object, may be used:

$$\frac{dC_{f,z}^t}{dt} = (\delta t)^{-1} (C_{f,z}^t - C_{f,z}^{t-\delta t}) + O(\delta t) \quad (2.66)$$

The zone air generic contaminant concentration update at the current time step using the EulerMethod may be expressed as follows:

$$\begin{aligned} \rho_{air} V_z M_{for} (\delta t)^{-1} (C_{f,z}^t - C_{f,z}^{t-\delta t}) = & \sum_{i=1}^{N_{source}} \rho_{air} G_{f,i} * 1.0^6 - \rho_{air} \sum_i^{N_{sink}} R_{f,i} C_{f,z} + \sum_{i=1}^{N_{zones}} \dot{m}_i (C_{f,z,i} - C_{f,z}^t) \\ & + \dot{m}_{inf} (C_{f,\infty} - C_{f,z}^t) + \dot{m}_{sys} (C_{f,sup} - C_{f,z}^t) + \sum_j h_j \rho A_j \left(\frac{C_{s,j}}{k_j} - C_{f,z} \right) + S_f \end{aligned} \quad (2.67)$$

To preserve the stability of the calculation of the zone generic contaminant concentration, the third order differential approximation, derived by a Taylor Series and used in the calculation of the next time step's zone air temperature, is also applied to the zone air carbon dioxide calculations. This algorithm is the default choice and is defined as ThirdOrderBackwardDifference in the ZoneAirHeatBalanceAlgorithm object.

The third order derivative resulting from a Taylor Series expansion is defined as:

$$\frac{dC_{f,z}^t}{dt} \approx \frac{\frac{11}{6}C_{f,z}^t - 3C_{f,z}^{t-\delta t} + \frac{3}{2}C_{f,z}^{t-2\delta t} - \frac{1}{3}C_{f,z}^{t-3\delta t}}{\delta t} + O(\delta t^3) \quad (2.68)$$

The coefficients of the approximated derivative are very close to the coefficients of the analogous Adams-Bashforth algorithm. Then the approximated derivative is substituted into the mass balance, and the terms with the carbon dioxide concentration at past time steps are all put on the right-hand side of the equation. This third order derivative zone carbon dioxide update increases the number of previous time steps that are used in calculating the new zone generic contaminant concentration and decreases the dependence on the most recent. The higher order derivative approximations have the potential to allow the use of larger time steps by smoothing transitions through sudden changes in zone operating conditions.

$$\begin{aligned} \frac{\rho_{air} V_z M_{for}}{\delta t} \left(\frac{11}{6} \right) C_{f,z}^t + \rho_{air} \sum_i^{N_{sink}} R_{f,i} C_{f,z}^t + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{f,z}^t + \dot{m}_{inf} C_{f,z}^t + \dot{m}_{sys} C_{f,z}^t + \sum_j h_j \rho A_j C_{f,z}^t \\ = \sum_{i=1}^{N_{source}} \rho_{air} G_{f,i} * 1.0^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{f,z,i} + \dot{m}_{inf} C_{f,\infty} + \dot{m}_{sys} C_{f,sup} + \sum_j h_j \rho A_j \frac{C_{s,j}}{k_j} + S_f \\ - \frac{\rho_{air} V_z M_{for}}{\delta t} \left(-3C_{f,z}^{t-\delta t} + \frac{3}{2}C_{f,z}^{t-2\delta t} - \frac{1}{3}C_{f,z}^{t-3\delta t} \right) \end{aligned} \quad (2.69)$$

This gives us the basic air mass balance equation that will be solved in two different ways, one way for the predict step and one way for the correct step.

Since the third choice of solution algorithms uses an integration approach, defined as AnalyticalSolution in the ZoneAirHeatBalanceAlgorithm object, it does not require any approximations and has no truncation errors. The solutions in both prediction and correction are provided below in detail.

2.6.1 Generic Contaminant Prediction

For the generic contaminant concentration prediction case, the equation is solved for the anticipated system response as shown below.

$$\text{PredictedSystemLoad} = \dot{m}_{sys} (C_{f,sup} - C_{f,z}^t) \quad (2.70)$$

Since the program provides three solution algorithms, the generic contaminant prediction from each solution algorithm is given below.

2.6.1.1 EulerMethod

For this solution algorithm, the air mass balance for the predicted air system load or response is:

$$\begin{aligned} \text{PredictedSystemLoad [kg/sec]} &= \rho_{air} V_z M_{for} (\delta t)^{-1} (C_{\text{setpoint}} - C_{f,z}^{t-\delta t}) \\ &- \left[\sum_{i=1}^{N_{source}} \rho_{air} G_{f,i} * 1.0^6 - \rho_{air} \sum_i^{N_{sink}} R_{f,i} C_{\text{setpoint}} + \sum_{i=1}^{N_{zones}} \dot{m}_i (C_{f,z,i} - C_{\text{setpoint}}) + S_f \right] \\ &- \left[\dot{m}_{inf} (C_{f,\infty} - C_{\text{setpoint}}) + \sum_j h_j \rho A_j \left(\frac{C_{s,j}}{k_j} - C_{\text{setpoint}} \right) \right] \end{aligned} \quad (2.71)$$

2.6.1.2 ThirdOrderBackwardDifference

For this solution algorithm, the air mass balance for the predicted system load or response is given below:

$$\begin{aligned} \text{PredictedSystemLoad [kg/sec]} &= \frac{\rho_{air} V_z M_{for}}{\delta t} \left(\frac{11}{6} \right) C_{\text{setpoint}} - \left[\rho_{air} \sum_i^{N_{sink}} R_{f,i} C_{\text{setpoint}} + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{\text{setpoint}} + \dot{m}_{inf} C_{\text{setpoint}} \right] \\ &- \left[\sum_j h_j \rho A_j C_{\text{setpoint}} + \sum_{i=1}^{N_{source}} \rho_{air} G_{f,i} * 1.0^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{f,z,i} + \dot{m}_{inf} C_{f,\infty} + \sum_j h_j \rho A_j \frac{C_{s,j}}{k_j} + S_f \right] \\ &+ \frac{\rho_{air} V_z M_{for}}{\delta t} \left(-3C_{f,z}^{t-\delta t} + \frac{3}{2}C_{f,z}^{t-2\delta t} - \frac{1}{3}C_{f,z}^{t-3\delta t} \right) \end{aligned} \quad (2.72)$$

2.6.1.3 AnalyticalSolution

For this solution algorithm, the air mass balance for the predicted air system load or response is given below:

$$\begin{aligned} \text{PredictedSystemLoad [kg/sec]} &= \left[\sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \rho_{air} \sum_i^{N_{sink}} R_{f,i} + \sum_j h_j \rho A_j \right] * \\ &\left[C_{\text{setpoint}}^t - C_z^{t-\delta t} * \exp \left(- \frac{\sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \rho_{air} \sum_i^{N_{sink}} R_{f,i} + \sum_j h_j \rho A_j}{\rho_{air} V_z M_{FOR}} \delta t \right) \right] * \\ &\left[1 - \exp \left(- \frac{\sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \rho_{air} \sum_i^{N_{sink}} R_{f,i} + \sum_j h_j \rho A_j}{\rho_{air} V_z M_{FOR}} \delta t \right) \right]^{-1} - \\ &\left(\sum_{i=1}^{N_{source}} \rho_{air} G_{f,i} * 1.0^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{f,z,i} + \dot{m}_{inf} C_{f,\infty} + \sum_j h_j \rho A_j \frac{C_{s,j}}{k_j} + S_f \right) \end{aligned} \quad (2.73)$$

At the prediction point in the simulation, the system air mass flows are not known; therefore, the system response is approximated. The predicted air system generic contaminant load is then used

in the system simulation to achieve the best results possible. If a central HVAC system provides the outdoor flow rate from a Controller:MechanicalVentilation object, the outdoor airflow rate may be approximated as:

$$\text{PredictedSystemLoad} = \dot{m}_{sys} (C_{f,\text{sup}} - C_{f,z}^t) \approx \dot{m}_{OA,z} (C_{f,\infty} - C_{\text{setpoint}}^t) \quad (2.74)$$

where:

$\dot{m}_{OA,z}$ = Supply outdoor airflow rate into the controlled zone [kg/s]

The above approximation is based on the assumption that the generic contaminant concentration at the outdoor air (OA) mixer inlet is equal to the zone air outlet concentration level, and the generic contaminant level at the zone supply air inlet is equal to the level at the outlet node of the OA mixer.

After the system simulation is completed, the actual response from the air system is used in the generic contaminant correction step, which is shown next.

2.6.2 Generic Contaminant Correction

For the correct step, the expanded air mass balance equation is solved for the final zone generic contaminant concentration at the current time step. In the same manner as described above for predicting the carbon dioxide load to be met by the air system, the zone air carbon dioxide correction calculation will be described individually for the three solution algorithms.

2.6.2.1 EulerMethod

$$C_{f,z}^t = \frac{\sum_{i=1}^{N_{source}} \rho_{air} G_{f,i} * 1.0^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{f,z,i} + \dot{m}_{inf} C_{f,\infty} + \dot{m}_{sys} C_{f,\text{sup}} + \sum_j h_j \rho A_j \frac{C_{s,j}}{k_j} + \rho_{air} V_Z M_{FOR} \frac{C_{f,z}^{t-\delta t}}{\delta t} + S_f}{\rho_{air} V_Z M_{for} (\delta t)^{-1} + \rho_{air} \sum_i^{N_{sink}} R_{f,i} + \sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys} + \sum_j h_j \rho A_j} \quad (2.75)$$

2.6.2.2 ThirdOrderBackwardDifference

$$C_{f,z}^t = \frac{\sum_{i=1}^{N_{source}} \rho_{air} G_{f,i} * 1.0^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{f,z,i} + \dot{m}_{inf} C_{f,\infty} + \dot{m}_{sys} C_{f,\text{sup}} + \sum_j h_j \rho A_j \frac{C_{s,j}}{k_j} + \frac{\rho_{air} V_Z M_{FOR}}{\delta t} (3C_{f,z}^{t-\delta t} - \frac{3}{2}C_{f,z}^{t-2\delta t} + \frac{1}{3}C_{f,z}^{t-3\delta t}) + S_f}{\rho_{air} V_Z M_{for} (\delta t)^{-1} (\frac{11}{6}) + \rho_{air} \sum_i^{N_{sink}} R_{f,i} + \sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys} + \sum_j h_j \rho A_j} \quad (2.76)$$

2.6.2.3 AnalyticalSolution

$$C_{f,z}^t = \left[C_{f,z}^{t-\delta t} - \frac{\sum_{i=1}^{N_{source}} \rho_{air} G_{f,i} * 1.0^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{f,z,i} + \dot{m}_{inf} C_{f,\infty} + \dot{m}_{sys} C_{f,\text{sys}} + \sum_j h_j \rho A_j \frac{C_{s,j}}{k_j}}{\sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys} + \rho_{air} \sum_i^{N_{sink}} R_{f,i} + \sum_j h_j \rho A_j} \right] * \exp \left[- \frac{\sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys} + \rho_{air} \sum_i^{N_{sink}} R_{f,i} + \sum_j h_j \rho A_j}{\rho_{air} V_Z M_{FOR}} \delta t \right] + \frac{\sum_{i=1}^{N_{source}} \rho_{air} G_{f,i} * 1.0^6 + \sum_{i=1}^{N_{zones}} \dot{m}_i C_{f,z,i} + \dot{m}_{inf} C_{f,\infty} + \dot{m}_{sys} C_{f,\text{sys}} + \sum_j h_j \rho A_j \frac{C_{s,j}}{k_j} + S_f}{\sum_{i=1}^{N_{zones}} \dot{m}_i + \dot{m}_{inf} + \dot{m}_{sys} + \rho_{air} \sum_i^{N_{sink}} R_{f,i} + \sum_j h_j \rho A_j} \quad (2.77)$$

The above solutions are implemented in the Correct Zone Air Generic Contaminant step in the Zone Contaminant Predictor Corrector module of EnergyPlus.

2.7 Zone Air Mass Flow Conservation

2.7.1 Overview

The zone air mass flow conservation object, ZoneAirMassFlowConservation, activates zone air mass flow balance calculations. This feature is available only for controlled zones (ZoneVAC:EquipmentConnections) which also have either a zone mixing or infiltration object. The user may specify that zone mixing, infiltration, or both can be overridden to balance the zone air mass flows. The following rules apply:

- If there are no zone mixing flows to adjacent zones, then the zone air mass flow is balanced by setting the Zone Mixing objects mass flow rate to zero.
- If there are no zone exhaust fans defined and there are no zone mixing objects specified, then a zone in an air loop is always balanced.
- Infiltration mass flow is included in the zone air mass flow balance depending upon one of three options: none (all infiltration is assumed to be self-balanced), all zones, or only zones that serve as a source zone for zone mixing objects.
- The base infiltration mass flow rate (calculated based on user inputs) may be controlled one of two ways for zone air mass flow balance purposes: adjust the base infiltration up or down as needed to balance the zone air mass flow, or assume the base infiltration rate is self-balanced and add infiltration if needed to balance the zone air mass flow.
- Optional user inputs can override the default return air flow rate.

The zone air mass flow conservation equation always includes: supply air flow rates, return air flow rates, and zone exhaust fan flow rates. Zone mixing and infiltration object flow rates may be included depending upon the selected options. A particular zone can be a source zone, receiving zone, or both depending on the number of ZoneMixing objects specified for that zone.

2.7.2 Return Air Flow Rate Calculations

The return air flow rate is calculated one of several ways, depending on whether ZoneAirMassFlowConservation is active, if there is more than one return node, and if Zone Return Air Node 1 Flow Rate Fraction Schedule Name or Zone Return Air Node 1 Flow Rate Basis Node or NodeList Name has been specified.

2.7.2.1 Base Zone Total Return Flow

The total zone return flow calculation with no ZoneAirMassFlowConservation is the sum of the zone inlets less the sum of the zone exhausts adjusted for any balanced exhaust fan flow:

$$\dot{m}_R = \text{MAX} (0.0, \dot{m}_S - [\dot{m}_{EX,tot} - \dot{m}_{EXF,bal}]) \quad (2.78)$$

If ZoneAirMassFlowConservation is active, then the total zone return air flow rate is

$$\dot{m}_R = \text{MAX} (0.0, \dot{m}_S - [\dot{m}_{EX,tot} - \dot{m}_{EXF,bal}] + [\dot{m}_{XR} - \dot{m}_{XS}]) \quad (2.79)$$

Note that the exhaust fan balanced flow component is not required to enforce the zone air flow balance when ZoneAirMassFlowConservation is active.

2.7.2.2 Zone Return Air Node 1

The first return air node is treated differently to maintain backward compatibility. If one or more Zone Return Air Node 1 Flow Rate Basis Nodes are specified in the ZoneHVAC:EquipmentConnections object, then the mass flow rate for the first return air node is:

$$\dot{m}_{R,1} = ReturnFlowSchedule * \sum_j \dot{m}_{BasisNode,j} \quad (2.80)$$

If there is only one return node and no Zone Return Air Node 1 Flow Rate Basis Nodes, then:

$$\dot{m}_{R,1} = ReturnFlowSchedule * \dot{m}_R \quad (2.81)$$

In the zone air mass flow conservation calculation, the calculated zone total return flow rate is modified using return node flow schedule value when the zone air flow balancing is enforced and assigned to return node 1.

$$\dot{m}_{R,1} = ReturnFlowSchedule * \dot{m}_R \quad (2.82)$$

The zone air mass flow conservation calculation also limits the zone return node air flow rate with air loop design supply to protect from large number the solution may throw as follows:

$$\dot{m}_{R,1} = MIN(\dot{m}_{R,1}, \dot{m}_{DesSupply,i}) \quad (2.83)$$

2.7.2.3 Allocation to Multiple Return Nodes

If there are multiple return air nodes in the zone, then each return air node is assumed to be paired with one supply air inlet node. The initial flow rate at a given return air node is based on the supply air inlet node for the same airloop and the AirloopHVAC Design Return Air Flow Fraction of Supply Air Flow:

$$\dot{m}_{R,i} = DesignReturnFrac_i * \dot{m}_{S,i} \quad (2.84)$$

For any air loop without an outdoor air inlet:

$$\dot{m}_{R,i} = \dot{m}_{R,i} \quad (2.85)$$

In the zone air mass flow conservation calculation, the calculated zone total return flow rate is distributed to the zone return nodes proportional to the return nodes current mass flow rates as follows:

$$\dot{m}_{R,i} = \dot{m}_{R,i} * \left(\frac{ReturnFlowSchedule * \dot{m}_R}{\sum_i \dot{m}_{R,i}} \right) \quad (2.86)$$

The zone air mass flow conservation calculation also limits the zone return node air flow rate with air loop design supply to protect from large number the solution may throw as follows:

$$\dot{m}_{R,1} = MIN(\dot{m}_{R,1}, \dot{m}_{DesSupply,AirLoop}) \quad (2.87)$$

2.7.2.4 Overall Return Air Balance

Once the initial allocation to multiple return air nodes is complete, the total return node flow is compared with the expected total zone return air mass flow rate. If the sum of the zone return node flows is greater than expected, then the surplus return flow is:

$$\dot{m}_{R,surplus} = \sum_i \dot{m}_{R,i} - \dot{m}_R \quad (2.88)$$

Return nodes without an outdoor air inlet are not adjusted. The remaining return node flow rates are reduced if necessary to balance the zone air mass flow:

$$\dot{m}_{R,i} = \dot{m}_{R,i} * \left(1 - \frac{\dot{m}_{R,surplus}}{\sum_{i,withOA} \dot{m}_{R,i}} \right) \quad (2.89)$$

2.7.2.5 Allocation of Excess Exhaust Flow

If the total (unbalanced) exhaust fan flow exceeds the supply flow in a given zone, this exhaust flow can be made up with outdoor air by any air loop serving the zone and the return air in other zones on the same air loop(s) will be reduced proportionally. First, the amount of excess exhaust for all zones on a given air loop is totalled. If a zone with excess exhaust is served by more than one air loop, the exhaust is shared by each air loop in proportion to the maximum available outdoor air for a given air loop.

$$\dot{m}_{ExcessExh,i} = \sum_j \frac{\dot{m}_{ExcessExh,j} * \dot{m}_{MaxOA,i}}{\dot{m}_{TotOA,j}} \quad (2.90)$$

The adjusted total return flow for each air loop is calculated by subtracting the excess exhaust from the total return flow calculated earlier.

$$\dot{m}_{AdjReturn,i} = \max(0.0, \dot{m}_{OrigReturn,i} - \dot{m}_{ExcessExh,i}) \quad (2.91)$$

Finally, the return flow for each return node on the air loop is proportioned to the adjusted total return flow.

$$\dot{m}_{R,i} = \dot{m}_{R,i} * \frac{\dot{m}_{AdjReturn,i}}{\dot{m}_{OrigReturn,i}} \quad (2.92)$$

where,

\dot{m}_R = total zone return air mass flow rate, (kg/s)

$\dot{m}_{R,i}$ = return air node i mass flow rate, (kg/s)

\dot{m}_S = total zone supply air mass flow rate, (kg/s)

$\dot{m}_{S,i}$ = zone supply air node i mass flow rate, (kg/s)

$\dot{m}_{BasisNode,j}$ = return air flow basis node j mass flow rate, (kg/s)

$\dot{m}_{EX,tot}$ = total zone exhaust air mass flow rate from all zone exhaust air nodes, (kg/s)

$\dot{m}_{EXF,bal}$ = balanced zone exhaust fan air mass flow rate, (kg/s)

$\dot{m}_{EXF,tot}$ = total (balanced+unbalanced) zone exhaust fan air mass flow rate, (kg/s)

\dot{m}_{XR} = zone mixing mass flow rate as a receiving zone, (kg/s)

\dot{m}_{XS} = zone mixing mass flow rate as a source zone, (kg/s)

ReturnFlowSchedule = optional Zone Return Air Node 1 Flow Rate Fraction Schedule value

$DesignReturnFrac_i$ = air loop Design Return Air Flow Fraction of Supply Air Flow for air loop i

$\dot{m}_{ExcessExh,j}$ = excess exhaust flow for zone j

$\dot{m}_{ExcessExh,i}$ = total excess exhaust flow for air loop i

$\dot{m}_{MaxOA,i}$ = current max available outdoor air flow for air loop i

$\dot{m}_{TotOA,j}$ = total max available outdoor air flow for air loops serving zone j

$\dot{m}_{OrigReturn,i}$ = total original return flow for air loop i

$\dot{m}_{AdjReturn,i}$ = total adjusted return flow for air loop i

$\dot{m}_{DesSupply,i}$ = air loop design supply air flow for air loop i

2.7.3 Zone Mixing Flow Rate Calculations

Figure 2.6 illustrates the zone mass flow components for an air loop system providing conditioned air to the two zones connected with a zone mixing object. Since Zone 1 is a source zone only, infiltration object is defined for zone 1 only. The zone mixing object air flow rate depends on the user specified values and the zone air mass flow balance requirements. When required the zone mixing object flow rate is adjusted from the user specified value for balancing purpose.

Figure 2.6: Illustration of zone air mass flow balance components

An individual zone may be a source zone for multiple receiving zones, and the same source zone may receive mixing flows from multiple adjacent zones in an air loop. The source and receiving mass flow rates of ZoneMixing objects are calculated from user defined mixing flow rates at the first HVAC iteration for each time step and adjusted in subsequent iterations to balance the zone air mass flow. The source zone mixing mass flow rate is calculated by tracking the mass flow rates of ZoneMixing objects connected to a zone and is given by:

$$\dot{m}_{XS} = \sum_j \dot{m}_{XS,j} \quad (2.93)$$

Similarly, the receiving zone mixing mass flow rate is calculated by tracking the mass flow rates of ZoneMixing objects connected to a receiving zone and is given by:

$$\dot{m}_{XR} = \sum_j \dot{m}_{XR,j} \quad (2.94)$$

Zone air mass flow balance can be enforced using four options: *AdjustMixingOnly*, *AdjustReturnOnly*, *AdjustMixingThenReturn*, or *AdjustReturnThenMixing*. These options involve either adjusting zone mixing objects flows, adjusting the zone total return air flows, or a combination of both. The zone air mass flow balance equation formulation for each of the four options is described next.

AdjustMixingOnly: adjusts the zone mixing object flows only to enforce zone air mass flow balance and the adjusted zone mixing mass flow rates are used to determine the zone total return air mass flow rate. Infiltration air flow can also adjusted if required depending on user preference as specified in Section *Infiltration Flow rates Adjustments*.

Determine the zone total return air mass flow rate as shown above, then adjust the zone mixing mass flow rates based on the zone total return air mass flow rate:

$$\dot{m}_{XR,new} = \dot{m}_R + \dot{m}_{EX} + \dot{m}_{XS} - \dot{m}_S \quad (2.95)$$

This updated receiving zone mixing air mass flow rate is distributed to the mixing objects connected to the current zone proportional to user specified design flow rate. A single zone may be connected to more than one adjacent zone using multiple ZoneMixing objects. Thus, the mixing flow rate of each contributing mixing objects defined in the current zone is updated as follows:

$$\dot{m}_{XR,new,j} = (\dot{m}_{XR,j,Design} / \dot{m}_{XR,Design}) \cdot \dot{m}_{XR,new} \quad (2.96)$$

AdjustReturnOnly: adjusts the zone total return air mass flow rate only to enforce zone air mass flow balance while the zone mixing object mass flow rate are kept at user specified values. Infiltration air flow can also adjusted if required depending on user preference as specified in Section *Infiltration Flow rates Adjustments*.

First, determine the user specified mixing object received and source air flow rates of the current zone, then determine the zone total return air flow rate as follows:

$$\dot{m}_{XS} = \sum_j \dot{m}_{XS,j} \quad (2.97)$$

$$\dot{m}_{XR} = \sum_j \dot{m}_{XR,j} \quad (2.98)$$

If ZoneAirMassFlowConservation is active, then determine the zone total return air flow rate:

$$\dot{m}_R = MAX(0.0, \dot{m}_S - \dot{m}_{EX,tot} + [\dot{m}_{XR} - \dot{m}_{XS}]) \quad (2.99)$$

Also checks that the zone total return air mass flow rate does not exceed the airloop design supply flow rate as follows:

$$\dot{m}_R = MIN(\dot{m}_R, \dot{m}_{DesSupply,i}) \quad (2.100)$$

AdjustMixingThenReturn: first adjusts the zone mixing air mass flow rates, then adjusts the zone total return air mass flow rate to enforce zone air mass flow balance. Infiltration air flow can also adjusted if required depending on user preference as specified in section *Infiltration Flow rates Adjustments*. For adjusting the mixing mass flow rates the set of equations for *AdjustMixingOnly* method described above are used and for adjusting the zone total return air mass flow rate the equation for *AdjustReturnOnly* method is used.

AdjustReturnThenMixing: first adjusts the zone total return air mass flow rate, then adjusts the zone mixing mass flow rates to enforce zone air mass flow balance. Infiltration air flow can also adjusted if required depending on user preference as specified in section *Infiltration Flow rates Adjustments*. For adjusting the zone total return air mass flow rate the equation for *AdjustReturnOnly* method described above is used and for adjusting the zone mixing mass flow rates the set of equations defined for *AdjustMixingOnly* method are used.

2.7.4 Infiltration Flow Rate Adjustments

There are three options for the treatment of infiltration in the zone air mass balance: None, AddInfiltrationFlow, and AdjustInfiltrationFlow. There are also two options to specify which zones are included in the infiltration adjustments: AllZones or MixingSourceZonesOnly.

If a zone is excluded from infiltration adjustments, then the base infiltration rate specified by the Infiltration:* object(s) in the zone is assumed to be self-balanced, and infiltration is not included in the mass flow calculations for that zone.

If a zone is included in the infiltration adjustment, the infiltration air mass flow rate required to balance the zone is determined as follows:

$$\dot{m}_{Inf-required} = MAX(0.0, \dot{m}_{XS} + \dot{m}_{EX} + \dot{m}_R - \dot{m}_S - \dot{m}_{XR,new}) \quad (2.101)$$

This infiltration air mass flow rate calculated is either added to the base infiltration air flow, which is calculated from user inputs, or overrides the base infiltration air flow depending on user choice. For AddInfiltrationFlow, the zoneinfiltration flow rate is:

$$\dot{m}_{Inf} = \dot{m}_{Inf-base} + \dot{m}_{Inf-required} \quad (2.102)$$

For AdjustInfiltrationFlow, the zone infiltration flow rate is:

$$\dot{m}_{Inf} = \dot{m}_{Inf-required} \quad (2.103)$$

where,

\dot{m}_{Inf} = zone infiltration mass flow rate, (kg/s)

$\dot{m}_{Inf-base}$ = base zone infiltration mass flow rate calculated from Infiltration:* objects, (kg/s)

$\dot{m}_{Inf-required}$ = required zone infiltration mass flow rate to balance the zone, (kg/s)

There is an additional constraint to the return air mass flow rate calculation. The sum of the return air mass flow rates of zones in air loop must satisfy the air loop return air mass flow balance. The above four sets of equations are iterated for each zone in an air loop until the convergence criterion is satisfied or until the maximum iteration limit is exceeded.

The mass conservation calculations are performed in routine `CalcZoneMassBalance` in the `ZoneEquipmentManager` module. The latest `ZoneMixing` and `Infiltration` object flow rates are communicated back to the zone air heat balance terms. This is done by re-simulating the simple flow objects as zone equipment during each HVAC iteration. This requires calling the routine `CalcAirFlowSimple` in `SimZoneEquipment` routine as zone equipment. Both of these routines are also in the `ZoneEquipmentManager` module.

The zone mass conservation calculation convergence criterion is based on the absolute difference of the zone mixing objects mass flow rates between successive iteration. If the difference is above tolerance limits of 0.00001 then the HVAC Air loop is simulated again.

2.8 Summary of Time Marching Solution

EnergyPlus models building performance over time spans of days to years using a time marching method based on *timesteps*. This section provides more information on issues related to timestep formulation.

2.8.1 Summary of Timestep Model Formulation

An EnergyPlus simulation covers a certain period of time, such as a day or a year, that is broken down into a series of discrete bins of time that are referred to as *timesteps*. The program marches through time by recalculating model equations at each timestep. The figure below diagrams some of these basic concepts.

Most models in EnergyPlus are quasi-steady energy balance equations used to predict the conditions present during each timestep. Various input data and boundary conditions for the models are time-varying and a “staircase” approach is used where such values are determined for a particular timestep and then essentially held constant over the entire timestep. Predictions for state variables, such as temperature, are averages over the timestep. Predictions for summed variables, such as energy use, are simple totals over the timestep.

EnergyPlus produces time-series results for selected output variables at selected frequencies. The time values associated with the time-series data, or timestamps, are output for the end of the timestep, but the values of the variables are for the entire bin of time prior to the timestamp. When data are reported at coarser frequencies such as hourly, then the results are averages or simple totals for all the timesteps that are contained within the larger bin of time.

To simplify solutions that would otherwise need to be simultaneous, models sometimes use data that are “lagged” which means that the values used in the calculations for the current timestep are actually results from the previous timestep. Many models just use the most current results available and so may use lagged data for a first iteration, but then use current data that are not lagged for subsequent iterations.

2.8.2 Zone Update Method

A zone is not necessarily a single room but is usually defined as a region of the building or a collection of rooms subject to the same type of thermal control and having similar internal load profiles that, subsequently, can be grouped together. Zones can interact with each other thermally through adjacent surfaces and by intermixing of zone air. In EnergyPlus, the conditions in each

Figure 2.7: Diagram of TimeStep Formulation

zone are updated by Equation 2.7, which uses previously calculated values of the zone conditions. This means that EnergyPlus does not have to iterate to find a self-consistent solution of the updated zone conditions. However, because heat transfer through each zone's surfaces and interzone mixing of air still occur, the new space temperatures must be computed at the same simulation time and on the same time step in all zones, even though conditions in one zone may be changing much more rapidly than conditions in the other zones. We have previously documented the method used to update the zone temperature at each time step. This method, called the predictor corrector method, has proved to be satisfactory over a wide range of conditions.

2.8.3 Variable Timestep

The need for a variable timestep in EnergyPlus was identified during development of its predecessor IBLAST. Prior to the integration of the central plant simulation in IBLAST, a time step Δt for the zone temperature update of 0.25 hours (15 minutes) was found to give stable results without a large increase in computation time. The first step in integrating plant was to implement the detailed coil models and coil control strategies without actually adding the plant models themselves. This meant that the user had to specify the coil water inlet temperature and the maximum coil inlet water flow rate to run the simulation. The real life analogy would be a chiller of very large, though not infinite, capacity. The coil capacity was controlled by adjusting the water flow rate, but the effect of the plant on the chilled water temperature was eliminated. After implementation of this step, experience with the program showed that updating the zone temperatures on a fixed time step frequently resulted in instabilities unless a very short time step was used. However, as the time step got shorter the time required to execute the program got prohibitively high.

Clearly, an adaptive time step was required. This would shorten the time step to maintain stability of the zone air energy balance calculation when zone conditions were changing rapidly and expand it to speed computation when zone conditions were relatively unchanging. But, the adaptive time step could not be applied easily to the surface heat transfer calculations, even using interpolation methods to determine new temperature and flux histories. The problem of updating the zone temperature was resolved by using a two-time-step approach in which the zone air temperature is updated using an adaptive time step that ensures stability. In this two time level scheme, the contributions to the zone loads from the surfaces, and user specified internal loads are updated at the default or user specified time step that is constant. This is often referred to as the "zone" time step. The contributions to the zone loads from HVAC system response, infiltration, and air mixing are updated at a second variable time step, referred to as the "system" time step. The system time step is limited to between one minute and the zone time step. The lower limit of the system time step can be increased to larger than one minute by the user with a System Convergence Limits object (which may be useful to decrease simulation run times at the expense of some accuracy).

The program's decision to adapt the time step is made by first using the usual zone time step and executing the full predictor-corrector calculations to find resulting zone temperatures. The maximum temperature change experienced by any zone in the model is determined. If this maximum zone temperature change is more than a preset limit of 0.3°C , then the simulation switches to using the shorter system time step. The number of system time steps (within a particular zone time step) is modeled from the results for the maximum zone temperature change (just obtained from the corrector) by assuming that temperature change is linear. The number of system time steps indicated by the temperatures is:

$$\left(\frac{\text{Maximum Zone Temperature Change}}{\text{Maximum Zone Temperature Difference } \{.3C\}} \right) + 1.0 \quad (2.104)$$

The limit for the number of system time steps is:

$$\left(\frac{\text{Zone Time Step}}{\text{Minimum System Time Step}} \right) \quad (2.105)$$

EnergyPlus takes the smallest of these two, truncates them to a whole number and calculates a system time step as:

$$\text{System Time Step} = \left(\frac{\text{Zone Time Step}}{\text{Number of System Time Steps}} \right) \quad (2.106)$$

The same length of time is used for all the system time steps within a particular zone time step, but the system time step length can vary between different zone time steps. Report variables that use the “detailed” frequency show results at the system time step time scale.

This approach can be justified because the internal loads and surface temperatures vary on a different and longer time scale than the system response and the zone air temperature.

When the simulation down-steps from using the zone time step to the system time step, linear interpolation is used to generate zone condition history terms:

$$\begin{aligned} T_z^{t-\delta t} \\ T_z^{t-2\delta t} \\ T_z^{t-3\delta t} \end{aligned} \quad (2.107)$$

for the system time steps using the history data for the zone time step. If two consecutive zone time steps both down-step to have the same number of system time steps, then the system time step history is preserved and used directly rather than being interpolated from zone time step history. The zone temperature update is made for each system time step using the same equation as for the zone time step except that the zone temperature history and time difference (δt) terms are for the system time step instead of for the zone time step.

2.8.4 Simultaneous Solution of Plant/System Water Loop

Simultaneous solution of the system and plant operating parameters required that the temperature of the water entering the coils must be the same as the temperature leaving the chillers or boilers. In addition, the temperature of the return water from the coils must be equal to the chiller or boiler entering water temperature. In practice so long as the plant is not out of capacity the leaving water temperature from chillers and boilers is constant and equal to the design value. No iteration was required to match system and plant boundary conditions. However, if either the chiller or boiler plant was overloaded then the temperature of the water leaving the plant was not equal to the design value and the maximum output of the plant could change because of the off-design conditions. An iterative scheme using the secant method to predict successive updates to the plant leaving water conditions was therefore employed to solve for the water loop conditions with the plant operating at its maximum capacity. The simulation of the system and plant loops is described in greater detail in the later sections.

Chapter 3

Surface Heat Balance Manager / Processes

3.1 Conduction Through The Walls

3.1.1 Conduction Transfer Function Module

The most basic time series solution is the response factor equation which relates the flux at one surface of an element to an infinite series of temperature histories at both sides as shown by Equation 3.1:

$$q''_{ko}(t) = \sum_{j=0}^{\infty} X_j T_{o,t-j\delta} - \sum_{j=0}^{\infty} Y_j T_{i,t-j\delta} \quad (3.1)$$

where q'' is heat flux, T is temperature, i signifies the inside of the building element, o signifies the outside of the building element, t represents the current time step, and X and Y are the response factors.

While in most cases the terms in the series decay fairly rapidly, the infinite number of terms needed for an exact response factor solution makes it less than desirable. Fortunately, the similarity of higher order terms can be used to replace them with flux history terms. The new solution contains elements that are called conduction transfer functions (CTFs). The basic form of a conduction transfer function solution is shown by the following equation:

$$q''_{ki}(t) = -Z_o T_{i,t} - \sum_{j=1}^{nz} Z_j T_{i,t-j\delta} + Y_o T_{o,t} + \sum_{j=1}^{nz} Y_j T_{o,t-j\delta} + \sum_{j=1}^{nq} \Phi_j q''_{ki,t-j\delta} \quad (3.2)$$

for the inside heat flux, and

$$q''_{ko}(t) = -Y_o T_{i,t} - \sum_{j=1}^{nz} Y_j T_{i,t-j\delta} + X_o T_{o,t} + \sum_{j=1}^{nz} X_j T_{o,t-j\delta} + \sum_{j=1}^{nq} \Phi_j q''_{ko,t-j\delta} \quad (3.3)$$

for the outside heat flux ($q'' = q/A$)

where:

X_j = Outside CTF coefficient, $j = 0, 1, \dots, nz$.

Y_j = Cross CTF coefficient, $j = 0, 1, \dots, nz$.

Z_j = Inside CTF coefficient, $j = 0, 1, \dots, nz$.

Φ_j = Flux CTF coefficient, $j = 1, 2, \dots, nq$.

T_i = Inside face temperature

T_o = Outside face temperature

q''_{ko} = Conduction heat flux on outside face

q'' = Conduction heat flux on inside face

The subscript following the comma indicates the time period for the quantity in terms of the time step (δ). Note that the first terms in the series (those with subscript 0) have been separated from the rest in order to facilitate solving for the current temperature in the solution scheme. These equations state that the heat flux at either face of the surface of any generic building element is linearly related to the current and some of the previous temperatures at both the interior and exterior surface as well as some of the previous flux values at the interior surface.

The final CTF solution form reveals why it is so elegant and powerful. With a single, relatively simple, linear equation with constant coefficients, the conduction heat transfer through an element can be calculated. The coefficients (CTFs) in the equation are constants that only need to be determined once for each construction type. The only storage of data required are the CTFs themselves and a limited number of temperature and flux terms. The formulation is valid for any surface type and does not require the calculation or storage of element interior temperatures.

3.1.2 Calculation of Conduction Transfer Functions

The basic method used in EnergyPlus for CTF calculations is known as the state space method (Ceylan and Myers 1980; Seem 1987; Ouyang and Haghighat 1991). Another common, older method used Laplace transformations to reach the solution; the Laplace method was used in BLAST (Hittle, 1979; Hittle & Bishop, 1983). The basic state space system is defined by the following linear matrix equations:

$$\frac{d[\mathbf{x}]}{dt} = [\mathbf{A}][\mathbf{x}] + [\mathbf{B}][\mathbf{u}] \quad (3.4)$$

$$[\mathbf{y}] = [\mathbf{C}][\mathbf{x}] + [\mathbf{D}][\mathbf{u}] \quad (3.5)$$

where \mathbf{x} is a vector of state variables, \mathbf{u} is a vector of inputs, \mathbf{y} is the output vector, t is time, and \mathbf{A} , \mathbf{B} , \mathbf{C} , and \mathbf{D} are coefficient matrices. Through the use of matrix algebra, the vector of state variables (\mathbf{x}) can be eliminated from the system of equations, and the output vector (\mathbf{y}) can be related directly to the input vector (\mathbf{u}) and time histories of the input and output vectors.

Seem (1987) summarizes the steps required to obtain the output vector (\mathbf{y}) from the \mathbf{A} , \mathbf{B} , \mathbf{C} , and \mathbf{D} matrices. Briefly, the solution for the first order differential system of equations with constant coefficients shown above is:

$$x_{t+\delta} = e^{A\delta}x_t + \int_t^{t+\delta} e^{A(t+\delta-\tau)}Bu(\tau)d\tau \quad (3.6)$$

where t is a particular point in time, δ is the time step, and $e^{A\delta}$ is the exponential matrix which is calculated using a power series:

$$e^{A\delta} = I + A\delta + \frac{A^2\delta^2}{2!} + \frac{A^3\delta^3}{3!} + \dots + \frac{A^L\delta^L}{L!} + \dots \quad (3.7)$$

where L is the term in the sequence that defines an adequate representation of the exponential matrix. In other words, terms beyond L are not needed because they will not supply any significant additional value to the overall exponential matrix. So, the calculation of the exponential matrix can be terminated after the Lth term. Seem (1987) also defines what L should be in Appendix A of his dissertation. It is based on an equation that relates L to the matrix row norm:

$$L = \text{minimum of } [3||A\delta||_{\infty} + 6] \text{ or } 100 \quad (3.8)$$

where $||A\delta||_{\infty}$ is the matrix row norm. Seem, as part of his algorithm, indicates that the matrix row norm should be normalized so that it is less than unity by finding the power of 2 that is larger than the matrix row norm and dividing all elements of the A matrix by that term. This is used later as part of the "scaling and squaring" approach to calculate the exponential matrix. This scaling would also affect L meaning that if the matrix row norm has been scaled so that it is never greater than 1 then L would never go higher than 9. In EnergyPlus, the matrix row norm is not scaled when used to calculate L. This can result in additional terms which in general will make the calculation slightly more accurate. To avoid excessive terms in the exponential matrix, the terms that are added in the exponential matrix calculation in EnergyPlus are limited so that if a new term is smaller than will impact the variable based on the precision of the variable it is then ignored. To see the implementation of these details in EnergyPlus, consult both Appendix A of Seem's dissertation and the routine calculateExponentialMatrix in the code.

As shown in Seem (1987), the above formulation can be used to solve the transient heat conduction equation by enforcing a finite difference grid over the various layers in the building element being analyzed. In this case, the state variables are the nodal temperatures, the environmental temperatures (interior and exterior) are the inputs, and the resulting heat fluxes at both surfaces are the outputs. Thus, the state space representation with finite difference variables would take the following form:

$$\frac{d \begin{bmatrix} T_1 \\ \vdots \\ T_n \end{bmatrix}}{dt} = [\mathbf{A}] \begin{bmatrix} T_1 \\ \vdots \\ T_n \end{bmatrix} + [\mathbf{B}] \begin{bmatrix} T_i \\ T_o \end{bmatrix} \quad (3.9)$$

$$\begin{bmatrix} q''_i \\ q''_o \end{bmatrix} = [\mathbf{C}] \begin{bmatrix} T_1 \\ \vdots \\ T_n \end{bmatrix} + [\mathbf{D}] \begin{bmatrix} T_i \\ T_o \end{bmatrix} \quad (3.10)$$

where T1, T2, ..., Tn-1, Tn are the finite difference nodal temperatures, n is the number of nodes, Ti and To are the interior and exterior environmental temperatures, and q''i and q''o are the heat fluxes (desired output).

Seem (1987) shows that for a simple one layer slab with two interior nodes as in Figure 3.1 and convection at both sides the resulting finite difference equations are given by:

$$C \frac{dT_1}{dt} = hA(T_o - T_1) + \frac{T_2 - T_1}{R} \quad (3.11)$$

$$C \frac{dT_2}{dt} = hA(T_i - T_2) + \frac{T_1 - T_2}{R} \quad (3.12)$$

$$q''_i = h(T_i - T_2) \quad (3.13)$$

$$q''_o = h(T_1 - T_o) \quad (3.14)$$

where:

$$R = \frac{\ell}{kA},$$

$$C = \frac{\rho c_p \ell A}{2}, \text{ and}$$

A is the area of the surface exposed to the environmental temperatures.

In matrix format:

$$\begin{bmatrix} \frac{dT_1}{dt} \\ \frac{dT_2}{dt} \end{bmatrix} = \begin{bmatrix} -\frac{1}{RC} - \frac{hA}{C} & \frac{1}{RC} \\ \frac{1}{RC} & -\frac{1}{RC} - \frac{hA}{C} \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \end{bmatrix} + \begin{bmatrix} \frac{hA}{C} & 0 \\ 0 & \frac{hA}{C} \end{bmatrix} \begin{bmatrix} T_o \\ T_i \end{bmatrix} \quad (3.15)$$

$$\begin{bmatrix} q''_o \\ q''_i \end{bmatrix} = \begin{bmatrix} 0 & -h \\ h & 0 \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \end{bmatrix} + \begin{bmatrix} 0 & h \\ -h & 0 \end{bmatrix} \begin{bmatrix} T_o \\ T_i \end{bmatrix} \quad (3.16)$$

The important aspect of the state space technique is that through the use of matrix algebra the state space variables (nodal temperatures) can be eliminated to arrive at a matrix equation that gives the outputs (heat fluxes) as a function of the inputs (environmental temperatures) only. This eliminates the need to solve for roots in the Laplace domain. In addition, the resulting matrix form has more physical meaning than complex functions required by the Laplace transform method.

The accuracy of the state space method of calculating CTFs has been addressed in the literature. Ceylan and Myers (1980) compared the response predicted by the state space method to various other solution techniques including an analytical solution. Their results showed that for an adequate number of nodes the state space method computed a heat flux at the surface of a simple one layer slab within 1% of the analytical solution. Ouyang and Haghighat (1991) made a direct comparison between the Laplace and state space methods. For a wall composed of insulation between two layers of concrete, they found almost no difference in the response factors calculated by each method.

While more time consuming than calculating CTFs using the Laplace Transform method, the matrix algebra (including the calculation of an inverse and exponential matrix for A) is easier to follow than root find algorithms. Another difference between the Laplace and State Space methods is the number of coefficients required for a solution. In general, the State Space method requires more coefficients. In addition, the number of temperature and flux history terms is identical ($n_z = n_q$). Note that as with the Laplace method that the actual number of terms will vary from construction to construction.

Two distinct advantages of the State Space method over the Laplace method that are of interest when applying a CTF solution for conduction through a building element are the ability to obtain CTFs for much shorter time steps and the ability to obtain 2- and 3-D conduction transfer functions. While not implemented in the Toolkit, both Seem (1987) and Strand (1995) have

Figure 3.1: Two Node State Space Example.

demonstrated the effectiveness of the State Space method in handling these situations that can have important applications in buildings.

3.1.3 Conduction Transfer Function (CTF) Calculations in EnergyPlus

Conduction transfer functions are an efficient method to compute surface heat fluxes because they eliminate the need to know temperatures and fluxes within the surface. However, conduction transfer function series become progressively more unstable as the time step decreases. This became a problem as investigations into short time step computational methods for the zone/system interactions progressed because, eventually, this instability caused the entire simulation to diverge. This phenomenon was most apparent for thermally massive constructions with long characteristic times and, correspondingly, requiring a large number of terms in the CTF series. This indicates that the problem is related to round-off and truncation error and is in no way an indictment of the CTF method itself. Methods that develop CTF series from finite difference approximations to the heat conduction equation (Meyers, 1980; Seem, 1987) were considered to address this problem. Seem's method did give better accuracy and stability at short time steps than the current BLAST technique but, the method still had difficulty computing stable CTF series for time steps of less than 1/4 hour for the heaviest constructions in the BLAST library.

The zone heat gains consist of specified internal heat gains, air exchange between zones, air exchange with the outside environment, and convective heat transfer from the zone surfaces. Of these, the surface convection load requires the most complicated calculations because a detailed energy balance is required at the inside and outside surface of each wall, floor, and roof. In addition, the transient heat conduction in the material between the surfaces must be solved. This solution gives the inside and outside temperatures and heat fluxes that must be known in order to calculate the convection component to the zone load for each zone surface. BLAST uses a conduction transfer function CTF method attributed to Hittle (1980) to solve the transient conduction problem for each surface. The method results in a time series of weighting factors that, when multiplied by previous values of the surface temperatures and fluxes and the current inside and outside surface temperatures, gives the current inside and outside heat flux. The method is easily applied to multilayered constructions for which analytical solutions are unavailable. In addition, determining the series of CTF coefficients is a one-time calculation, making the method much faster than finite difference calculations.

A problem with CTF methods is that the series time step is fixed; that is, a CTF series computed for a one hour time step takes information at $t-1$ hours, $t-2$ hours, etc. and computes conditions at the current time t . As time advances the oldest term in the input series is dropped and the data moved back one time step to allow the newest value to be added to the series. For convenience, the time step used to determine the CTF series should be the same as the time step used to update the zone mean air temperature in the zone energy balance. But, as the time step used to calculate the CTF series gets shorter, the number of terms in the series grows. Eventually, with enough terms, the series becomes unstable due to truncation and round-off error. Heavy constructions, such as slab-on-grade floors (12" heavyweight concrete over 18" dirt), have accuracy and stability problems at time steps as large as 0.5 hours when modeled by Hittle's CTF method. In an attempt to overcome this problem, Hittle's method was replaced by Seem's method (1987) in IBLAST. This resulted in some improvement in stability at shorter time steps, but not enough to allow IBLAST to run at a 0.1 hour time step without restricting the types of surfaces that could be used.

Even though CTF methods require that values of the surface temperatures and fluxes be stored

for only a few specific times before the current time, the temperature and flux histories are, actually, continuous functions between those discrete points. However, there is no way to calculate information at these intermediate times once a series has been initialized. The terms in the temperature and flux histories are out of phase with these points. However, they can be calculated by shifting the phase of the temperature and flux histories by only a fraction of a time step. This procedure would allow a CTF series computed for a time step Dt , to be used to compute information at times $t+Dt/2$, $t+Dt/3$, $t+Dt/4$, or any other arbitrary fraction of the time step, so long as the surface temperatures and flux values were still Dt apart. Several ways of doing this are described below.

The method shown in the Figure 3.2 maintains two sets of histories out of phase with each other. The figure shows how this would work for two sets of histories out of phase by one half of a time step. More sets of temperature and flux histories could be used, allowing the simulation time step to take on values: $1/3$, $1/4$, $1/5$, etc., of the minimum time step allowed for the CTF calculations. The time step between inputs to the CTF series would be the smallest convenient interval at which the CTF series is stable. This scenario is illustrated in this figure for two separate sets of temperature and flux histories. Cycling through each history, in order, allowed calculations of the zone energy balance to be performed with updated surface information at a shorter time step than one CTF history series would otherwise allow. This method required no interpolation between the series once each set of histories was initialized. However, if the smallest time step for a stable CTF series was large compared to the zone temperature update time step, significant memory was required to store all the sets of histories.

Figure 3.2: Multiple, staggered time history scheme

Another method is shown in Figure 3.3. Sequential interpolation of new histories that uses successive interpolations to determine the next set of temperature and flux histories. The current history is interpolated directly from the previous history set using the required time phase shift between the two. This method required permanent storage for only one set of temperature and flux histories at a time, but smoothed out temperature and flux data as more interpolations were performed. As a result, at concurrent simulation times current values of history terms were different from previous “in phase” history terms. This was unacceptable from, a physical point of view, because it allowed current information to change data from a previous time.

A final method, shown in Figure 3.4. Master history with interpolation, was something of a hybrid of the previous two methods. One “master” history set was maintained and updated for all

Figure 3.3: Sequential interpolation of new histories

time; this solved the problem of current events propagating information backwards in time. When surface fluxes needed to be calculated at times out of phase with this master history a new, temporary history was interpolated from the master values. This method proved to be the best of the three options described because it eliminated propagation of information backwards in time and only required concurrent storage of two sets of temperature and flux histories. This method was subsequently incorporated into the IBLAST program in conjunction with Seem's procedure for calculating the coefficients of the CTF series.

Figure 3.4: Master history with interpolation

3.1.4 Conduction Transfer Function (CTF) Calculations Special Case: R-Value Only Layers

Most users will elect to enter materials with four parameters that are of interest for calculating conduction transfer functions: thickness, conductivity, density, and specific heat. For these materials, EnergyPlus will divide each material layer within a construction into between 6 and 18 nodes for the application of the state-space method. For multi-layered constructions, nodes are also placed at the interface between two layers. These interface nodes consist of half a node of the first layer and half a node of the second layer.

In some cases, either due to a lack of information or a desire to simplify input, a user may choose to enter a material layer as a “no mass” or “R-Value only” material. This assumption essentially says that these layers add nothing to the thermal mass of the overall construction and only add to the overall resistance or R-Value of the construction as a whole. While this is not recommended, it is allowed and in some cases is not a poor assumption for extremely lightweight materials such as some types of insulation.

In the past, when a user enters such a “no mass” material into EnergyPlus, internally the properties of this layer are converted to approximate the properties of air (density, specific heat, and conductivity) with the thickness adjusted to maintain the user’s desired R-Value. This allowed such layers to be handled internally in the same way as other layers without any additional changes to the code. This solution was deemed accurate enough as air has very little thermal mass and it made the coding of the state space method simpler.

It is possible to account for layers that have no thermal mass in the state space solution without resorting to the assignment of fictitious material properties. The EnergyPlus internal equations for assigning values to portions of the A, B, C, and D matrices as shown in the previous subsections have been altered to account for the potential presence of R-Value only (or no mass) layers without resorting to assigning these materials the properties of air. This is handled by assuming that the “no mass” layer is a single node layer. As nodes are defined that the interface between material layers, the “no mass” layer is essentially two “half nodes” that are shared with the surrounding layers. This allows the surrounding material layers to provide thermal capacitance for each of the nodes at the material interfaces.

In EnergyPlus, there are two possible cases for the existence of “no mass” layers: either between two other solid, thermally massive layers (multiple “no mass” layers next to each other are simply combined in this approach) or at the inner or outer most layers of a construction. There are potential issues with having a resistance-only layer at either the inner or outer most layers of a construction. A little or no mass layer there could receive intense thermal radiation from internal sources or the sun causing the temperature at the inner or outer surface to achieve very high levels. This is undesirable from a simulation standpoint as there are limits to temperature levels in EnergyPlus that could be exceeded causing the simulation to terminate and is likely unrealistic from a real-world perspective. Thus, for such potentially problematic calculational scenarios, EnergyPlus will continue to convert a “no mass” layer at either the inner or outer most layer of a construction into a thermal mass layer using the properties of air as has been done in the past.

The case where a resistance-only layer is defined anywhere except the inner or outer layer of a construction is handled by treating the “no mass” layer as a single node layer. This will result in a node at each interface as in the standard material layer cases. When a “no mass” material is present, the R-Value only layer will not add any thermal capacitance to the nodes at the interfaces at either side of the material. It will simply add resistance between the two nodes.

From the EnergyPlus code, the A matrix (AMat) is assigned with values at the interface using the following equations (taken from the actual code):

```
cap = ( rho(Layer)*cp(Layer)*dx(Layer) + rho(Layer+1)*cp(Layer+1)*dx(Layer+1) ) \* 0.5D0
AMat(Node,Node-1) = rk(Layer)/dx(Layer)/cap      ! Assign matrix values for the current node
AMat(Node,Node)   = -1.0D0 \* ( rk(Layer)/dx(Layer)+rk(Layer+1)/dx(Layer+1) ) / cap
AMat(Node,Node+1) = rk(Layer+1)/dx(Layer+1)/cap    ! node.
```

Note that these equations do not change. For “no mass” layers, the density (rho) and the specific heat (cp) variables will be assigned zero values. In addition, the thickness (dx) will be equated with the user-defined R-Value and conductivity (rk) will be assigned a value of unity. In

Figure 3.5: Illustration of no-mass layer between two mass layers

addition, the number of nodes for the “no mass” layer will be set to 1.

This handles resistive layers correctly without resorting to assigning the properties of air to the “no mass” layer. The only potential problem with this is if two resistive layers are placed next to each other. In that case, the interface between the two resistive layers would have no mass (variable “cap” would equal zero) and a divide by zero would result. To avoid this, adjacent “no mass” layers are combined internally so that the user does not have to do this and also to avoid any divide by zero errors.

While from a results standpoint, the difference in output between assigning air properties for specific heat, density, etc. and handling the no mass materials explicitly is negligible, handling the no mass layers properly does provide better code efficiency from a calculation speed standpoint.

3.2 Conduction Finite Difference Solution Algorithm

3.2.1 Basic Finite Difference Solution Approach

EnergyPlus models follow fundamental heat balance principles very closely in almost all aspects of the program. However, the simulation of building surface constructions has relied on a conduction transfer function (CTF) transformation carried over from BLAST. This has all the usual restrictions of a transformation-based solution: constant properties, fixed values of some parameters, and do not produce results for the interior of the surface. As the energy analysis field moves toward simulating more advanced constructions, such as phase change materials (PCM), it becomes necessary to step back from transformations to more fundamental forms. Accordingly, a conduction finite difference (CondFD) solution algorithm has been incorporated into EnergyPlus. This does not replace the CTF solution algorithm, but complements it for cases where the user needs to simulate phase change materials or variable thermal conductivity. It is also possible to use the finite difference algorithm for zone time steps as short as one minute.

EnergyPlus includes two different options for the specific scheme or formulation used for the finite difference model. The first scheme is referred to as Crank- Nicholson and was the formulation used in EnergyPlus prior to version 7. As of version 7 a second scheme was added and is referred to as fully implicit. The selection between the two can be made by the user with the HeatBalanceSettings:ConductionFiniteDifference input object. Once selected, the same scheme is used throughout the simulation. Although the two different schemes differ in their fundamental heat transfer equations, they share nearly all the same supporting models for material properties, data storage, solution schemes, and spatial discretization algorithms.

The Crank-Nicholson scheme is semi-implicit and based on an Adams-Moulton solution approach. It is considered second-order in time. The algorithm uses an implicit finite difference scheme coupled with an enthalpy-temperature function to account for phase change energy accurately. The implicit formulation for an internal node is shown in the equation below.

$$C_p \rho \Delta x \frac{T_i^{j+1} - T_i^j}{\Delta t} = \frac{1}{2} \left(k_W \frac{T_{i+1}^{j+1} - T_i^{j+1}}{\Delta x} + k_E \frac{T_{i-1}^{j+1} - T_i^{j+1}}{\Delta x} + k_W \frac{T_{i+1}^j - T_i^j}{\Delta x} + k_E \frac{T_{i-1}^j - T_i^j}{\Delta x} \right) \quad (3.17)$$

where:

T = node temperature

Δt = calculation time step

Δx = finite difference layer thickness (always less than construction layer thickness)

C_p = specific heat of material

k_W = thermal conductivity for interface between node i and node $i + 1$

k_E = thermal conductivity for interface between node i and node $i - 1$

ρ = density of material

with superscripts and subscripts:

i = node being modeled

$i + 1$ = adjacent node to interior of construction

$i - 1$ = adjacent node to exterior of construction

$j + 1$ = new time step

j = previous time step

Then, this equation is accompanied by a second equation that relates enthalpy and temperature.

$$h_i = \text{HTF}(T_i) \quad (3.18)$$

where HTF is an enthalpy-temperature function that uses user input data.

The fully implicit scheme is also based on an Adams-Moulton solution approach. It is considered first order in time. The model equation for this scheme is shown in the following equation.

$$C_p \rho \Delta x \frac{T_i^{j+1} - T_i^j}{\Delta t} = \left(k_W \frac{T_{i+1}^{j+1} - T_i^{j+1}}{\Delta x} + k_E \frac{T_{i-1}^{j+1} - T_i^{j+1}}{\Delta x} \right) \quad (3.19)$$

For both schemes, EnergyPlus uses the following four types of nodes, as shown in the figure below (1) interior surface nodes, (2) interior nodes, (3) material interface nodes and (4) external surface nodes. The grid for each material is established by specifying a half node for each edge of a material and equal size nodes for the rest of the material. Equations such as 3.17 are formed for all nodes in a construction. The formulation of all node types is basically the same.

Figure 3.6: Node depiction for Conduction Finite Difference Model

In the CondFD model, surface discretization depends on the thermal diffusivity of the material (α) and time step (Δt) selected, as shown in the equation below. The default value of 3 for the space discretization constant, C , is the inverse of a grid Fourier Number:

$$Fo = \frac{\alpha \Delta t}{\Delta x^2} \quad (3.20)$$

and is based on the stability requirement for the explicit mode that requires values higher than 2, or a Fourier number lower than 0.5. However, CondFD uses implicit schemes that do not have the same stability requirements as the explicit mode. Thus, the default 3 was originally set rather arbitrary. As of version 7, the value of this constant can be controlled by the user with the input field called Space Discretization Constant in the HeatBalanceSettings:ConductionFiniteDifference input object. The discretization method allows CondFD to assign different node spacing or grid size to different material layers in a wall or roof, as building walls and roofs typically consist of several layers of different materials having different thermal properties.

$$\Delta x = \sqrt{C\alpha\Delta t} \quad (3.21)$$

The actual integer number of nodes for each layer is then calculated by rounding off the result from dividing the length of the material layer by the result of the equation above. After this, Δx is recalculated by dividing the length of the material by the number of nodes. A full node is equal to two half nodes. Lower values for the Space Discretization Constant yield more nodes, with higher values yield fewer nodes.

Because the solution is implicit, a Gauss-Seidel iteration scheme is used to update to the new node temperatures in the construction and under-relaxation is used for increased stability. The Gauss-Seidel iteration loop is the inner-most solver and is called for each surface. It is limited to 30 iterations but will exit early when the sum of all the node temperatures changes between the last call and the current call, normalized by the sum of the temperature values, is below ~ 0.000001 C. This convergence criteria is typically met after 3 iterations, except when PCMs are simulated as it takes an average of 2-3 more iterations when PCM are changing phase. If the number of iterations needed to meet convergence criteria start to increase, an automatic internal relaxation factor stabilizes the solution and in most cases keep the number of iterations less than 10.

EnergyPlus also uses a separate, outer iteration loop across all the different inside surface heat balances so that internal long-wave radiation exchange can be properly solved. For CTF formulations, this iteration is controlled by a maximum allowable temperature difference of 0.002°C for inside face surface temperatures from one iteration to the next (or a limit of 100 iterations). CondFD uses the same default value for allowable temperature difference as CTF. However, this parameter was found to often need to be smaller for stability and so the inside surface heat balance manager uses a separate allowable maximum temperature difference when modeling CondFD. The user can control the value of the relaxation factor by using the input field called Inside Face Surface Temperature Convergence Criteria in the HeatBalanceSettings:ConductionFiniteDifference input object. In addition, if the program detects that there is instability by watching for excessive numbers of iterations in this outer loop and may decrease the relaxation factor. Users can also output the number of iterations inside of CondFD loop for each surface and the outer internal heat balance loop for each zone with “CondFD Inner Solver Loop Iterations” and “Heat Balance Inside Surfaces Calculation Iterations” respectively.

$$T_{i,\text{new}} = T_{i,\text{old}} + \text{Relax} (T_{i,\text{new}} - T_{i,\text{old}}) \quad (3.22)$$

Because of the iteration scheme used for CondFD, the node enthalpies get updated each iteration, and then they are used to develop a variable Cp if a phase change material is being simulated. This is done by including a third equation for Cp.

Figure 3.7: Hysteresis PCM Model Curves

For inputs with `MaterialProperty:PhaseChange`, the specific heat is calculated from the tabulated input data of temperature/enthalpy pairs:

$$Cp = \frac{h_{i,\text{new}} - h_{i,\text{old}}}{T_{i,\text{new}} - T_{i,\text{old}}} \quad (3.23)$$

For inputs with `MaterialProperty:PhaseChangeHysteresis`, the specific heat is not only dependent on the current state, but also the previous state, as it captures the hysteresis physics present between the melting and freezing processes.

$$Cp = f(T_{i,\text{new}}, T_{i,\text{prev}}, \text{PhaseState}_{\text{new}}, \text{PhaseState}_{\text{prev}}) \quad (3.24)$$

The hysteresis model also has inputs for solid and liquid state values for thermal conductivity and density. Within the transition region of the hysteresis model the average of the two is used. If the dynamic nature of these parameters is not known, the user may enter the same value for both states and that static value will be used throughout.

The actual formulation of the hysteresis model is captured in Figure 3.7. The inputs that led to those curves were as follows:

- All temperature “difference” inputs were set to 1.0 as this is an example only. Using smaller or larger temperature differences would shrink or expand the freezing or melting regions accordingly.
- The total latent heat transferred during the phase transition process is set to 25000 J/kg
- The peak freezing temperature is set to 23 °C, where the freezing curve transition is centered.
- The peak melting temperature is set to 27 °C, where the melting curve transition is centered.

The iteration scheme assures that the correct enthalpy, and therefore the correct C_p is used in each time step, and the enthalpy of the material is accounted for accurately. Of course, if the material is regular, the user input constant C_p is used.

For non-hysteresis finite difference calculations, the algorithm also has a provision for including a temperature coefficient to modify the thermal conductivity. The thermal conductivity is obtained from:

$$k = k_o + k_1 (T_i - 20) \quad (3.25)$$

where:

k_o = is the 20 °C value of thermal conductivity (normal IDF input)

k_1 = is the change in conductivity per degree temperature difference from 20 °C

As of Version 7, the CondFD implementation was changed to evaluate the thermal conductivity at the interface between nodes, as shown below. In this case, EnergyPlus uses a linear interpolation between nodal points.

$$C_p \rho \Delta x \frac{T_i^{j+1} - T_i^j}{\Delta t} = \frac{1}{2} \left[\left(k_W \frac{T_{i+1}^{j+1} - T_i^{j+1}}{\Delta x} + k_E \frac{T_{i-1}^{j+1} - T_i^{j+1}}{\Delta x} \right) + \left(k_W \frac{T_{i+1}^j - T_i^j}{\Delta x} + k_E \frac{T_{i-1}^j - T_i^j}{\Delta x} \right) \right] \quad (3.26)$$

where,

$$k_W = \frac{k_{i+1}^{j+1} + k_i^{j+1}}{2} \quad (3.27)$$

and

$$k_E = \frac{k_{i-1}^{j+1} + k_i^{j+1}}{2} \quad (3.28)$$

These additional property information values are put into the input file as explained in the Input/Output Reference Document, but it consists simply of a value for k_1 and set of enthalpy temperature pairs that describe the enthalpy of the phase change material in straight line segments with respect to temperature.

A graph showing the effect of a large PCM on the outside surface of a zone is shown below. The phase change temperature was 30 °C, and the flat temperature response during the phase change is obvious. This example was run with a zone time step of one minute to show that such small time steps can be done with the finite difference solution technique. It is more efficient to set the zone time step shorter than those used for the CTF solution algorithm. It should be set to 20 time steps per hour or greater, and can range up to 60. The finite difference algorithm actually works better with shorter zone time steps. The computation time has a minimum at a zone time step around two minutes (30 time steps/hr), and increases for shorter or longer zone time steps.

3.2.2 Finite Difference Node Arrangement in Surfaces

The Conduction Finite Difference algorithm determines the number of nodes in each layer of the surface based on the Fourier stability criteria. The node thicknesses are normally selected so that the time step is near the explicit solution limit in spite of the fact that the solution is implicit. For very thin, high conductivity layers, a minimum of two nodes is used. This means two half thickness

Figure 3.8: Effects of Large PCM on Outside Zone Surface

nodes with the node temperatures representing the inner and outer faces of the layer. All thicker layers also have two half thickness nodes at their inner and outer faces. These nodes produce layer interface temperatures.

The ConductionFiniteDifferenceSimplified capability was removed as of Version 7.2.

3.2.3 Conduction Finite Difference Variable Thermal Conductivity

The Conduction Finite Difference algorithm has also been given the capability to use an expanded thermal conductivity function. This function, explained in the input/output document, is similar to the temperature enthalpy function. It consists of pairs of temperature and thermal conductivity values that form a linear segmented function. It is established with the MaterialProperty:VariableThermalConductivity object.

3.2.4 Conduction Finite Difference Source Sink Layers

The Conduction Finite Difference algorithm can also invoke the source/sink layer capability by using the **ConstructionProperty:InternalHeatSource** object.

3.2.5 Conduction Finite Difference Heat Flux Outputs

The Conduction Finite Difference algorithm can output the heat flux at each node and the heat capacitance of each half-node. During the CondFD solution iterations, the heat capacitance of each half node (CondFD Surface Heat Capacitance Node < n >) is stored:

$$\text{HeatCap}_i = \frac{1}{2} C_{p,i} \Delta x_i \rho_i \quad (3.29)$$

For nodes which are at the inside or outside face of the surface, there is only one half-node.

After the CondFD node temperatures have been solved for a given timestep, the heat fluxes (CondFD Surface Heat Flux Node $< i >$) are calculated beginning with the inside face of the surface.

$$Q_{Dreport_N} = Q_{inside} \quad (3.30)$$

for the remaining nodes

$$Q_{Dreport_i} = Q_{Dreport_{i+1}} + HeatCap1_{i+1} \frac{T_{i+1,new} - T_{i+1,old}}{\Delta t} - Q_{Source_i} + HeatCap2_i \frac{T_{i,new} - T_{i,old}}{\Delta t} \quad (3.31)$$

where:

$HeatCap1_i$ = heat capacitance associated with a given outer half-node

$HeatCap2_i$ = heat capacitance associated with a given inner half-node

$Q_{Dreport_i}$ = CondFD Surface Heat Flux Node $< i >$

Q_{Source_i} = internal source heat flux at node i

Q_{inside} = Surface Inside Face Conduction Heat Transfer Rate per Area [W/m²]

N = total number of nodes in a surface including the surface inside face node.

Note that the variable *TotNodes* used in the source code is actually $N-1$. The surface inside face node is referenced as *TotNodes+1*.

3.3 Combined Heat and Moisture Transfer (HAMT) Model

3.3.1 Overview

The combined heat and moisture transfer finite (HAMT) solution algorithm is a completely coupled, one-dimensional, finite element, heat and moisture transfer model simulating the movement and

storage of heat and moisture in surfaces simultaneously from and to both the internal and external environments. As well as simulating the effects of moisture buffering, HAMT is also be able to provide temperature and moisture profiles through composite building walls, and help to identify surfaces with high surface humidity.

3.3.2 HAMT Nomenclature

Dependencies on moisture content are indicated by a superscript ^w, on heat by a superscript ^h and vapor pressure by a superscript ^v.

Table 3.1: Combined Heat and Moisture Transfer Model
Nomenclature

Symbol	Units	Meaning
A	m^2	Contact Surface area
C	J/kgC	Specific heat capacity of dry material
C_i^h	J/C	Heat Capacitance of cell i
C_i^w	kg	Moisture Capacitance of cell i
c^w	J/KgC	Specific heat capacity of water (= 4,180 J/kg°C@ 20°C)
D^w	m^2/s	Liquid Transport Coefficient
h_v	J/kg	Evaporation enthalpy of water (= 2,489,000 J/kg)
$\partial H/\partial T$	J/m^3C	Moisture dependent heat storage capacity
i,j	—	Cell indices
k^w	W/mC	Moisture dependent thermal conductivity
p	Pa	Vapor pressure
p_{ambient}	Pa	Ambient air pressure
p(as a superscript)	s	Present Time Step
P	m^3/m^3	Material Porosity
q_i^{adds}	W	Heat from additional Sources
q_i^v	W	Heat due to Vaporisation

ϕ	fraction	Relative humidity

3.3.3 HAMT Model Description

Equations 3.32 and 3.33 are derived from heat and moisture balance equations and are taken from [Künzel, H.M. (1995)]. They describe a theoretical model for the transfer of heat and moisture through a material.

$$\frac{\partial H}{\partial T} \frac{\partial T}{\partial \tau} = \frac{\partial}{\partial x} \left(k^w \frac{\partial T}{\partial x} \right) + h_v \frac{\partial}{\partial x} \left(\frac{\delta}{\mu} \frac{\partial p}{\partial x} \right) \quad (3.32)$$

The three terms in Equation 3.32 describe the storage, transport and generation of heat respectively.

$$\frac{\partial w}{\partial \phi} \frac{\partial \phi}{\partial \tau} = \frac{\partial}{\partial x} \left(D^w \frac{\partial w}{\partial \phi} \frac{\partial \phi}{\partial x} \right) + \frac{\partial}{\partial x} \left(\frac{\delta}{\mu} \frac{\partial p}{\partial x} \right) \quad (3.33)$$

The three terms in Equation 3.33 describe the storage of moisture, the transport of liquid moisture and the transport of vapor respectively. The equation to calculate the vapor diffusion coefficient in air (δ) used in the third term of both equations, is also taken from Künzel,

$$\delta = \frac{(2 \times 10^{-7} \times (T + 273.15)^{0.81})}{p_{ambient}} \quad (3.34)$$

The heat storage capacity ($\frac{\partial H}{\partial T}$) depends on the moisture content w of the material by the following equation.

$$\frac{\partial H}{\partial T} = (c\rho + c^w w) \quad (3.35)$$

The moisture content of the material w and the vapor diffusion resistance factor μ depend on the relative humidity inside the material. The parameters $\frac{\partial w}{\partial \phi}$, k^w and D^w are also moisture dependent parameters.

The following sections describe how the above equations are used within the HAMT model.

3.3.3.1 Surfaces, Material Layers and Cells

“Surfaces” are made of a number of layers of potentially any combination of materials. Each surface is split into its constituent materials and is then split up further into cells through its depth. HAMT will generate no more than 10 cells per material with widths that are thinner near the boundaries of each material where most changes are expected and detail is needed.

3.3.3.2 Heat Transfer

Equation 3.32 can be re-written and used to describe the heat storage and transfer through the i^{th} cell in a surface.

$$(c_i \rho_i + c^w w_i) \Delta V_i \frac{T_i^{p+1} - T_i^p}{\Delta \tau} = \sum_j k_{ij}^w A_{ij} \frac{T_j^{p+1} - T_i^{p+1}}{x_{ij}} + \sum_j h_v \frac{\delta_{ij}}{\mu_{ij}} A_{ij} \frac{p_j^{p+1} - p_i^{p+1}}{x_{ij}} \quad (3.36)$$

In the one dimensional case there are only two adjacent cells each labeled j . The heat generated due to vaporization q_i^v can be calculated separately.

$$q_i^v = \sum_j h_v \frac{\delta_{ij}}{\mu_{ij}} A_{ij} \frac{p_j^{p+1} - p_i^{p+1}}{x_{ij}} \quad (3.37)$$

Rearranging Equation 3.32 and including other sources of heat (q_i^{adds}) such as radiation from other surfaces in the calculation gives the temperature in a cell in the next time step as,

$$T_i^{p+1} = \frac{\sum_j \frac{T_j^{p+1}}{R_{ij}^h} + q_i^v + q_i^{adds} + C_i^h \frac{T_i^p}{\Delta \tau}}{\frac{C_i^h}{\Delta \tau} + \sum_j \frac{1}{R_{ij}^h}} \quad (3.38)$$

where $C_i^h = (c_i \rho_i + c^w w_i) \Delta V_i$ is thermal heat capacitance of cell i and $R_{ij}^h = \frac{x_{ij}}{k_{ij} A_{ij}}$ is the thermal resistance between cells i and j .

This equation can be solved using the Gauss-Seidel iteration technique. The i^{th} cell temperature is calculated whilst the j^{th} cell temperatures are kept as up to date as possible. The iteration is stopped when the maximum difference between two consecutive calculations in all cells is less than a threshold of 0.002°C .

3.3.3.3 Moisture Content w

The moisture content (w) of a cell is needed for the calculation of the heat transfer through the cell as it affects the thermal resistance and heat capacitance. The moisture content of cells is calculated from the relative humidity (RH) of the material. The relationship between w and the RH for each material is known as the sorption isotherm and measured data points are entered into EnergyPlus as a series of coordinates. HAMT interpolates between the measurements to obtain the moisture content of a material for any RH value. The sorption isotherm input is via the MaterialProperty:HeatAndMoistureTransfer:SorptionIsotherm object and is described in the Input Output Reference document.

3.3.3.4 Porosity P

The porosity of a material (P) is an input variable and defined as the maximum fraction, by volume, of a material that can be taken up with moisture. It is used to calculate the maximum point on the sorption isotherm curve. The porosity is entered for each material via the MaterialProperty:HeatAndMoistureTransfer:Settings object, as described in the Input Output Reference document.

3.3.3.5 Moisture Dependant Thermal Conductivity k^w

The thermal conductivity (k^w) of the cell is determined by interpolating between data points of thermal conductivity versus the moisture content of the material, entered into EnergyPlus via the MaterialProperty:HeatAndMoistureTransfer:ThermalConductivity object. The moisture content is determined via the sorption isotherm which gives the moisture content as a function of Relative Humidity.

3.3.3.6 Moisture Dependant Moisture Diffusion Coefficient

This is used in the third term of Equation 3.32 to describe the heat transfer due to vapor movement. It is determined by interpolating between data points of moisture diffusion coefficient versus the moisture content of the material, entered into EnergyPlus via the MaterialProperty:HeatAndMoistureTransfer:Diffusion object. A simple linear interpolation is used to obtain the conductivity between measured points.

3.3.3.7 Moisture Transfer

Moisture, as well as heat, is transported through materials as either liquid (w) or vapor (p). There are two different potentials that control the movement through the material. Liquid transfer is driven by differences in relative humidity whereas vapor transfer is driven by differences in vapor pressure. Materials also have a capacity to store moisture. Equation 3.33 can be re-written for a discrete cell in a continuous material.

$$\frac{dw}{d\phi_i} \Delta V_i \frac{\phi_i^{p+1} - \phi_i^p}{\Delta \tau} = \sum_j k_{ij} A_{ij} \frac{\phi_j^{p+1} - \phi_i^{p+1}}{x_{ij}} + \sum_j \frac{\delta_{ij}}{\mu_{ij}} A_{ij} \frac{p_j^{p+1} - p_i^{p+1}}{x_{ij}} \quad (3.39)$$

Equation 3.39 can be rearranged to provide the relative humidity of the i^{th} cell in the next time step.

$$\phi_i^{p+1} = \frac{\sum_j \frac{\phi_j^{p+1}}{R_{ij}^w} + \sum_j \frac{p_j^{p+1}}{R_{ij}^v} + C_i^w \frac{\phi_i^p}{\Delta \tau}}{\frac{C_i^w}{\Delta \tau} + \sum_j \frac{1}{R_{ij}^w} + \sum_j \frac{p_i^{sat}}{R_{ij}^v}} \quad (3.40)$$

where $C_i^w = \frac{dw}{d\phi_i} \Delta V_i$ is the “Moisture Capacitance” of cell i,

$$R_{ij}^w = \frac{x_{ij}}{A_{ij} D_{ij}^w \frac{dw}{d\phi}} \quad (3.41)$$

is the moisture resistance between cells i and j and $R_{ij}^v = \frac{\mu_{ij} x_{ij}}{A_{ij} \delta_{ij}}$ is the vapor resistance between cells i and j.

Equation 3.40 can be used together with the heat equation 3.38 in an alternate step by step fashion to calculate the new temperature and relative humidity profiles for each cell for the next time step.

Surfaces with Ground exterior boundary condition assumes saturated air (100% relative humidity) condition to calculate the exterior mass transfer coefficient, which is used to model mass transport through a ground contact surfaces.

3.3.3.8 Liquid Transport Coefficient D^w

The Moisture Dependant Liquid Transport Coefficient is entered as a series of moisture density and liquid transport coefficient data points. There are two different coefficients, one for suction, where the surface is wet due to rain, and one for redistribution where the surface is no longer wet. If the weather file has a rain flag it is used to switch between these two types of coefficient. HAMT-SUCTION and HAMT-REDISTRIBUTION.

3.3.3.9 Moisture Dependent Moisture Capacity $\frac{\partial w}{\partial \phi}$

This is simply the gradient of moisture sorption isotherm at the RH of the material.

3.3.3.10 Convective Heat Transfer

The internal and external heat transfer coefficients are used to calculate the thermal resistance of the boundary layer between the zone air and the surface of the surface. They are either supplied by the user via the advanced surface concepts object “SurfaceProperty:ConvectionCoefficients” or, if these are not provided, dynamic values are calculated.

3.3.3.11 Convective Vapor Transfer

The internal and external vapor transfer coefficients are used to calculate the resistance to vapour transfer of the boundary layer between the zone air and the surface of the surface. They are also either supplied by the user via the advanced surface concept object SurfaceProperties:VaporCoefficients. If these are not provided then dynamic values are calculated based on the convective heat transfer coefficients.

3.3.3.12 Initial Moisture Content

At the start of an EnergyPlus simulation “warm up” days are used to ensure that the temperatures of surfaces come to equilibrium with the environment before the simulation starts proper. Moisture content within some building fabrics can take a very long time to come to equilibrium with its environment and it is therefore necessary to set initial or typical values of moisture content for each material to be used at the start of the simulation. These initial values are entered for each material via the MaterialProperty:HeatAndMoistureTransfer:Settings object as described in the Input Output Reference document.

3.3.3.13 Using the Model

As an illustration of the use of the Heat and Moisture Transfer (HAMT) model, the material properties for a small sample of six generic materials have been provided in the EnergyPlus Reference

DataSets (MoistureMaterials.idf). The properties were synthesised from the Annex 24 database [Kumar Kumaran, M. (1996)], supplemented, when required, by data from the database of the WUFI model [WUFI (1999)] and are therefore not related to any unique, measured material. Users should consult material property catalogues and other primary sources when the properties of a specific material are required.

Moisture and heat from the surfaces are used by EnergyPlus to calculate the room air temperature and moisture content. EnergyPlus with HAMT works best with as short a time step as possible. However the optimum time step which gives a good prediction for a short computing time will very much depend on the nature of the weather and type of building. Buildings with frequent and large changes in internal and external temperature will need a small time step, maybe even 60 steps per hour. Slowly evolving temperatures and relative humidity's will not require such a short time step and 20, or even 6, steps per hour may be sufficient.

3.4 Effective Moisture Penetration Depth (EMPD) Model

3.4.1 Overview

The EMPD (Effective Moisture Penetration Depth) model is a simplified, lumped approach to simulate surface moisture adsorption and desorption. It estimates moisture adsorption and desorption from building surfaces and calculates the effect this adsorption/desorption has on the humidity in each zone. There are two fictitious layers of material with uniform moisture content: a surface layer, which accounts for short-term moisture buffering, and a deep layer, which accounts for more slowly responding moisture buffering. The model calculates the moisture transfer between the air and the surface layer and between the surface layer and the deep layer. This moisture transfer impacts the zone humidity, and also impacts the zone temperature through latent-to-sensible conversion from the heat of adsorption.

3.4.2 EMPD Model Description

The EMPD concept is based on the assumption of cyclical variations in humidity, and therefore material moisture content, u . In other words, the following constraint must be met:

$$\int_{t_1}^{t_2} \frac{du}{dt} dt = 0 \quad (3.42)$$

This is generally a reasonable assumption for buildings, with daily internal latent gains. The EMPD model uses a thin material layer of constant thickness at each material surface. The moisture content is assumed constant across this thickness, termed the *surface penetration depth*. For most building materials, the equilibrium moisture sorption isotherm can be defined by the following general equation (Kerestecioglu et al. 1988):

$$u = a\phi^b + c\phi^d \quad (3.43)$$

where a , b , c , and d are fitting parameters and ϕ is relative humidity.

This surface layer (labeled with subscript 1 below) exchanges moisture with the zone air based on the difference between the zone air vapor density and the material vapor density. The model converts the surface layer moisture content to a vapor density ρ_v through the material's sorption curve:

$$\rho_{v1} = \frac{0.622\rho_{air}u_1}{\frac{du}{d\phi} \frac{P}{P_{sat}} - u_1} \quad (3.44)$$

where

$\frac{du}{d\phi}$ = slope of the moisture sorption curve, kg/kg-RH

P_{sat} = saturated vapor pressure

ρ_{air} = dry-air density

The moisture flux between the material and the zone air, j_{zone} , is the difference in vapor densities divided by the overall mass transfer resistance, which is the sum of the diffusive resistance of the surface layer, the diffusive resistance of any coating, and the convective resistance of the air boundary layer:

$$j_{zone} = \frac{\rho_{v1} - \rho_{v,zone}}{R_{MT1} + R_{MT,coating} + R_{MT,BL}} \quad (3.45)$$

Figure 3.9: Nodal network for effective moisture penetration depth model

The surface layer resistance is calculated with:

$$R_{MT,1} = \frac{d_{EMPD,1}}{2\bar{R}_{water}T\delta_{perm}} \quad (3.46)$$

where

$d_{EMPD,1}$ = depth of surface layer, m

\bar{R}_{water} = universal gas constant for water (461.52 J/kg-K)

T = temperature, K

δ_{perm} = water vapor permeability of the material, kg/m-s-Pa

The coating resistance is:

$$R_{MT,coating} = \frac{t_{coating}P_{ambient}}{\delta_{perm,coating}\bar{R}_{water}T} \quad (3.47)$$

where

$t_{coating}$ = coating thickness, m

$P_{ambient}$ = ambient pressure, Pa

$\delta_{perm,coating}$ = permeability of the coating, kg/m-s-Pa.

Finally, the boundary layer mass-transfer resistance is calculated by converting the heat-transfer coefficient to mass transfer with the Lewis relation:

$$R_{MT,BL} = \frac{\rho_{air}C_{p,air}}{h_{conv}} \quad (3.48)$$

Behind the surface layer is a deep layer (labeled with subscript 2 below) of thickness $d_{EMPD,2}$. The surface layer accounts for buffering of high-frequency changes in the zone air humidity, while the deep layer accounts for the material's response to longer term changes in the zone air humidity. The model calculates the moisture flux between the surface and deep layers with:

$$j_2 = \frac{\rho_{v,1} - \rho_{v,2}}{R_{MT,2}} \quad (3.49)$$

where $R_{MT,2}$ is:

$$R_{MT,2} = \frac{d_{EMPD,1} + d_{EMPD,2}}{2\bar{R}_{water}T\delta_{perm}} \quad (3.50)$$

These moisture fluxes are used to update the moisture content (or equivalent RH, ϕ of each layer:

$$\phi_1(t) = \phi_1(t - \delta t) - \frac{(j_{zone} + j_2) \cdot TimeStep}{\rho_{matl}d_{EMPD,1}\frac{du}{d\phi}} \quad (3.51)$$

$$\phi_2(t) = \phi_2(t - \delta t) + \frac{j_2 \cdot TimeStep}{\rho_{matl}d_{EMPD,2}\frac{du}{d\phi}} \quad (3.52)$$

where

ρ_{matl} = Material dry density, kg/m³

$TimeStep$ = Simulation timestep, s

$\frac{du}{d\phi}$ = slope of moisture curve (change in moisture content / change in RH), kg/kg · RH

The equivalent RH and equivalent vapor density are related with:

$$\rho_{v,1} = \frac{\phi_1 P_{sat}(T)}{\bar{R}_{water} T} \quad (3.53)$$

$$\rho_{v,2} = \frac{\phi_2 P_{sat}(T)}{\bar{R}_{water} T} \quad (3.54)$$

The zone flux is used, along with the area of the particular surface, to update the zone humidity ratio, as discussed in 2.4.

The zone flux is also used to calculate the sensible heat released (during adsorption) or absorbed (during desorption) at the material surface:

$$Q_{flux} = j_{zone} h_{fg} \quad (3.55)$$

where h_{fg} is the enthalpy of vaporization of water, assumed to be 2500 kJ/kg. This is added to the heat balance calculations at the interior surface.

For further information on the EMPD model, see References below.

3.4.3 EMPD Nomenclature

A = surface area [m^2]

d = penetration depth [m]

j = water mass flux $\left[\frac{kg}{m^2 \cdot s} \right]$

\bar{R}_{water} = universal gas constant for water, $461.52 \left[\frac{J}{kg \cdot K} \right]$

R_{MT} = Mass transfer resistance [s/m]

T = temperature [K]

u = moisture content $\left[\frac{kg}{kg} \right]$

3.4.3.1 Greek letters

δ = permeability $\left[\frac{kg}{m \cdot s \cdot Pa} \right]$

ϕ = relative humidity

ρ = density $\left[\frac{kg}{m^3} \right]$

ρ_v = vapor density $\left[\frac{kg}{m^3} \right]$

3.4.3.2 Subscripts

1 = surface layer node
 2 = deep layer node
 BL = boundary layer
 matl = solid material
 zone = zone air

3.5 Outside Surface Heat Balance

The heat balance on the outside face is:

$$q''_{\alpha sol} + q''_{LWR} + q''_{conv} - q''_{ko} = 0 \quad (3.56)$$

where:

$q''_{\alpha sol}$ = Absorbed direct and diffuse solar (short wavelength) radiation heat flux

q''_{LWR} = Net long wavelength (thermal) radiation flux exchange with the air and surroundings

q''_{conv} = Convective flux exchange with outside air

q''_{ko} = Conduction heat flux (q/A) into the wall

All terms are positive for net flux to the face except the conduction term, which is traditionally taken to be positive in the direction from outside to inside of the wall. Simplified procedures generally combine the first three terms by using the concept of a *sol-air temperature*. Each of these heat balance components is introduced briefly below.

Figure 3.10: Outside Heat Balance Control Volume Diagram

3.5.1 External Shortwave Radiation

$q''_{\alpha sol}$ is calculated using procedures presented later in this manual and includes both direct and diffuse incident solar radiation absorbed by the surface face. This is influenced by location, surface facing angle and tilt, surface face material properties, weather conditions, etc.

3.5.2 External Longwave Radiation

q''_{LWR} is a standard radiation exchange formulation between the surface, the sky, and the ground. The radiation heat flux is calculated from the surface absorptivity, surface temperature, sky and ground temperatures, and sky and ground view factors.

The longwave radiation heat exchange between surfaces is dependent on surface temperatures, spatial relationships between surfaces and surroundings, and material properties of the surfaces. The relevant material properties of the surface, emissivity ϵ and absorptivity α , are complex functions of temperature, angle, and wavelength for each participating surface. However, it is generally agreed that reasonable assumptions for building loads calculations are (Chapman 1984; Lienhard 1981):

- each surface emits or reflects diffusely and is gray and opaque ($\alpha = \epsilon$, $\tau = 0$, $\rho = 1 - \epsilon$)
- each surface is at a uniform temperature
- energy flux leaving a surface is evenly distributed across the surface,
- the medium within the enclosure is non-participating.

These assumptions are frequently used in all but the most critical engineering applications.

Table 3.2: Nomenclature List of Variables

Mathematical variable	Description	Units	Range
q''_{LWR}	Exterior surface longwave radiation flux	W/m^2	—
h_r	Linearized radiative heat transfer coefficient to air temperature	$W/m^2.K$	—
T_{surf}	Surface Outside face temperatures	K	—
T_{air}	Outside air temperature	K	—
T_{gnd}	Environmental ground surface temperature	K	—
T_{sky}	Sky Effective temperature	K	—
F_{gnd}	view factor of wall surface to ground surface	—	0–1
F_{sky}	View factor of wall surface to sky	—	0–1
F_{air}	View factor of wall surface to air	—	0–1
ϵ	Surface long-wave emissivity	—	0–1
σ	Stefan-Boltzmann constant	$W/m^2.K^4$	5.67×10^{-8}

Consider an enclosure consisting of building exterior surface, surrounding ground surface, and sky. Using the assumptions above, we can determine the longwave radiative heat flux at the building exterior surface (Walton 1983; McClellan and Pedersen 1997). The total longwave radiative heat flux is the sum of components due to radiation exchange with the ground, sky, and air.

$$q''_{LWR} = q''_{gnd} + q''_{sky} + q''_{air} \quad (3.57)$$

Applying the Stefan-Boltzmann Law to each component yields:

$$q''_{LWR} = \varepsilon\sigma F_{gnd}(T_{gnd}^4 - T_{surf}^4) + \varepsilon\sigma F_{sky}(T_{sky}^4 - T_{surf}^4) + \varepsilon\sigma F_{air}(T_{air}^4 - T_{surf}^4) \quad (3.58)$$

where

ε = long-wave emittance of the surface

σ = Stefan-Boltzmann constant

F_{gnd} = view factor of wall surface to ground surface temperature

F_{sky} = view factor of wall surface to sky temperature

F_{air} = view factor of wall surface to air temperature

T_{surf} = outside surface temperature

T_{gnd} = ground surface temperature

T_{sky} = sky temperature

T_{air} = air temperature

Linearized radiative heat transfer coefficients are introduced to render the above equation more compatible with the heat balance formulation,

$$q''_{LWR} = h_{r,gnd}(T_{gnd} - T_{surf}) + h_{r,sky}(T_{sky} - T_{surf}) + h_{r,air}(T_{air} - T_{surf}) \quad (3.59)$$

where

$$h_{r,gnd} = \frac{\varepsilon\sigma F_{gnd}(T_{surf}^4 - T_{gnd}^4)}{T_{surf} - T_{gnd}} \quad (3.60)$$

$$h_{r,sky} = \frac{\varepsilon\sigma F_{sky}(T_{surf}^4 - T_{sky}^4)}{T_{surf} - T_{sky}} \quad (3.61)$$

$$h_{r,air} = \frac{\varepsilon\sigma F_{air}(T_{surf}^4 - T_{air}^4)}{T_{surf} - T_{air}} \quad (3.62)$$

The longwave view factors to ground and sky are calculated with the following expressions (Walton 1983):

$$F_{ground} = 0.5(1 - \cos \phi) \quad (3.63)$$

$$F_{sky} = 0.5(1 + \cos \phi) \quad (3.64)$$

where ϕ is the tilt angle of the surface. The view factor to the sky is further split between sky and air radiation by:

$$\beta = \sqrt{0.5(1 + \cos \phi)} \quad (3.65)$$

The ground surface temperature is assumed to be the same as the air temperature. The final forms of the radiative heat transfer coefficients are shown here.

$$h_{r,gnd} = \frac{\varepsilon\sigma F_{gnd}(T_{surf}^4 - T_{air}^4)}{T_{surf} - T_{air}} \quad (3.66)$$

$$h_{r,sky} = \frac{\varepsilon\sigma F_{sky}\beta(T_{surf}^4 - T_{sky}^4)}{T_{surf} - T_{sky}} \quad (3.67)$$

$$h_{r,air} = \frac{\varepsilon\sigma F_{sky}(1 - \beta)(T_{surf}^4 - T_{air}^4)}{T_{surf} - T_{air}} \quad (3.68)$$

Optionally, however, the long wave radiation from surrounding surfaces to an exterior surface, can also be considered if explicitly defined. Then the equation above should be modified as:

$$q''_{LWR} = \varepsilon\sigma[F_{gnd}(T_{gnd}^4 - T_{surf}^4) + F_{sky}(T_{sky}^4 - T_{surf}^4) + F_{s_1}(T_{s_1}^4 - T_{surf}^4) + \dots + F_{s_n}(T_{s_n}^4 - T_{surf}^4) + F_{air}(T_{air}^4 - T_{surf}^4)] \quad (3.69)$$

where

F_{s_i} = View factor of surrounding surface i to the exterior surface.

T_{s_i} = Outside surface temperature of the surrounding surface i.

3.5.4 Atmospheric Variation

All buildings are located in the troposphere, the lowest layer of the atmosphere. The troposphere extends from sea level to an altitude of 11 km. Throughout the troposphere, air temperature decreases almost linearly with altitude at a rate of approximately 1°C per 150 m. Barometric pressure decreases more slowly. Wind speed, on the other hand, increases with altitude.

Because the atmosphere changes with altitude (defined as *height above ground* in this case), tall buildings can experience significant differences in local atmospheric properties between the ground floor and the top floor. Buildings interact with the atmosphere through convective heat transfer between the outdoor air and the exterior surfaces of the building envelope, and through the exchange of air between the outside and inside of the building via infiltration and ventilation.

Impetus for using this modeling is illustrated in the next table. Using a 70 story (284 meters) building as an example, the atmospheric variables are significant.

Table 3.3: Atmospheric Variables at Two Different Altitudes above Ground Level

Variable	1.5 Meters	284 meters	Absolute Diff	Percent Diff
Air Temperature	15°C	13.15°C	1.85°C	12.3%
Barometric Pressure	101,325 Pa	97,960 Pa	3,365 Pa	3.3%
Wind Speed	2.46 m/s	7.75 m/s	5.29 m/s	215%

Comparing the annual energy usage between 60 discretely modeled floors of a building, it turns out that the effect due to wind speed change is dominant over the first ten floors. But at floor 25, surprisingly, the effect due to air temperature has caught up and is about equal to the effect of wind speed. Above floor 25 the effect due to air temperature is now dominant. Clearly it is desirable to model air temperature variation with altitude for high-rise buildings.

To accommodate atmospheric variation EnergyPlus automatically calculates the local outdoor air temperature and wind speed separately for each zone and surface that is exposed to the outdoor environment. The zone centroid or surface centroid are used to determine the height above ground. Only local outdoor air temperature and wind speed are currently calculated because they are important factors for the exterior convection calculation for surfaces (see Exterior Convection below) and can also be factors in the zone infiltration and ventilation calculations. Variation in barometric pressure, however, is considered when using the Airflow Network objects.

3.5.4.1 Local Outdoor Air Temperature Calculation

Variation in outdoor air temperature is calculated using the U.S. Standard Atmosphere (1976). According to this model, the relationship between air temperature and altitude in a given layer of the atmosphere is:

$$T_z = T_b + L(H_z - H_b) \quad (3.70)$$

where

T_z = air temperature at altitude z

T_b = air temperature at the base of the layer, i.e., ground level for the troposphere

L = air temperature gradient, equal to -0.0065 K/m in the troposphere

H_b = offset equal to zero for the troposphere

H_z = geopotential altitude.

The variable H_z is defined by:

$$H_z = \frac{Ez}{(E + z)} \quad (3.71)$$

where

$E = 6,356$ km, the radius of the Earth

z = altitude.

For the purpose of modeling buildings in the troposphere, altitude z refers to the height above ground level, not the height above sea level. The height above ground is calculated as the height of the centroid, or area-weighted center point, for each zone and surface.

The air temperature at ground level, T_b , is derived from the weather file air temperature by inverting the equation above:

$$T_b = T_{z,met} - L \left(\frac{E z_{met}}{E + z_{met}} - H_b \right) \quad (3.72)$$

where

$T_{z,met}$ = weather file air temperature (measured at the meteorological station)

z_{met} = height above ground of the air temperature sensor at the meteorological station.

The default value for z_{met} for air temperature measurement is 1.5 m above ground. This value can be overridden by using the Site:WeatherStation object.

3.5.4.2 Local Wind Speed Calculation

In Chapter 16 of the Handbook of Fundamentals (ASHRAE 2005), the wind speed measured at a meteorological station is extrapolated to other altitudes with the equation:

$$V_z = V_{met} \left(\frac{\delta_{met}}{z_{met}} \right)^{\alpha_{met}} \left(\frac{z}{\delta} \right)^{\alpha} \quad (3.73)$$

where

z = altitude, height above ground

V_z = wind speed at altitude z

α = wind speed profile exponent at the site

δ = wind speed profile boundary layer thickness at the site

z_{met} = height above ground of the wind speed sensor at the meteorological station

V_{met} = wind speed measured at the meteorological station

α_{met} = wind speed profile exponent at the meteorological station

δ_{met} = wind speed profile boundary layer thickness at the meteorological station.

The wind speed profile coefficients α , δ , α_{met} , and δ_{met} , are variables that depend on the roughness characteristics of the surrounding terrain. Typical values for α and δ are shown in the following table:

Table 3.4: Wind Speed Profile Coefficients (ASHRAE Fundamentals 2005).

Terrain Description	Exponent, α	Boundary Layer Thickness, δ (m)
Flat, open country	0.14	270
Rough, wooded country	0.22	370
Towns and cities	0.33	460
Ocean	0.10	210
Urban, industrial, forest	0.22	370

The terrain types above map to the options in the *Terrain* field of the Building object. The *Terrain* field can be overridden with specific values for α and δ by using the Site:HeightVariation

object.

The default value for z_{met} for wind speed measurement is 10 m above ground. The default values for α_{met} and δ_{met} are 0.14 and 270 m, respectively, because most meteorological stations are located in an open field. These values can be overridden by using the Site:WeatherStation object.

3.5.5 Outdoor/Exterior Convection

Heat transfer from surface convection is modeled using the classical formulation:

$$Q_c = h_{c,ext} A (T_{surf} - T_{air}) \quad (3.74)$$

where

Q_c = rate of exterior convective heat transfer

$h_{c,ext}$ = exterior convection coefficient

A = surface area

T_{surf} = surface temperature

T_{air} = outdoor air temperature

Substantial research has gone into the formulation of models for estimating the exterior convection coefficient. Since the 1930's there have been many different methods published for calculating this coefficient, with much disparity between them (Cole and Sturrock 1977; Yazdanian and Klems 1994). More recently Palyvos (2008) surveyed correlations cataloging some 91 different correlations into four categories based on functional form of the model equation. EnergyPlus therefore offers a wide selection of different methods for determining values for $h_{c,ext}$. The selection of model equations for $h_{c,ext}$ can be made at two different levels. The first is the set of options available in the input object SurfaceConvectionAlgorithm:Outside that provides a way of broadly selecting which model equations are applied throughout the model. The input objects SurfaceProperty:ConvectionCoefficients and SurfaceProperty:ConvectionCoefficients:MultipleSurface also provide ways of selecting which model equations or values are applied for specific surfaces. These basic options are identified by the key used for input and include:

- SimpleCombined
- TARP
- MoWiTT
- DOE-2
- AdaptiveConvectionAlgorithm

Note that when the outside environment indicates that it is raining, the exterior surfaces (exposed to wind) are assumed to be wet. The convection coefficient is set to a very high number (1000) and the outside temperature used for the surface will be the wet-bulb temperature. (If you choose to report this variable, you will see 1000 as its value.)

When the AdaptiveConvectionAlgorithm is used, there is a second, deeper level of control available for selecting among a larger variety of $h_{c,ext}$ equations and also defining custom equations using curve or table objects. These options are described in this section.

In addition to the correlation choices described below, it is also possible to override the convection coefficients on the outside of any surface by other means:

- Use the SurfaceProperty:ConvectionCoefficients object in the input file to set the convection coefficient value on either side of any surface.
- Use the SurfaceProperty:OtherSideCoefficients object in the input file to set heat transfer coefficients and temperatures on surfaces.
- Use the EnergyManagementSystem Actuators that are available for overriding h_c values.

These options can also use schedules to control values over time. Specific details are given in the Input Output Reference document.

For exterior simple-glazing windows modeled with the WindowMaterial:SimpleGlazingSystem object, $h_{c,ext}$ is scaled with an adjustment ratio. This enables the modeling of simple windows with highly conductive frames (large input U values). The calculation of the adjustment ratio is detailed in Section 7.7.4.8.

3.5.5.1 Simple Combined

The simple algorithm uses surface roughness and local surface windspeed to calculate the exterior heat transfer coefficient (key:SimpleCombined). The basic equation used is:

$$h = D + EV_z + FV_z^2 \quad (3.75)$$

where

h = heat transfer coefficient

V_z = local wind speed calculated at the height above ground of the surface centroid

D, E, F = material roughness coefficients

The roughness correlation is taken from Figure 1, Page 22.4, ASHRAE Handbook of Fundamentals (ASHRAE 1989). The roughness coefficients are shown in the following table:

Table 3.5: Roughness Coefficients D, E, and F.

Roughness Index	D	E	F	Example Material
1 (Very Rough)	11.58	5.894	0.0	Stucco
2 (Rough)	12.49	4.065	0.028	Brick
3 (Medium Rough)	10.79	4.192	0.0	Concrete
4 (Medium Smooth)	8.23	4.0	-0.057	Clear pine
5 (Smooth)	10.22	3.1	0.0	Smooth Plaster
6 (Very Smooth)	8.23	3.33	-0.036	Glass

Note that the simple correlation yields a combined convection and radiation heat transfer coefficient. Radiation to sky, ground, and air is included in the exterior convection coefficient for this algorithm.

All other algorithms yield a *convection only* heat transfer coefficient. Radiation to sky, ground, and air is calculated automatically by the program.

3.5.5.2 TARP ALGORITHM

TARP, or Thermal Analysis Research Program, is an important predecessor of EnergyPlus (Walton 1983). Walton developed a comprehensive model for exterior convection by blending correlations from ASHRAE and flat plate experiments by Sparrow et. al. In older versions of EnergyPlus, prior to version 6, the “TARP” model was called “Detailed.” The model was reimplemented in version 6 to use Area and Perimeter values for the group of surfaces that make up a facade or roof, rather than the single surface being modeled.

Table 3.6: Nomenclature List of Variables.

Variable	Description	Units	Range
A	Surface area of the surface	m ²	/=0
h_c	Surface exterior convective heat transfer coefficient	W/(m ² K)	-
h_f	Forced convective heat transfer coefficient	W/(m ² K)	-
h_n	Natural convective heat transfer coefficient	W/(m ² K)	-
P	Perimeter of surface	m	-
R_f	Surface roughness multiplier	-	-
T_{air}	Local outdoor air temperature calculated at the height above ground of the surface centroid	°C	-
T_{so}	Outside surface temperature	°C	-
ΔT	Temperature difference between the surface and air,	°C	-
V_z	Local wind speed calculated at the height above ground of the surface centroid	m/s	-
W_f	Wind direction modifier	-	-
ϕ	Angle between the ground outward normal and the surface outward normal	degree	-
Roughness Index	Surface roughness index (6=very smooth, 5=smooth, 4=medium smooth, 3=medium rough, 2=rough, 1=very rough)	-	1-6

The Detailed, BLAST, and TARP convection models are very similar. In all three models, convection is split into forced and natural components (Walton 1981). The total convection coefficient is the sum of these components.

$$h_c = h_f + h_n \quad (3.76)$$

The forced convection component is based on a correlation by Sparrow, Ramsey, and Mass (1979):

$$h_f = 2.537W_f R_f \left(\frac{PV_z}{A} \right)^{1/2} \quad (3.77)$$

where

$W_f = 1.0$ for windward surfaces

or

$W_f = 0.5$ for leeward surfaces

Leeward is defined as greater than 90 degrees from normal incidence (Yazdanian and Klems 1994).

The surface roughness multiplier R_f is based on the ASHRAE graph of surface conductance (ASHRAE 1981) and may be obtained from the following table:

Table 3.7: Surface Roughness Multipliers (Walton 1981).

Roughness Index	Rf	Example Material
1 (Very Rough)	2.17	Stucco
2 (Rough)	1.67	Brick
3 (Medium Rough)	1.52	Concrete
4 (Medium Smooth)	1.13	Clear pine
5 (Smooth)	1.11	Smooth Plaster
6 (Very Smooth)	1.00	Glass

The natural convection component h_n is calculated in the same way as the interior “Detailed” model. The detailed natural convection model correlates the convective heat transfer coefficient to the surface orientation and the difference between the surface and zone air temperatures (where $\Delta T = \text{Air Temperature} - \text{Surface Temperature}$). The algorithm is taken directly from Walton (1983). Walton derived his algorithm from the ASHRAE Handbook (2001), Table 5 on p. 3.12, which gives equations for natural convection heat transfer coefficients in the turbulent range for large, vertical plates and for large, horizontal plates facing upward when heated (or downward when cooled). A note in the text also gives an approximation for large, horizontal plates facing downward when heated (or upward when cooled) recommending that it should be half of the facing upward value. Walton adds a curve fit as a function of the cosine of the tilt angle to provide intermediate values between vertical and horizontal. The curve fit values at the extremes match the ASHRAE values very well.

For no temperature difference OR a vertical surface the following correlation is used:

$$h_n = 1.31|\Delta T|^{\frac{1}{3}} \quad (3.78)$$

For ($\Delta T < 0.0$ AND an upward facing surface) OR ($\Delta T > 0.0$ AND an downward facing

surface) an enhanced convection correlation is used:

$$h_n = \frac{9.482|\Delta T|^{\frac{1}{3}}}{7.283 - |\cos \Sigma|} \quad (3.79)$$

where Σ is the surface tilt angle.

For ($\Delta T > 0.0$ AND an upward facing surface) OR ($\Delta T < 0.0$ AND an downward facing surface) a reduced convection correlation is used:

$$h_n = \frac{1.810|\Delta T|^{\frac{1}{3}}}{1.382 + |\cos \Sigma|} \quad (3.80)$$

where Σ is the surface tilt angle.

3.5.5.3 MoWiTT Algorithm

Table 3.8: Nomenclature List of Variables.

Variable	Description	Units	Range
A	Constant	W/(m ² K(m/s) ^b	-
B	Constant	-	-
C _t	Turbulent natural convection constant	W/(m ² K ^{4/3})	-
h _c	Surface exterior convective heat transfer coefficient	W/(m ² K)	-
T _{so}	Outside surface temperature	°C/K	-
ΔT	Temperature difference between the surface and air	°C/K	-

The MoWiTT model is based on measurements taken at the Mobile Window Thermal Test (MoWiTT) facility (Yazdanian and Klems 1994). The correlation applies to very smooth, vertical surfaces (e.g. window glass) in low-rise buildings and has the form:

$$h_c = \sqrt{\left[C_t(\Delta T)^{\frac{1}{3}}\right]^2 + [aV_z^b]^2} \quad (3.81)$$

Constants a, b and turbulent natural convection constant C_t are given in Table 3.9. The original MoWiTT model has been modified for use in EnergyPlus so that it is sensitive to the local surface's wind speed which varies with the height above ground. The original MoWiTT model was formulated for use with the air velocity at the location of the weather station. As of Version 7.2, EnergyPlus uses the “a” model coefficients derived by Booten et al. (2012) rather than the original values from Yazdanian and Klems (1994).

NOTE: The MoWiTT algorithm may not be appropriate for rough surfaces, high-rise surfaces, or surfaces that employ movable insulation.

Table 3.9: MoWiTT Coefficients (Yazdanian and Klems 1994, Booten et al. 2012)

Wind Direction (Units)	C_t $W/(m^2K^{4/3})$	a $W/(m^2K(m/s)^b)$	b
Windward	0.84	3.26	0.89
Leeward	0.84	3.55	0.617

3.5.5.4 DOE-2 Model

Table 3.10: Nomenclature List of Variables.

Variable	Description	Units	Range
a	Constant	$W/(m^2K(m/s)^b)$	-
b	Constant	-	-
h_c	Surface exterior convective heat transfer coefficient	$W/(m^2K)$	-
$h_{c,glass}$	Convective heat transfer coefficient for very smooth surfaces (glass)	$W/(m^2K)$	-
h_n	Natural convective heat transfer coefficient	$W/(m^2K)$	-
R_f	Surface roughness multiplier	-	-
T_{so}	Outside surface temperature	$^{\circ}C/K$	-
ΔT	Temperature difference between the surface and air,	$^{\circ}C/K$	-
Φ	Angle between the ground outward normal and the surface outward normal	radian	-

The DOE-2 convection model is a combination of the MoWiTT and BLAST Detailed convection models (LBL 1994). The convection coefficient for very smooth surfaces (e.g. glass) is calculated as:

$$h_{c,glass} = \sqrt{h_n^2 + [aV_z^b]^2} \quad (3.82)$$

h_n is calculated using Equation 3.78, 3.79 or 3.80. Constants a and b are given in Table 3.9. For less smooth surfaces, the convection coefficient is modified according to the equation

$$h_c = h_n + R_f(h_{c,glass} - h_n) \quad (3.83)$$

where R_f is the roughness multiplier given by Table 3.7.

3.5.5.5 Adaptive Convection Algorithm

This algorithm has a structure that allows for finer control over the models used for particular surfaces. The algorithm for the outside face was developed for EnergyPlus but it borrows concepts and its name from the research done by Beausoleil-Morrison (2000, 2002) for convection at the inside face (see the description below for interior convection).

The adaptive convection algorithm implemented in EnergyPlus for the outside face is much simpler than that for the inside face. The surface classification system has a total of 4 different categories for surfaces that depend on current wind direction and heat flow directions. However it is more complex in that the h_c equation is split into two parts and there are separate model equation selections for forced convection, h_f , and natural convection, h_n . The following table summarizes the categories and the default assignments for h_c equations. The individual h_c equations are documented below.

Table 3.11: Adaptive Convection Algorithm Details

#	Surface Classification	Heat Flow Direction	Wind Direction	h_f Models	h_n Models
1	Roof Stable	Down	Any	TARPWindward MoWiTTWindward DOE2Windward NusseltJurges BlockenWindward EmmelRoof ClearRoof	WaltonStableHorizontalOrTilt AlamdariStableHorizontal
2	Roof Unstable	Up	Any	TARPWindward MoWiTTWindward DOE2Windward NusseltJurges BlockenWindward EmmelRoof ClearRoof	WaltonUnstableHorizontalOrTilt AlamdariUnstableHorizontal
3	Vertical Wall Windward	Any	Windward	TARPWindward MoWiTTWindward NusseltJurges McAdams Mitchell BlockenWindward EmmelVertical	ASHRAEVerticalWall AlamdariHammondVerticalWall FohannoPolidoriVerticalWall ISO15099Windows
4	Vertical Wall Leeward	Any	Leeward	TARPLEeward MoWiTTLeeward DOE2Leeward EmmelVertical NusseltJurges McAdams Mitchell	ASHRAEVerticalWall AlamdariHammondVerticalWall FohannoPolidoriVerticalWall ISO15099Windows

One slight difference in the Adaptive Convection Algorithm is the calculation of the perimeter used in the various components of the model. In the TARP Algorithm, the perimeter is calculated by making an assumption that the surface is rectangular in shape. However, when the Adaptive Convection Algorithm is utilized, a slightly more sophisticated perimeter calculation that is better able to handle non-rectangular surfaces is employed. This slight difference in the perimeter calculation can result in differences between the TARP Algorithm and the Adaptive Convection Algorithm even when the options for the surface classifications noted above match the TARP Algorithm details.

3.5.5.5.1 Outside Face Surface Classification

During an initial setup phase, all the heat transfer surfaces in the input file are analyzed in groups to determine appropriate values for geometry scales used in many of the convection correlations. Eight separate groups are assembled for nominally vertical exterior surfaces for eight bins of azimuth: north, northeast, east, southeast, south, southwest, west, northwest. Surfaces with the same range of azimuth are grouped together and analyzed for overall geometry parameters. A ninth group is assembled for nominally horizontal exterior surfaces for a roof bin that is also analyzed for geometry. These geometry routines find bounds and limits of all the surfaces in the group and

then model geometric parameters from these limits.

3.5.5.5.2 Sparrow Windward

As discussed above for the TARP algorithm, a Sparrow et al. (1979) conducted flat plate measurements and develop the following correlation for finite-size flat plates oriented to windward.

$$h_f = 2.53 R_f \left(\frac{PV_z}{A} \right)^{1/2} \quad (3.84)$$

3.5.5.5.3 Sparrow Leeward

Sparrow et al. (1979) conducted flat plate measurements and develop the following correlation for finite-size flat plates oriented to leeward.

$$h_f = \frac{2.53}{2} R_f \left(\frac{PV_z}{A} \right)^{1/2} \quad (3.85)$$

3.5.5.5.4 MoWITT Windward

As discussed above, Yazdanian and Klems (1994) used outdoor laboratory measurements to develop the following correlation for smooth surfaces oriented to windward. Booten et al. (2012) developed revised coefficients for use with local surface wind speeds.

$$h_c = \sqrt{\left[0.84 |\Delta T|^{1/3} \right]^2 + [2.38 V_z^{0.89}]^2} \quad (3.86)$$

This model equation is for the total film coefficient and includes the natural convection portion. Therefore it should not be used in conjunction with a second natural convection model equation.

3.5.5.5.5 MoWITT Leeward

Yazdanian and Klems (1994) used outdoor laboratory measurements to develop the following correlation for smooth surfaces oriented to leeward. Booten et al. (2012) developed revised coefficients for use with local surface wind speeds.

$$h_c = \sqrt{\left[0.84 |\Delta T|^{1/3} \right]^2 + [2.86 V_z^{0.617}]^2} \quad (3.87)$$

This model equation is for the total film coefficient and includes the natural convection portion. Therefore it should not be used in conjunction with a second natural convection model equation.

3.5.5.5.6 Blocken

Blocken et al. (2009) developed a set of correlations for windward facing outdoor surfaces using numerical methods (key: BlockenWindward).

$$\begin{aligned}
h_f &= 4.6V_{10m}^{0.89} & : & \theta \leq 11.25 \\
h_f &= 5.0V_{10m}^{0.80} & : & 11.25 < \theta \leq 33.75 \\
h_f &= 4.6V_{10m}^{0.84} & : & 33.75 < \theta \leq 56.25 \\
h_f &= 4.5V_{10m}^{0.81} & : & 56.25 < \theta \leq 100.0
\end{aligned} \tag{3.88}$$

Where V_{10m} is the air velocity at the location of the weather station and θ is the angle of incidence between the wind and the surface in degrees. This model is only applicable to windward surfaces and lacks a natural convection component and therefore cannot be used on its own but only within the adaptive convection algorithm for the outside face.

3.5.5.5.7 Clear

Clear et al. (2003) developed correlations from measurements for horizontal roofs on two commercial buildings. In EnergyPlus the implementation uses the model for natural convection plus turbulent forced convection (eq. 8A in the reference) and applies it to the center point of each surface section that makes up the roof.

$$h_c = \eta \frac{k}{L_n} 0.15 Ra_{L_n}^{1/3} + \frac{k}{x} R_f 0.0296 Re_x^{4/5} Pr^{1/3} \tag{3.89}$$

Where

- x is the distance to the surface centroid from where the wind begins to intersect the roof. In EnergyPlus this is currently simplified to half the square root of the roof surface.
- $L_n = \frac{Area}{Perimeter}$ of overall roof
- k is the thermal conductivity of air
- $\eta = \frac{\ln\left(1 + \frac{Gr_{L_n} x}{Re_x^2}\right)}{1 + \ln\left(1 + \frac{Gr_{L_n} x}{Re_x^2}\right)}$ is the weighting factor for natural convection (suppressed at high forced convection rates)
- $Ra_{L_n} = Gr_{L_n} Pr$ is the Rayleigh number
- $Gr_{L_n} = \frac{g \rho^2 L_n^3 \Delta T}{T_f \mu^2}$ is the Grashof number
- $Re_x = \frac{V_z \rho x}{\mu}$ is the Reynolds number at x
- Pr is the Prandtl number

This model only claims to be applicable to horizontal roof surfaces so it may not be applicable to tilted roofs. It combines natural and forced convection and therefore should not be used in conjunction with yet another natural convection model.

3.5.5.5.8 Emmel

Emmel et al. (2007) developed a set of correlations for outdoor surfaces using numerical methods. The following equations are for vertical surfaces (key: EmmelVertical):

$$\begin{aligned}
 h_f &= 5.15V_{10m}^{0.81} & : \theta \leq 22.5 \\
 h_f &= 3.34V_{10m}^{0.84} & : 22.5 < \theta \leq 67.5 \\
 h_f &= 4.78V_{10m}^{0.71} & : 67.5 < \theta \leq 112.5 \\
 h_f &= 4.05V_{10m}^{0.77} & : 112.5 < \theta \leq 157.5 \\
 h_f &= 3.54V_{10m}^{0.76} & : 157.5 < \theta \leq 180.0
 \end{aligned} \tag{3.90}$$

Where V_{10m} is the air velocity at the location of the weather station and θ is the angle of incidence between the wind and the surface in degrees. The following equations are used for horizontal (roof) surfaces (key: EmmelRoof):

$$\begin{aligned}
 h_f &= 5.11V_{10m}^{0.78} & : \theta \leq 22.5 \\
 h_f &= 4.60V_{10m}^{0.79} & : 22.5 < \theta \leq 67.5 \\
 h_f &= 3.67V_{10m}^{0.85} & : 67.5 < \theta \leq 90
 \end{aligned} \tag{3.91}$$

Where θ is the angle of incidence between the wind and the longest edge of the roof surface in degrees.

This model is for all wind directions but lacks a natural convection component. The model was developed for simple, rectangular low-rise buildings. It is available only within the adaptive convection algorithm for the outside face

3.5.5.5.9 Nusselt Jurges

Perhaps the oldest equation for wind-driven convection was developed by Nusselt and Jurges (1922). Palyvos (2008) casts their model in simplified form in SI units as:

$$h_c = 5.8 + 3.94 V_z \tag{3.92}$$

Where V_z is the wind velocity in m/s, in EnergyPlus that velocity is adjusted for height above ground using the z axis coordinate of the surface's centroid and the site wind model. This model can be applied to all surfaces and the relatively large constant is assumed to represent the natural convection portion of a total convection coefficient. The model is not sensitive to wind direction nor surface roughness.

3.5.5.5.10 McAdams

A venerable equation for wind-driven convection was developed by McAdams (1954) which Palyvos (2008) casts in SI units as:

$$h_c = 5.7 + 3.8 V_z \tag{3.93}$$

Where V_z is the wind velocity in m/s that has been adjusted for height above ground using the z axis coordinate of the surface's centroid. This model can be applied to all surfaces and the relatively large constant is assumed to represent the natural convection portion of a total convection coefficient. The model is not sensitive to wind direction nor surface roughness.

3.5.5.5.11 Mitchell

A useful geometric scale based on building volume is used in an equation developed by Mitchell (1976). The wind-driven convection equation is cast by Palyvos as:

$$h_f = \frac{8.6 V_z^{0.6}}{L^{0.4}} \quad (3.94)$$

Where V_z is the wind velocity in m/s that has been adjusted for height above ground using the z axis coordinate of the surface's centroid and L is the cube root of the building's total volume. EnergyPlus interprets this as the sum of the volume of all the zones in the input file.

3.5.6 Exterior/External Conduction

The conduction term, q''_{ko} , can in theory be calculated using a wide variety of heat conduction formulations. Typically in EnergyPlus, the Conduction Transfer Function (CTF) method is used. The available models are described in this section: Conduction Through The Walls.

3.5.7 Additional Heat Balance Source

EnergyPlus also enables importing the pre-calculated results of other heat transfer processes, such as evaporative cooling envelope. An additional heat source term defined as a surface property would enable the consideration of these processes to be imported as schedules in the exterior surface heat balance calculation in EnergyPlus.

The heat balance on the outside face is then modified as:

$$q''_{\alpha sol} + q''_{LWR} + q''_{conv} + q''_{add} - q''_{ko} = 0 \quad (3.95)$$

where: q''_{add} = Pre-calculated results of the heat flux to the outside face from other heat transfer processes.

3.6 Inside Heat Balance

The heart of the heat balance method is the internal heat balance involving the inside faces of the zone surfaces. This heat balance is generally modeled with four coupled heat transfer components: 1) conduction through the building element, 2) convection to the air, 3) short wave radiation absorption and reflectance and 4) longwave radiant interchange. The incident short wave radiation is from the solar radiation entering the zone through windows and emittance from internal sources such as lights. The longwave radiation interchange includes the absorption and emittance of low temperature radiation sources, such as all other zone surfaces, equipment, and people.

The heat balance on the inside face can be written as follows:

$$q''_{LWX} + q''_{SW} + q''_{LWS} + q''_{ki} + q''_{sol} + q''_{conv} = 0 \quad (3.96)$$

where:

q''_{LWX} = Net longwave radiant exchange flux between surfaces in a zone or group of zones (enclosure).

q''_{SW} = Net short wave radiation flux to surface from lights.

q''_{LWS} = Longwave radiation flux from equipment in a zone or group of zones (enclosure).

q''_{ki} = Conduction flux through the wall.

q''_{sol} = Transmitted solar radiation flux absorbed at surface.

q''_{conv} = Convective heat flux to zone air.

Each of these heat balance components is introduced briefly below.

3.6.1 Internal Long-Wave Radiation Exchange

Long-wave radiation exchange is balanced within an enclosure which may be a single zone or a group of zones connected by air boundaries (see Construction:AirBoundary). Throughout this section, “Zone” refers to either type of enclosure.

Figure 3.11: Inside Heat Balance Control Volume Diagram

3.6.1.1 LW Radiation Exchange Among Zone Surfaces

There are two limiting cases for internal LW radiation exchange that are easily modeled:

- The zone air is completely transparent to LW radiation.
- The zone air completely absorbs LW radiation from the surfaces within the zone.

The limiting case of completely absorbing air has been used for load calculations and also in some energy analysis calculations. This model is attractive because it can be formulated simply using a combined radiation and convection heat transfer coefficient from each surface to the zone air. However, it oversimplifies the zone surface exchange problem, and as a result, the heat balance formulation in EnergyPlus treats air as completely transparent. This means that it does not participate in the LW radiation exchange among the surfaces in the zone. The model, which considers room air to be completely transparent, is reasonable physically because of the low water vapor concentrations and the short mean path lengths. It also permits separating the radiant and convective parts of the heat transfer at the surface, which is an important attribute of the heat balance method.

EnergyPlus uses a grey interchange model for the longwave radiation among zone surfaces. EnergyPlus offers two algorithms for modeling long wave radiation: The “ScriptF” method, and the “CarrollMRT” methods. Users can select between these two algorithms using the “Performance-PrecisionTradeoffs” object.

3.6.1.1.1 ScriptF

The “ScriptF” algorithm was developed by Hottel (Hottel and Sarofim, Radiative Transfer, Chapter 3, McGraw Hill, 1967). This procedure relies on a matrix of exchange coefficients between

pairs of surfaces that include all exchange paths between the surfaces. In other words all reflections, absorptions and re-emissions from other surfaces in the enclosure are included in the exchange coefficient, which is called ScriptF. The major assumptions are that all surface radiation properties are grey and all radiation is diffuse. Both assumptions are reasonable for building zone interchange.

The ScriptF coefficients are developed by starting with the traditional direct radiation view factors. In the case of building rooms and zones, there are several complicating factors in finding the direct view factors—the main one being that the location of surfaces such as thermal mass representing furniture and partitions are not known. The other limitation is that the exact calculation of direct view factors is computationally very intensive even if the positions of all surfaces are known. Accordingly, EnergyPlus uses a procedure to approximate the direct view factors. The procedure has two steps:

- 1) Determine the total area of other surfaces “seen” by a surface.
- 2) Approximate the direct view factor from surface 1 to surface 2 as the ratio of the area of surface 2 to the total area “seen” by surface 1.

The determination of the “seen” area has several constraints:

- No surface sees itself.
- All surfaces see thermal mass surfaces.
- No surface facing within 10 degrees of another surface is seen by the other surface.
- All surfaces see roofs, floors and ceilings (subject to the preceding facing direction constraint).

Because the approximate view factors may not satisfy the basic requirements of reciprocity (two surfaces should exchange equal amounts of heat in each direction), and completeness (every surface should have a direct view factor sum of 1.0), EnergyPlus does a view factor fix operation before they are used in the ScriptF determination. Normally both of the requirements are satisfied, but in some special situations they are not, and special rules are applied.

- If a user includes less than four surfaces in a zone, the enforcement of “completeness” is not strictly possible because it is not possible to have a completed enclosure with less than four surfaces. In this situation, reciprocity is enforced initially and then view factors from each surface are summed. When dealing with this few surfaces, the result of using approximate view factors is that once reciprocity is enforced that the largest surface in the zone will end up having view factors that sum up to greater than unity. This is not physically possible. So, to correct this and maintain completeness for one surface, the entire view factor matrix is divided by the largest summation of view factors for any surface in the zone. By dividing the entire view factor matrix by the same value, the reciprocity established by the standard algorithm is maintained and completeness for one surface is established. All of the other surfaces will not have view factors that sum up to unity and thus will not satisfy completeness. However, these other surfaces will not have view factors that sum up to greater than unity thus avoiding a physically impossible situation.
- When there are four or more surfaces in a zone but the area of one surface in a zone is greater than roughly (0.9) the sum of the areas of all other surfaces, reciprocity only is enforced. Sometimes, for these very large surfaces, that enforcement of completeness without resorting to the very large surface seeing itself becomes impossible. In these rare cases, the large surface

is allowed to see itself. Once this adjustment has been made, the calculation of the Script F values can proceed as normal via iteration until both completeness and reciprocity are satisfied. Note that this adjustment might happen for very "flat" zones where one or two surfaces have a much larger area than the other surfaces like a Trombe Walls, a large single-story interior areas that are modeled as a single zone, or a space where a very large internal mass element has been added. Thermal mass surfaces also participate in internal long-wave radiation exchange and thus must have view factors calculated.

Warning messages are produced for both of these cases, and the results should be examined very carefully to ascertain that they are reasonable. The suggested action for the second case (the extra-large surface) is to divide the large surface into several smaller surfaces; then the enclosure will be treated as normal.

Once the ScriptF coefficients are determined, the longwave radiant exchange is calculated for each surface using:

$$q_{i,j} = A_i F_{i,j} (T_i^4 - T_j^4) \quad (3.97)$$

where $F_{i,j}$ is the ScriptF between surfaces i and j.

3.6.1.1.2 CarrollMRT

The Carroll method is an approximation of gray-body long-wave radiation exchange within an enclosure that simplifies the surface-to-surface radiation exchange by using a single, mean radiant temperature node, Tr , that acts as a clearinghouse for the radiation heat exchange between surfaces. Instead of solving a dense-matrix, linear algebra problem, the mean radiant temperature can be calculated using a single equation, and subsequently used to determine the net long-wave radiation to/from each surface. Unlike the $O(n^2)$ complexity of the current dense-matrix solution, this approach has linear complexity.

The mean radiant temperature is calculated using three steps:

1. Calculation of the mean radiant temperature "view factor", F_i . These view factors represent each surface's "view" to the mean radiant temperature node as though all surfaces were part of a spherical enclosure (i.e., they all have equal view of the node regardless of their orientation to each other). F_i is calculated as:

$$F_i = \frac{1}{1 - \frac{A_i F_i}{\sum_1^n A_j F_j}} \quad (3.98)$$

Because of the circular reference in this equation, the collection of all "view factors" must be solved iteratively, but only once per simulation as surface areas do not change throughout. This converges for realistic enclosures but won't necessarily converge for "enclosures" having only two or three surfaces, particularly if there are large area disparities.

2. Calculating the gray-body radiation resistance, F'_i . This calculation must be computed every time surface emissivity changes. F'_i is calculated as:

$$F'_i = \frac{\sigma \varepsilon_i}{\frac{\varepsilon_i}{F_i} + 1 - \varepsilon_i} \quad (3.99)$$

3. Finally, the mean radiant temperature, T_r , is:

$$T_r = \frac{\sum_1^n A_i F'_i T_i}{\sum_1^n A_i F'_i} \quad (3.100)$$

Once the mean radiant temperature is known, the net radiation heat transfer for each surface can be calculated as:

$$q = F'_i A_i (T_r^4 - T_i^4) \quad (3.101)$$

3.6.1.2 Thermal Mass and Furniture

Furniture in a zone has the effect of increasing the amount of surface area that can participate in the radiation and convection heat exchanges. It also adds participating thermal mass to the zone. These two changes both affect the response to temperature changes in the zone and also affect the heat extraction characteristics.

The proper modeling of furniture is an area that needs further research, but the heat balance formulation allows the effect to be modeled in a realistic manner by including the furniture surface area and thermal mass in the heat exchange process.

3.6.1.3 LW Radiation From Internal Sources

The traditional model for this source is to define a radiative/convective split for the heat introduced into a zone from equipment. The radiative part is then distributed over the surfaces within the zone in some prescribed manner. This, of course, is not a completely realistic model, and it departs from the heat balance principles. However, it is virtually impossible to treat this source in any more detail since the alternative would require knowledge of the placement and surface temperatures of all equipment.

3.6.2 Internal Short-Wave Radiation

3.6.2.1 SW Radiation from Lights

The short wavelength radiation from lights is distributed over the surfaces in the zone in some prescribed manner.

3.6.2.2 Transmitted Solar

Transmitted solar radiation is also distributed over the surfaces in the zone in a prescribed manner. It would be possible to calculate the actual position of beam solar radiation, but that would involve partial surface irradiation, which is inconsistent with the rest of the zone model that assumes uniform conditions over an entire surface. The current procedures incorporate a set of prescribed distributions. Since the heat balance approach can deal with any distribution function, it is possible to change the distribution function if it seems appropriate.

3.6.2.3 Convection to Zone Air

The convection flux is calculated using the heat transfer coefficients as follows:

$$q''_{conv} = h_c(T_s - T_a) \quad (3.102)$$

The inside convection coefficients (h_c) can be calculated using one of many different models. Currently the implementation uses coefficients based on correlations for natural, mixed, and forced convection.

3.6.3 Interior Conduction

This contribution to the inside surface heat balance is the wall conduction term, q''_{ki} shown in Equation 3.96. This represents the heat transfer to the inside face of the building element. Again, a CTF formulation is used to determine this heat flux.

3.6.4 Interior Convection

There are many different modeling options available in EnergyPlus for inside convection coefficients, h_c . There are four different settings to direct how EnergyPlus managers select h_c models during a simulation. There are numerous individual model equations for h_c in EnergyPlus to cover different situations that arise from surface orientations, room airflow conditions, and heat flow direction. Additionally, in many cases multiple researchers have developed competing models for the same situations that differ and there is no way to declare one is better than another. An overall default for the simulation is selected in the “SurfaceConvectionAlgorithm:Inside” object and can be overridden by selecting a different option in a zone description. These models are explained in the following sections. In addition to the correlation choices described below, it is also possible to override the convection coefficients on the inside of any surface by using the “SurfaceProperty:ConvectionCoefficients” object in the input file to set the convection coefficient value on the inside of any surface. The values can be specified directly or with schedules. Specific details are given in the Input Output Reference document.

For exterior simple-glazing windows modeled with the WindowMaterial:SimpleGlazingSystem object, h_c is scaled with an adjustment ratio. This enables the modeling of simple windows with highly conductive frames (large input U values). The calculation of the adjustment ratio is detailed in Section 7.7.4.8.

3.6.4.1 Adaptive Convection Algorithm

Beausoleil-Morrison (2000, 2002) developed a methodology for dynamically managing the selection of h_c equations called *adaptive convection algorithm*. The algorithm is used to select among the available h_c equations for the one that is most appropriate for a given surface at a given time. As Beausoleil-Morrison notes, the adaptive convection algorithm is intended to be expanded and altered to reflect different classification schemes and/or new h_c equations. The implementation in EnergyPlus has been modified from the original in the following ways:

- An input mechanism is provided (see the SurfaceConvectionAlgorithm:Inside:AdaptiveModelSelections object) so that the user can customize the specific selections of h_c equations that are applied for different flow regimes and surface orientations. The changes apply in a general way to the entire model (but can be overridden by setting surface properties).
- To avoid requiring additional user input on the position of ZoneHVAC-type equipment within a zone, there is no distinction between zones that have convective zone heater equipment located underneath the windows and those that have convective heaters located away from the windows. This applies to the air flow regime associated with convective zone heaters. Using Beausoleil-Morrison's terminology, regimes B1 and B2 are combined into just one B regime.
- To avoid requiring additional user input on the position of ZoneHVAC-type equipment within a zone, there is no distinction between surfaces that are directly blown on the fan and those that are away from the fan for the air flow regime associated with mechanical circulation from a zone fan (ZoneHVAC type equipment).
- The correlation for horizontal free jet developed by Fisher (1995) is not used. Ceiling diffuser models are used for all mechanical circulation from central air system. This decision was made for two reasons: (1) to avoid requiring additional user input on the position of, and momentum generated by, air terminal units, and (2) because Fisher (1995) found that the Coanda effect is so significant that in practice a free horizontal jet is difficult to maintain and mechanical-driven room airflows generally attach to surfaces and tend to match the flow regime of a ceiling diffuser much more often than a free jet.
- EnergyPlus supports arbitrary geometry so surfaces can be tilted with respect to vertical or horizontal. Beausoleil-Morrison's adaptive convection algorithm was originally structured to use h_c equations that have no functional dependence on surface tilt angle. However, tilted surfaces do perform differently than vertical or horizontal surface when buoyancy forces are significant. Therefore, the EnergyPlus implementation expands the structure of the algorithm to include additional categories for tilted surfaces. The h_c equations developed by Walton (1983) are selected as the defaults for tilted surfaces because they have a functional dependence on tilt angle.
- Fohanno and Polidari (2006) produced a new h_c equation for vertical walls inside buildings with a simple buoyancy flow regime. They used a theoretical approach based on integral formalism and uniform heat flux (rather than uniform temperature) that covers both laminar and turbulent flow situations. In EnergyPlus, this model is selected as the default in place of the model by Alamdari and Hammond (1983) for vertical walls.

- Karadag (2009) produced a new h_c equation for ceiling surfaces that are actively chilled. He used computation fluid dynamics and various sized rooms and temperature conditions. In EnergyPlus, this model is selected as the default for surfaces that have active, in-ceiling cooling (in place of the model by Alamdari and Hammond (1983) for unstable ceilings).
- International Standard Organization (ISO) completed Standard 15099-2003 which includes h_c equations for the inside face of windows. EnergyPlus strives to adhere to formal modeling Standards where possible. Therefore the implementation includes a larger structure for the adaptive algorithm that includes additional categories for windows in all flow regimes and ISO 15099-2003 models are used as the default for windows in natural convection flow regimes. The ISO 15099 model applies to various tilt angles.
- Goldstein and Novosalec (2010) produced new h_c equations for forced air situations with ceiling slot diffusers along perimeters with significant glazing fractions. They used experiments with full-sized test room. These new equations are selected as the default for windows, ceilings and floors when there is an active central air system.
- Interior mass surfaces are assigned the h_c equation that would apply (stable or unstable) to a horizontal, upward facing surface for each flow regime.
- The algorithm switches between forced, mixed, and natural flow regimes by calculating the Richardson number, $Ri = Gr/Re^2$, for the zone. Large values of Ri indicate buoyancy dominates, while small values indicate forced flows dominate. To distinguish between opposing Zone unit type equipment (with fans) are assumed to force air up walls, and central air type equipment (with diffusers) are assumed to force air down walls.

The adaptive convection algorithm implemented in EnergyPlus for the inside face has a total of 45 different categories for surfaces and 29 different options for h_c equation selections. The following table summarizes the categories and the default assignments for h_c equations. The individual h_c equations are documented below.

3.6.4.2 Inside Face Surface Classification

The adaptive convection algorithm is based on classifying surfaces by flow regime and orientation so that the correct h_c equation can be chosen at a particular point in time during the simulation. The classification depends on user input with some aspects processed only once at the beginning and others during each timestep. There are also various parameters or inputs to the h_c equations that need static or dynamic processing.

For each surface, it and the zone it is attached to are processed for the following static characteristics.

- Characteristic height for convection is taken as the zone height.
- Surfaces listed as receiving heat from Zone HVAC equipment with radiative models are considered “near” the heater.
- Zones are examined for low temperature radiant systems. The surfaces that contain the active elements are examined and the zone characterized to know if it has in-floor heating, in-ceiling cooling, or in-wall heating.
- A hydraulic diameter is calculated for horizontal surfaces for the entire zone.

and calculating various parameters needed by h_c equations. Selecting flow regime is done in the following manner. For each surface, we examine the zone on the inside face for the following:

- HVAC system type
- HVAC operating status
- HVAC system ACH

During initial zone and system sizing calculations, HVAC system characteristics are not known yet, so the flow regime is selected assuming an uncontrolled zone. During simulations, including HVAC sizing simulations, the HVAC system characteristics are used.

The surfaces are evaluated to determine:

- Surface classification: Floor, wall, roof, window, types
- Tilt angle
- Convective stability (sign of ΔT)

The individual h_c model equations and their respective references are listed in next by the keyword used to identify them.

3.6.4.3 ASHRAE Vertical Wall

Walton adopted the following equation for natural convection from ASHRAE .

$$h = 1.31|\Delta T|^{\frac{1}{3}} \quad (3.103)$$

This is usually bound at a minimum of .1 in EnergyPlus. This is a component of the TARP overall algorithm described below.

3.6.4.4 Walton Unstable Horizontal Or Tilt

Walton (1983) developed the following equation by fitting curves from various sources.

$$h = \frac{9.482|\Delta T|^{\frac{1}{3}}}{7.238 - |\cos \Sigma|} \quad (3.104)$$

Unstable refers to the direction of heat flow and the associated buoyancy relative to the surfaces. Unstable is when the natural tendency is to enhance flow in the sense that rising warmer air, or falling cooler air, is free to move away from the surface. This is usually bound at a minimum of .1 in EnergyPlus. This is a component of the TARP overall algorithm described below.

3.6.4.5 Walton Stable Horizontal Or Tilt

Walton (1983) developed the following equation by fitting curves from various sources.

$$h = \frac{1.810|\Delta T|^{\frac{1}{3}}}{1.382 + |\cos \Sigma|} \quad (3.105)$$

Stable refers to the direction of heat flow and the associated buoyancy relative to the surfaces. Stable is when the natural tendency is to retard flow in the sense that rising warmer air, or falling cooler air, is driven against the surface. This is usually bound at a minimum of .1 in EnergyPlus. This is a component of the TARP overall algorithm described below.

3.6.4.6 Fisher Pedersen Ceiling Diffuser Walls

Fisher and Pedersen (1997) developed the following equation from laboratory chamber measurements.

$$h = 1.208 + 1.012 * ACH^{0.604} \quad (3.106)$$

This is a component of the CeilingDiffuser overall algorithm described below.

3.6.4.7 Fisher Pedersen Ceiling Diffuser Ceiling

Fisher and Pedersen (1997) developed the following equation from laboratory chamber measurements.

$$h = 2.234 + 4.099 * ACH^{0.503} \quad (3.107)$$

This is a component of the CeilingDiffuser overall algorithm described below.

3.6.4.8 Fisher Pedersen Ceiling Diffuser Floor

Fisher and Pedersen (1997) developed the following equation from laboratory chamber measurements.

$$h = 3.873 + 0.082 * ACH^{0.98} \quad (3.108)$$

This is a component of the CeilingDiffuser overall algorithm described below.

3.6.4.9 Alamdari Hammond Stable Horizontal

Alamdari and Hammond (1983) developed the following correlation for horizontal surfaces in stable thermal situation.

$$h = 0.6 \left(\frac{|\Delta T|}{D_h^2} \right)^{1/5} \quad (3.109)$$

where,

$D_h = \frac{4A}{P}$, hydraulic diameter of horizontal surface, A is area (m^2) and P is the perimeter (m) of the entire zone.

3.6.4.10 Alamdari Hammond Unstable Horizontal

Alamdari and Hammond (1983) developed the following correlation for horizontal surfaces in a buoyant thermal situation.

$$h = \left\{ \left[1.4 \left(\frac{|\Delta T|}{D_h} \right)^{1/4} \right]^6 + \left[1.63 |\Delta T|^{1/3} \right]^6 \right\}^{1/6} \quad (3.110)$$

3.6.4.11 Alamdari Hammond Vertical Wall

Alamdari and Hammond (1983) developed the following correlation for vertical surfaces.

$$h = \left\{ \left[1.5 \left(\frac{|\Delta T|}{H} \right)^{1/4} \right]^6 + \left[1.23 |\Delta T|^{1/3} \right]^6 \right\}^{1/6} \quad (3.111)$$

where,

H is the characteristic height for the surface. In EnergyPlus this is the zone's ceiling height (which could be larger than the height of an individual surface when wall are subdivided into more than one surface).

3.6.4.12 Khalifa Eq3 Wall Away From Heat

Khalifa (1989) conducted experiments with test chambers and developed correlations for certain types of surfaces. One of them, identified as “Equation 3” in original reference, is for convectively heated zones and applies to the inside surfaces of walls away from the heat source:

$$h = 2.07 |\Delta T|^{0.23} \quad (3.112)$$

3.6.4.13 Khalifa Eq4 Ceiling Away From Heat

Khalifa (1989) conducted experiments with test chambers and developed correlations for certain types of surfaces. One of them, identified as “Equation 4” in original reference, is for convectively heated zones and applies to the inside surfaces of ceilings away from the heat source:

$$h = 2.72 |\Delta T|^{0.13} \quad (3.113)$$

3.6.4.14 Khalifa Eq5 Wall Near Heat

Khalifa (1989) conducted experiments with test chambers and developed correlations for certain types of surfaces. One of them, identified as “Equation 5” in original reference, is for convectively heated zones and applies to the inside surfaces of walls near the heat source:

$$h = 1.98 |\Delta T|^{0.32} \quad (3.114)$$

3.6.4.15 Khalifa Eq6 Non Heated Walls

Khalifa (1989) conducted experiments with test chambers and developed correlations for certain types of surfaces. One of them, identified as “Equation 6” in original reference, is for heated zones and applies to the inside surfaces of walls that are not heated:

$$h = 2.30 |\Delta T|^{0.24} \quad (3.115)$$

3.6.4.16 Khalifa Eq7 Ceiling

Khalifa (1989) conducted experiments with test chambers and developed correlations for certain types of surfaces. One of them, identified as “Equation 7” in original reference, is for heated zones and applies to the inside surfaces of ceilings:

$$h = 3.10|\Delta T|^{0.17} \quad (3.116)$$

3.6.4.17 Awbi Hatton Heated Floor

Awbi and Hatton (1999) conducted laboratory measurements using environmental chambers and developed the following correlation for floor surfaces that are being actively heated.

$$h = \frac{2.175|\Delta T|^{0.308}}{D_h^{0.076}} \quad (3.117)$$

where,

$D_h = \frac{4A}{P}$, hydraulic diameter of horizontal surface, A is area (m^2) and P is the perimeter (m) of the entire zone (all of the adjacent floor surfaces if more than one in the zone).

3.6.4.18 Awbi Hatton Heated Wall

Awbi and Hatton (1999) developed the following correlation for wall surfaces that are being actively heated.

$$h = \frac{1.823|\Delta T|^{0.293}}{D_h^{0.076}} \quad (3.118)$$

where,

$D_h = \frac{4A}{P}$, hydraulic diameter of wall surface, A is area (m^2) and P is the perimeter (m) of the entire wall (all of the adjacent wall surfaces if more than one along the wall).

3.6.4.19 Beausoleil Morrison Mixed Assisted Wall

Beausoleil-Morrison (2000) used blending techniques to combine correlations originally developed by Alamdari and Hammond (1983) and Fisher and Pedersen (1997) to create the following correlation is for walls where the flow driving forces from mechanical forces are augmented by the driving forces from buoyancy.

$$h = \left(\left\{ \left[1.5 \left(\frac{|\Delta T|}{H} \right)^{1/4} \right]^6 + [1.23|\Delta T|^2]^{1/6} \right\}^{1/2} + \left\{ \left[\frac{T_{surf} - T_{SAT}}{|\Delta T|} \right] [-0.199 + 0.190 \cdot ACH^{0.8}] \right\}^3 \right)^{1/3} \quad (3.119)$$

where,

T_{SAT} is the supply air temperature at the diffuser.

Here the reference temperature is the zone air temperature rather than the diffuser supply air temperature.

3.6.4.20 Beausoleil Morrison Mixed Opposing Wall

Beausoleil-Morrison (2000) used blending techniques to combine correlations originally developed by Alamdari and Hammond (1983) and Fisher and Pedersen (1997) to create the following correlation is for walls where the flow driving forces from mechanical forces are opposed by the driving forces from buoyancy.

$$h = \max \left\{ \begin{array}{l} \left(\left\{ \left[1.5 \left(\frac{|\Delta T|}{H} \right)^{1/4} \right]^6 + [1.23 |\Delta T|^2]^{1/6} \right\}^{1/2} - \left\{ \left[\frac{T_{surf} - T_{SAT}}{|\Delta T|} \right] \cdot [-0.199 + 0.190 \cdot ACH^{0.8}] \right\}^3 \right)^{1/3} \\ 0.8 \cdot \left\{ \left[1.5 \left(\frac{|\Delta T|}{H} \right)^{1/4} \right]^6 + [1.23 |\Delta T|^2]^{1/6} \right\}^{1/6} \\ 0.8 \cdot \left\{ \left[\frac{T_{surf} - T_{SAT}}{|\Delta T|} \right] \cdot [-0.199 + 0.190 \cdot ACH^{0.8}] \right\} \end{array} \right. \quad (3.120)$$

3.6.4.21 Beausoleil Morrison Mixed Stable Floor

Beausoleil-Morrison (2000) used blending techniques to combine correlations originally developed by Alamdari and Hammond (1983) and Fisher and Pedersen (1997) to create the following correlation is for floors where the flow driving forces include both mechanical forces and thermally stable buoyancy.

$$h = \left(\left\{ 0.6 \cdot \left(\frac{|\Delta T|}{D_H} \right)^{1/5} \right\}^3 + \left\{ \left[\frac{T_{surf} - T_{SAT}}{|\Delta T|} \right] \cdot [0.159 + 0.116 ACH^{0.8}] \right\}^3 \right)^{1/3} \quad (3.121)$$

3.6.4.22 Beausoleil Morrison Mixed Unstable Floor

Beausoleil-Morrison (2000) used blending techniques to combine correlations originally developed by Alamdari and Hammond (1983) and Fisher and Pedersen (1997) to create the following correlation is for floors where the flow driving forces include both mechanical forces and thermally unstable buoyancy.

$$h = \left(\left\{ \left[1.4 \left(\frac{|\Delta T|}{D_h} \right)^{1/4} \right]^6 + [1.63 |\Delta T|^{1/3}]^6 \right\}^{3/6} + \left\{ \left[\frac{T_{surf} - T_{SAT}}{|\Delta T|} \right] \cdot [0.159 + 0.116 ACH^{0.8}] \right\}^3 \right)^{1/3} \quad (3.122)$$

3.6.4.23 Beausoleil Morrison Mixed Stable Ceiling

Beausoleil-Morrison (2000) used blending techniques to combine correlations originally developed by Alamdari and Hammond (1983) and Fisher and Pedersen (1997) to create the following correlation

is for ceilings where the flow driving forces include both mechanical forces and thermally Stable buoyancy.

$$h = \left(\left\{ 0.6 \cdot \left(\frac{|\Delta T|}{D_H} \right)^{1/5} \right\}^3 + \left\{ \left[\frac{T_{surf} - T_{SAT}}{|\Delta T|} \right] \cdot [-0.166 + 0.484ACH^{0.8}] \right\}^3 \right)^{1/3} \quad (3.123)$$

3.6.4.24 Beausoleil Morrison Mixed Unstable Ceiling

Beausoleil-Morrison (2000) used blending techniques to combine correlations originally developed by Alamdari and Hammond (1983) and Fisher and Pedersen (1997) to create the following correlation is for ceilings where the flow driving forces include both mechanical forces and thermally unstable buoyancy.

$$h = \left(\left(\left[1.4 \left(\frac{|\Delta T|}{D_h} \right)^{1/4} \right]^6 + [1.63|\Delta T|^{1/3}]^6 \right)^{3/6} + \left(\left[\frac{T_{surf} - T_{SAT}}{|\Delta T|} \right] \cdot [-0.166 + 0.484 \cdot ACH^{0.8}] \right)^3 \right)^{1/3} \quad (3.124)$$

3.6.4.25 Fohanno Polidori Vertical Wall

Fohanno and Polidori (2006) developed the following equation for h_c for vertical walls under simple buoyancy flow conditions.

$$h = \begin{cases} 1.332 \left(\frac{|\Delta T|}{H} \right)^{1/4} & , \quad Ra_H^* \leq 6.3 \times 10^9 \\ 1.235 e^{(0.0467H)} |\Delta T|^{0.316} & , \quad Ra_H^* > 6.3 \times 10^9 \end{cases} \quad (3.125)$$

where,

$$Ra_H^* = \frac{g\beta_f q''_c H^4}{k_f \nu_f^2} Pr_f \quad (3.126)$$

3.6.4.26 Karadag Chilled Ceiling

Karadag (2009) used numerical methods to develop the following equation for h_c for chilled-ceiling surfaces.

$$h = 3.1 |\Delta T|^{0.22} \quad (3.127)$$

3.6.4.27 ISO 15099 Windows

ISO Standard 15099-2003 includes the equations for h_c for room-side of windows and surfaces with any tilt angle and heat flow direction. The ISO 15099 correlation is for still room air angle and is determined in terms of the Nusselt number, Nu , where

$$h_i = Nu \left(\frac{\lambda}{H} \right) \quad (3.128)$$

where,

λ is the thermal conductivity of air, and

H is the height of the window.

The Rayleigh number based on height, Ra_H , is calculated using:

$$Ra_H = \frac{\rho^2 H^3 g c_p |T_{surf,i} - T_{air}|}{T_{m,f} \mu \lambda} \quad (3.129)$$

where,

ρ is the density of air

g is the acceleration due to gravity,

c_p is the specific heat of air,

μ is the dynamic viscosity of air, and

$T_{m,f}$ is the mean film temperature in Kelvin given by,

$$T_{m,f} = T_{air} + \frac{1}{4} (T_{surf,i} - T_{air}) \quad (3.130)$$

There are four cases for the Nusselt correlation that vary by the tilt angle in degrees, γ , and are based on heating conditions. For cooling conditions (where $T_{surf,i} > T_{air}$) the tilt angle is complemented so that $\gamma = 180 - \gamma$

Case A. $0^\circ \leq \gamma < 15^\circ$

$$Nu = 0.13 Ra_H^{1/3} \quad (3.131)$$

Case B. $15^\circ \leq \gamma \leq 90^\circ$

$$Ra_{cv} = 2.5 \times 10^5 \left(\frac{e^{0.72\gamma}}{\sin \lambda} \right)^{1/5} \quad (3.132)$$

$$Nu = 0.56 (Ra_H \sin \gamma)^{1/4}; \text{ for } Ra_H \leq Ra_{CV} \quad (3.133)$$

$$Nu = 0.13 \left(Ra_H^{1/3} - Ra_{CV}^{1/3} \right) + 0.56 (Ra_{CV} \sin \gamma)^{1/4}; \text{ } Ra_H > Ra_{CV} \quad (3.134)$$

Case C. $90^\circ < \gamma \leq 179^\circ$

$$Nu = 0.56 (Ra_H \sin \gamma)^{1/4}; \text{ } 10^5 \leq Ra_H \sin \gamma < 10^{11} \quad (3.135)$$

Case D. $179^\circ < \gamma \leq 180^\circ$

$$Nu = 0.58 Ra_H^{1/5}; \text{ } Ra_H \leq 10^{11} \quad (3.136)$$

The material properties are evaluated at the mean film temperature. Standard EnergyPlus psychrometric functions are used for ρ and c_p . Thermal conductivity is calculated using:

$$\lambda = 2.873 \times 10^{-3} + 7.76 \times 10^{-8} T_{m,f} .$$

Kinematic viscosity is calculated using:

$$\mu = 3.723 \times 10^{-6} + 4.94 \times 10^{-8} T_{m,f} .$$

This correlation depends on the surface temperature of the room-side glazing surface and is therefore included inside the window heat balance iteration loop.

3.6.4.28 Goldstein Novoselac Ceiling Diffuser Window

Goldstein and Novoselac (2010) used laboratory chamber measurements to develop convection correlations for perimeter zones with highly glazed spaces served by overhead slot-diffuser-based air systems. The following are for bare windows in such spaces.

For WWR<50% with window in upper part of wall:

$$h = 0.117 \left(\frac{\dot{V}}{L} \right)^{0.8} \quad (3.137)$$

For WWR<50% with window in lower part of wall

$$h = 0.093 \left(\frac{\dot{V}}{L} \right)^{0.8} \quad (3.138)$$

For WWR > 50%

$$h = 0.103 \left(\frac{\dot{V}}{L} \right)^{0.8} \quad (3.139)$$

Where,

WWR is the window to wall ratio.

L is the length of exterior wall with glazing in the zone.

\dot{V} is the air system flow rate in m³/s.

3.6.4.29 Goldstein Novoselac Ceiling Diffuser Walls

Goldstein and Novoselac (2010) used laboratory chamber measurements to develop convection correlations for perimeter zones with highly glazed spaces served by overhead slot-diffuser-based air systems. The following are for exterior walls in such spaces.

For walls located below a window

$$h = 0.063 \left(\frac{\dot{V}}{L} \right)^{0.8} \quad (3.140)$$

For walls located above a window

$$h = 0.093 \left(\frac{\dot{V}}{L} \right)^{0.8} \quad (3.141)$$

3.6.4.30 Goldstein Novoselac Ceiling Diffuser Floor

Goldstein and Novoselac (2010) used laboratory chamber measurements to develop convection correlations for perimeter zones with highly glazed spaces served by overhead slot-diffuser-based air systems. The following is for floors in such spaces.

$$h = 0.048 \left(\frac{\dot{V}}{L} \right)^{0.8} \quad (3.142)$$

Separate from the above model structure, there are also other comprehensive algorithm structures which are described below.

3.6.4.31 TARP Algorithm

The comprehensive natural convection model, accessed using the keyword “TARP,” correlates the convective heat transfer coefficient to the surface orientation and the difference between the surface and zone air temperatures (where $DT = \text{Surface Temperature} - \text{Air Temperature}$). The algorithm is taken directly from Walton (1983). Walton derived his algorithm from ASHRAE literature which can now be found for example in the ASHRAE Handbook (HoF 2001), Table 5 on p. 3.12, which gives equations for natural convection heat transfer coefficients in the turbulent range for large, vertical plates and for large, horizontal plates facing upward when heated (or downward when cooled). A note in the text also gives an approximation for large, horizontal plates facing downward when heated (or upward when cooled) recommending that it should be half of the facing upward value. Walton adds a curve fit as a function of the cosine of the tilt angle to provide intermediate values between vertical and horizontal. The curve fit values at the extremes match the ASHRAE values very well.

For no temperature difference OR a vertical surface the following correlation is used:

$$h = 1.31|\Delta T|^{\frac{1}{3}} \quad (90)$$

For ($\Delta T < 0.0$ AND an upward facing surface) OR ($\Delta T > 0.0$ AND an downward facing surface) an enhanced convection correlation is used:

$$h = \frac{9.482|\Delta T|^{\frac{1}{3}}}{7.238 - |\cos \Sigma|} \quad (91)$$

where Σ is the surface tilt angle.

For ($\Delta T > 0.0$ AND an upward facing surface) OR ($\Delta T < 0.0$ AND an downward facing surface) a reduced convection correlation is used:

$$h = \frac{1.810|\Delta T|^{\frac{1}{3}}}{1.382 + |\cos \Sigma|} \quad (92)$$

where Σ is the surface tilt angle.

3.6.4.32 Simple Natural Convection Algorithm

The simple convection model uses constant coefficients for different heat transfer configurations, using the same criteria as the detailed model to determine reduced and enhanced convection. The coefficients are also taken directly from Walton (1983). Walton derived his coefficients from the surface conductances for $e = 0.90$ found in the ASHRAE Handbook (1985) in the table found on p. 23.2. The radiative heat transfer component was estimated at $1.02 * 0.9 = 0.918$ BTU/h-ft²-F and then subtracted off. Finally the coefficients were converted to SI units to yield the values below.

For a vertical surface:

$$h = 3.076 \quad (3.143)$$

For a horizontal surface with reduced convection:

$$h = 0.948 \quad (3.144)$$

For a horizontal surface with enhanced convection:

$$h = 4.040 \quad (3.145)$$

For a tilted surface with reduced convection:

$$h = 2.281 \quad (3.146)$$

For a tilted surface with enhanced convection:

$$h = 3.870 \quad (3.147)$$

3.6.4.33 Ceiling Diffuser Algorithm

The ceiling diffuser algorithm is based on empirical correlations developed by Fisher and Pedersen (1997). The correlation was reformulated to use the room outlet temperature as the reference temperature. The correlations are shown below.

For Floors:

$$h = 3.873 + 0.082 * ACH^{0.98} \quad (93) \quad (3.148)$$

The correlation for floors is illustrated in Figure 3.12.

For ceilings:

$$h = 2.234 + 4.099 * ACH^{0.503} \quad (3.149)$$

The correlation for ceilings is illustrated in Figure 3.13.

For Walls:

$$h = 1.208 + 1.012 * ACH^{0.604} \quad (3.150)$$

The correlation for walls is illustrated in Figure 3.14.

It should be noted that the conditions under which the correlations were developed included ACH values down to around 3.0. So, within EnergyPlus, for ACH values of 3.0 or greater, the ceiling diffuser correlations as shown above are used. Below ACH values of 0.5, the natural convection is determined using the TARP Algorithm (see above). Between ACH values of 0.5 and 3.0, convection is assumed to be a mix between natural and forced convection. Thus, between these two ACH values, EnergyPlus will use a linear interpolation between the natural convection algorithm value and the forced convection value at ACH=3.0 to avoid any discontinuities in the convection coefficient calculated and also maintain stability within the solution.

Figure 3.12: Ceiling Diffuser Correlation for Floors

Figure 3.13: Ceiling Diffuser Correlation for Ceilings

Figure 3.14: Ceiling Diffuser Correlation for Walls

3.6.4.34 Trombe Wall Algorithm

The Trombe wall algorithm is used to model convection in a “Trombe wall zone”, i.e. the air space between the storage wall surface and the exterior glazing. (See the later sections on Passive and Active Trombe Walls below for more information about Trombe walls.) The algorithm is identical to the convection model (based on ISO 15099) used in Window5 for convection between glazing layers in multi-pane window systems. The use of the algorithm for modeling an unvented Trombe wall has been validated against experimental data by Ellis (2003).

This algorithm gives the convection coefficients for air in a narrow vertical cavity that is sealed and not ventilated. This applies both to the air gap in between panes of a window or to the air gap between the Trombe wall glazing and the inner surface (often a selective surface). These convection coefficients are really the only difference between a normal zone and a Trombe zone. The rest of the zone heat balance is the same, e.g., transmitted solar, long-wave radiation between surfaces, etc.

For a vertical cavity, the correlation from ISO 15099 is:

$$\begin{aligned} NU1 &= 0.0673838Ra^{\frac{1}{3}} & \text{for } 5E4 < Ra < 1E6 \\ NU1 &= 0.028154Ra^{0.4134} & \text{for } 1E4 < Ra < 5E4 \\ NU1 &= 1 + 1.7596678E^{-10}Ra^{2.2984755} & \text{for } Ra \leq 1E4 \end{aligned} \quad (3.151)$$

$$NU2 = 0.242 \left(Ra/A \right)^{0.272} \quad (3.152)$$

$$NU = \text{MAX}(NU1, NU2) \quad (3.153)$$

where

Nu = Nusselt number

Ra = Rayleigh number

A = aspect ratio of cavity

This is then used in EnergyPlus as follows:

Net convection coefficient from glazing to wall is:

$$h_{net} = k \left(NU/L \right) \quad (3.154)$$

where

k = conductivity of air

L = air gap thickness

Convection coefficient applied to each wall separately and actually used in the zone heat balance is:

$$h_c = 2h_{net} \quad (3.155)$$

3.6.4.35 ASTM C1340 Algorithm

The algorithm is based on ASTM C1340 Standard. This algorithm specifies to simulate heat flows in attic zone. The correlations account for the effects of surface-to-air temperature difference, heat flow direction, surface length along the heat flow direction, surface tilt angle, air speed past surface,

and surface orientation. The correlations are in the form of a Nusselt number, Nu , as a function of a Rayleigh number, Ra , Grashof number, Gr , or a Reynolds number, Re .

$$Nu = hL/k \quad (3.156)$$

$$Ra = g\beta\rho C_p \Delta T L^3 / \nu k \quad (3.157)$$

$$Gr = Ra/Pr \quad (3.158)$$

$$Pr = \nu/\alpha \quad (3.159)$$

$$Re = VL/\nu \quad (3.160)$$

h = convection heat transfer coefficient

L = characteristic length of surface

k = thermal conductivity of air

g = acceleration of gravity

β = volume coefficient of expansion of air

ρ = density of air

C_p = specific heat of air

ΔT = temperature difference between surface and air

ν = kinematic viscosity of air

Pr = Prandtl number for air

α = thermal diffusivity of air

V = velocity of air stream

The correlations used in the model are as below. (reference: Table 1 of ASTM C1340 standard)

1. Natural Convection:

(a) Horizontal surface, heat flow up

$$Nu_n = 0.54 Ra^{1/4} \text{ for } Ra < 8 * 10^6$$

$$Nu_n = 0.15 Ra^{1/3} \text{ for } Ra > 8 * 10^6$$

(b) Horizontal surface, heat flow down

$$Nu_n = 0.58 Ra^{0.2}$$

(c) Vertical surface

$$Nu_n = 0.59 Ra^{1/4} \text{ for } Ra < 1 * 10^9$$

$$Nu_n = 0.10 Ra^{1/3} \text{ for } Ra > 1 * 10^9$$

(d) Nearly horizontal surface (tilt angle less than 2°), heat flow down

$$Nu_n = 0.58 Ra^{0.2}$$

(e) Tilted surfaces (greater than 2° tilt), heat flow down

$$Nu_n = 0.56 (Ra \sin(\Phi))^{1/4} \quad \Phi = \text{tilt angle}$$

(f) Tilted surfaces, heat flow up

$$Nu_n = 0.56 (Ra \sin(\Phi))^{1/4} \text{ for } Ra/Pr < Gr_c$$

$$Nu_n = 0.14 (Ra^{1/3} - (Gr_c Pr)^{1/3})$$

$$+ 0.56 (Gr_c Pr \sin(\Phi))^{1/4} \text{ for } Ra/Pr > Gr_c$$

$$Gr_c = 1 * 10^6 \text{ for } \Phi < 15^\circ$$

$$Gr_c = 10^{(\Phi/(1.1870 + 0.0870*\Phi))} \text{ for } 15^\circ < \Phi < 75^\circ$$

$$Gr_c = 5 * 10^9 \text{ for } \Phi > 75^\circ$$

2. Forced Convection:

$$Nu_f = 0.664 Pr^{1/3} Re^{1/2} \text{ for } Re < 5 * 10^5$$

$$Nu_f = Pr^{1/3} (0.037 Re^{0.8} - 850) \text{ for } Re > 5 * 10^5$$

Separate coefficients are calculated for natural and forced flow, and a mixed coefficient is calculated by taking the third root of the sum of the cubes of the two separate coefficients.

$$h_n = Nu_n * k / L \quad (3.161)$$

$$h_f = Nu_f * k / L \quad (3.162)$$

$$h_c = (h_n^3 + h_f^3)^{1/3} \quad (3.163)$$

More information regarding the implemented equations in the code is provided in detail in Appendix A, section 7.7 and 7.8 of the reference: Fontanini, A. D., Aguilar, J. L. C., Mitchell, M. S., Kosny, J., Merket, N., DeGraw, J. W., and Lee, E. (2018). Predicting the performance of radiant technologies in attics: Reducing the discrepancies between attic specific and whole-building energy models. *Energy and Buildings*, 169, 69-83.

3.6.5 Additional Heat Balance Source

EnergyPlus also enables importing the pre-calculated results of other heat transfer processes to be considered in the inside heat balance calculation. An additional heat source term defined as a surface property would enable the consideration of these processes to be imported as schedules in the interior surface heat balance calculation in EnergyPlus.

The heat balance on the inside face can be written as follows:

$$q''_{LWX} + q''_{SW} + q''_{LWS} + q''_{ki} + q''_{sol} + q''_{conv} + q''_{add} = 0 \quad (3.164)$$

where: q''_{add} = Pre-calculated results of the heat flux to the inside face from other heat transfer processes.

3.7 Adiabatic Boundary Conditions

Adiabatic boundary conditions are applied to two surface types in EnergyPlus:

- 1) Surfaces with adiabatic outside boundary conditions
- 2) Internal Mass objects

For both surface types, EnergyPlus will apply the same boundary conditions to each side of the construction so that there is no temperature difference across the surface. In this case, all heat transfer into the surface is a result of the dynamic response of the construction to varying inside boundary conditions. The surface will store and release heat only at the inside face of the surface (it is assumed that the outside face is not within the zone). If both faces are within the zone, this situation can be modeled either by creating another adiabatic or internal mass surface with the reverse construction, or, for symmetric constructions, simply doubling the area of the surface.

3.8 Infrared Radiation Transfer Material

One of the important technical features of EnergyPlus is that the fundamental zone model includes infrared (IR) radiation exchange among all surfaces within the zone. A zone can consist of a single room or multiple rooms having similar thermal characteristics. The other fundamental characteristic of a zone in EnergyPlus is that the air within the zone is modeled with the assumption that it is well-stirred, so it is characterized by a single uniform air temperature. Normally, this corresponds to the desired physical state of the air within a zone. Practically, this is accomplished with the mixing caused by the air distribution system or even with the addition of ceiling fans. However, there are situations where the well-stirred model condition does not fit the physical conditions within a space (e.g., large atria spaces, displacement ventilation systems, and under floor air distribution systems). In these cases, the air temperature varies spatially within the zone, but the surfaces in the regions

that have different air temperatures still exchange IR radiation with the other surfaces in the zone, even those in regions having a different air temperature.

Historically, several approaches have been taken to model such situations. They all involve unrealistically modifying the convective heat transfer characteristics within a single zone to produce reasonable total heat transfer for the zone while maintaining the zone IR radiation in its basic form. The IRT model takes a different, more fundamental approach. The space is divided into subzones, each having the basic well-stirred air model, but surfaces in these subzones are able to exchange IR radiation with other surfaces throughout the original space. Any convective air exchange between subzones is handled using the existing flexible capabilities within EnergyPlus. In other words, the subzones are standard EnergyPlus zones but they have been given the capability of allowing IR radiation to be exchanged with surfaces in adjacent zones.

The IR radiation exchange is accomplished by introducing special IR Transparent (IRT) surfaces to link adjacent zones. These surfaces transmit the IR radiation incident on them to the surfaces in adjacent zone. The special surfaces have no thermal resistance, and they also have zero convective heat transfer coefficients on both sides. Consider a stratified atrium as an example. The atrium would be divided into stacked vertical zones, with each zone having the special IRT surface between it and the next lower zone. All physical surfaces in the two zones exchange radiation with the IRT surface, but it does not impede the transfer of radiation from one zone to the other. On each side it interacts as a black body surface and any radiation incident on it is absorbed. Since it has no other heat transfer mechanisms, it comes to equilibrium with zero net radiation transfer.

Schematic diagrams of the application of the IRT surfaces are shown in Figure 3.15 and Figure 3.16. The first figure shows it applied between two stacked zones that could be part of an atrium. All radiation incident on the IRT in the lower and upper zone is completely absorbed by the surface. It is prevented from participating in the zone air heat balance by fixing the heat transfer coefficients on either side at zero.

The same arrangement can be used for simulating a underfloor air distribution system (UFAD). The two zones represent the lower occupied (mixed) zone and the upper stratified zone. Since the upper zone is being modeled as a mixed EnergyPlus zone, it is not precisely the stratified zone concept. However, if a user has concern about having the entire upper part of the space at a single average temperature, the space could be modeled with two stacked upper zones. In that case the stratified temperature profile would be established by the relative size of the mixing from the convective plumes. The user would have to supply those estimates from external knowledge of the behavior of UFAD systems and plumes.

3.8.1 Radiation Exchange Basics

The behavior of the IRT surface can be analyzed by considering three parallel black plates infinite in extent, as shown in Figure 3.17. The outside plates are held at two different temperatures, and the intermediate plate assumes an equilibrium temperature when the net heat flux goes to zero. All plates have black body surface characteristics.

The radiant exchange between surface 1 and 2 is:

$$q_{1-2} = \sigma A (T_1^4 - T_2^4) \quad (3.165)$$

The exchange between surfaces 2 and 3 is:

$$q_{2-3} = \sigma A (T_2^4 - T_3^4) \quad (3.166)$$

Figure 3.15: Schematic View of Stacked Zones

Figure 3.16: Schematic Model of a UFAD Zone

Figure 3.17: Radiation Exchange Model

Equating heat fluxes and eliminating T_2 gives:

$$q_{1-3} = \frac{\sigma}{2} A (T_1^4 - T_3^4) \quad (3.167)$$

where:

q is the heat flux in W/m^2

σ is the Stephan Boltzman constant

A is the plate area in m^2 , and

T is the temperature in K.

Equation 3.167 shows that the presence of a black body surface between a source and a sink reduces the heat flux by a factor of two.

3.8.2 IRT Radiation Exchange in EnergyPlus

Ideally, this same doubling of radiation would need to occur when an IRT surface is between two zones in EnergyPlus. However, due to the complexity of the EnergyPlus heat balances and the treatment of an IRT as equivalent to any other surface in EnergyPlus, simply doubling the impact of the IRT on either zone is not possible. In testing, this resulted in either net radiation imbalances within the zones or potentially unstable conditions. So, the radiation is not doubled in EnergyPlus as in the simple example in the previous subsection. Despite this difference between the theory of the ideal case and the actual implementation in EnergyPlus, an IRT surface will still allow a zone to be separated into two separate zones with two different air temperature and the adjacent zones behave as black body cavities at some equivalent temperature.

It should be noted that for IRT surfaces any visible or solar short wavelength radiation incident on the surface will be absorbed and included with the long wavelength (IR) exchange with the adjacent zone. No energy will be lost, but zones with IRT surfaces should not be used in any lighting analyses.

3.8.3 Radiation Transfer Surface Details

3.8.3.1 Specifying an Infrared Transparent (IRT) surface

The Infrared Transparent (IRT) surface is similar to a resistance-only surface. The idd object for this type of surface is shown below. The fields indicate that the surface will actually participate in the transfer of visible and solar radiation by doing a wavelength transformation and making all short wavelength radiation that is incident on the surface into long wavelength radiation and having it participate in the long wavelength radiant exchange. The Material:InfraredTransparent object requires only a name. All other parameters are set internally.

The Infrared Transparent surface should not participate in a convective/conductive exchange between the zones it separates. In order to minimize this effect, the SurfaceProperty:ConvectionCoefficients object must be used. Outside and Inside values for the surface's convection coefficients should be on the order of .1. Further examples are given in the Input Output Reference document.

3.8.4 Behavior Checks

The behavior of multi zones separated with infrared transparent surfaces can be checked with a simple comparison. Begin with a single zone model as shown below. This model has a south-facing window, and four walls exposed to wind and sun, and a roof exposed to wind and sun.

Figure 3.18: Single Zone Model

The single zone model will be compared with a stacked three zone model that has zones separated by interzone infrared transparent surfaces. This model is shown below.

The two upper zones have south facing windows whose total area is the same as the area of the single window in the single zone model. The top and the sides are again exposed to sun and wind. The separating surfaces are modeled as IRT surfaces. All zones in both models are controlled at the same setpoint temperature using purchased air.

The sensible heating results are shown below. The results show the sum of the sensible cooling load for the three stacked zones and the single zone. It is clear that the IRT surfaces are very

Figure 3.19: Stacked Three Zone Model

effective in transmitting infrared radiation between the zones. Some small differences, such as those shown, will occur because of the conversion from short wavelength solar to infrared through the special IRT dividing surfaces.

Figure 3.20: Comparison of Single and Three Stacked Zones

3.9 Transparent Insulation Material (TIM)

3.9.1 Introduction

The input object “SurfaceControl:MovableInsulation” allows modeling Transparent Insulation Materials (TIM) that were originally designed for use in solar collector systems, where there was a need to increase the insulation in the solar collector without dramatically reducing solar energy transmittance. Transparent Insulation provides both these properties, insulation from heat loss and transmittance of solar energy. The combination of these properties is achieved, because Transparent Insulation is a transmitter of short wave radiation but a barrier to longwave radiation. Therefore short wave solar radiation passes through the Transparent Insulation and longwave heat radiation is insulated by the transparent insulation. Incident solar energy falling on the transparent insulation is reflected and re-reflected within the material and eventually falls on the absorber. In

addition, transparent insulation materials also have increase thermal resistance due to conduction in comparison to standard glass.

Transparent Insulation is now used in the housing industry as a passive solar feature. It is attached to the walls of houses for insulation and solar energy gains are transmitted to the house during the right ambient conditions. The walls of the house act as a thermal mass, absorbing the sunlight at the surface and converting it into heat which is slowly transmitted to the inside of the house.

3.9.2 Comparison of Opaque and Transparent Insulation

A qualitative comparison between the performance of Transparent Insulation and opaque insulation is shown diagrammatically in the figure below. The upper half of the figure represents approximate heat transfer through the wall cross-section for both transparent and opaque insulation cases. The lower half of this figure shows representative temperature variations through the wall cross-sections for different solar conditions.

Figure 3.21: Energy Flows of Opaquely and Transparently Insulated Walls (Wood and Jesch 1993).

While both types of insulation reduce energy losses from the building via conduction through the building surfaces, transparent insulation allows solar radiation to penetrate deeper into the surface construction. This increases the construction internal temperature and can result in heat being conducted into the building under the proper weather conditions. This can be seen in the lower half of the above figure during a sunny day. The temperature plot shows a maximum between the transparent insulation and the rest of the surface construction. As a result, the temperature gradient results in heat transfer from this point into the interior space, causing a heating effect on the zone. Thus, the advantage of transparent insulation is that, like opaque insulation, it reduces winter heat transfer losses during low or no solar conditions and has the possibility of providing

heating during sunny winter days. It should be noted that this same effect in summer could be detrimental to the cooling loads of a building since the introduction of solar radiation closer to the space will increase the solar heating within the zone. Most systems counteract this with a shading device or with sophisticated transparent insulation systems.

3.9.3 Types of Transparent Insulation Materials

Transparent insulation can be classified into four general categories:

- Absorber Parallel Covers
- Cavity Structures
- Absorber Vertical Covers
- Quasi-Homogeneous Structures

Cross-sections of each of these types is shown in the figure below. The arrows in these diagrams indicate solar rays and the path these rays trace as they are transmitted through the transparent insulation layer. The most advantageous set-up (see absorber-parallel below) would send most of the rays downward towards the interior of the building while minimizing the rays that are reflected back to the exterior environment.

Figure 3.22: Geometrical Categories of Classification for Transparent Insulation Material (Wood and Jesch 1993).

3.9.4 TIM- Basic Mathematical Model

Figure 3.23: Cross Section of TIM and wall, showing energy flow

Mathematical model to calculate amount of energy absorbed at the surface of moveable insulation (TIM) and at the Outside surface of the Wall.

$$QSM = \alpha_{TIM} \cdot Incident\ Solar \quad (3.168)$$

The total solar gain on any exterior surface is a combination of the absorption of direct and diffuse solar radiation given by

$$IncidentSolar = (I_b \cdot \cos \theta \cdot \frac{S_s}{S} + I_s \cdot F_{ss} + I_g \cdot F_{sg}) \quad (3.169)$$

Where,

α = solar absorptance of the surface

θ = angle of incidence of the sun's rays

S = area of the surface

S_s = sunlit area of the surface

I_b = intensity of the beam (direct) radiation

I_s = intensity of the sky diffuse radiation
 I_g = intensity of the beam (direct) radiation
 F_{ss} = angle factor between the surface and the sky
 F_{sg} = angle factor between the surface and the ground
 Now,

$$\alpha_{wall} + \rho_{wall} = 1 \quad (3.170)$$

The model for TIM is simplified in that it assumes that absorption of solar radiation takes place at the inside and outside of the TIM only, not throughout the material. In addition, the model assumes that the solar radiation absorbed during the first pass through the TIM affects the outside surface of the TIM while the solar radiation reflected at the outer wall surface that gets absorbed during the back reflection will affect the inside TIM surface (which is also the outside surface of the wall). Thus, the heat absorbed at the outside of the TIM is as shown in Equation 3.168.

The heat absorbed at the inside of the TIM/outside of the wall includes two components. The first component is the amount of solar that is transmitted through the TIM and absorbed at the inside of the wall. This is characterized by the following equation:

$$\text{First pass solar absorbed by wall} = (\tau_{TIM} \cdot \text{Incident Solar}) \cdot (\alpha_{wall}) \quad (3.171)$$

The amount of solar absorbed by the TIM and aggregated at the inside surface of the TIM (outside wall surface) is:

$$\text{Amount of back reflection absorbed by TIM} = (\tau_{TIM} \cdot \text{Incident Solar}) \cdot (1 - \alpha_{wall}) \cdot \alpha_{TIM} \quad (3.172)$$

The heat absorbed at the interface between the wall and the TIM includes both of these components. Thus, QSO is equal to:

$$QSO = (\tau_{TIM} \cdot \text{Incident Solar}) \cdot \{\alpha_{wall} + (1 - \alpha_{wall}) \cdot \alpha_{TIM}\} \quad (3.173)$$

Substituting the definition for QSM into this equation and rearranging results in:

$$QSO = \left\{ \frac{\tau_{TIM} \cdot QSM}{\alpha_{TIM}} \right\} \cdot \{\alpha_{wall} + (1 - \alpha_{wall}) \cdot \alpha_{TIM}\} \quad (3.174)$$

$$QSO = (\tau_{TIM} \cdot QSM) \cdot \left\{ \left(\frac{\alpha_{wall}}{\alpha_{TIM}} \right) + (1 - \alpha_{wall}) \right\} \quad (3.175)$$

Where,

QSM = Short wave radiant flux absorbed at surface of Movable Insulation

QSO = Short wave radiant flux absorbed at surface of Wall.

α_{TIM} = Absorptance of TIM

τ_{TIM} = Transmittance of TIM.

α_{WALL} = Absorptance of Wall.

ρ_{WALL} = Reflectance of Wall surface

Following is the C++ code in the current version of EnergyPlus used in the HeatBalanceSurface-Manager module, to determine the short wave radiation absorbed on outside of movable insulation and the short wave radiation absorbed on outside of opaque surface of the wall.

```
// Calculate absorbed solar on outside if movable exterior insulation in place
if (AnyMovableInsulation) EvalOutsideMovableInsulation();
if (SurfMovInsulHExt(SurfNum)) { // Movable outside insulation in place
    SurfQRadSWOutMvIns(SurfNum) = SurfOpqQRadSWOutAbs(SurfNum) * AbsExt / Material(Construct(ConstrNum).
    LayerPoint(1)).AbsorpSolar;
    SurfOpqQRadSWOutAbs(SurfNum) = Material(Surface(SurfNum).MaterialMovInsulExt).Trans *
    SurfQRadSWOutMvIns(SurfNum) *
        ((Material(Construct(ConstrNum).LayerPoint(1)).AbsorpSolar / AbsExt) +
        (1 - Material(Construct(ConstrNum).LayerPoint(1)).AbsorpSolar));
    SWOutAbsTotalReport(SurfNum) = SurfOpqQRadSWOutAbs(SurfNum) * Surface(SurfNum).Area;
    SWOutAbsEnergyReport(SurfNum) = SWOutAbsTotalReport(SurfNum) * TimeStepZoneSec;
}
```

3.9.5 Sample Test Run Cases: – Comparison

A series of test cases were run in EnergyPlus to test the TIM model. The building was a very simple box with walls facing north, south, east, and west, all of which are exterior walls. Transparent Insulation Material has been applied to the south wall (except as noted in the table below). The program was run for this fictional 1 zone building located in Chanute AFB IL, for two design days, (21st June and 21st January). The main purpose of these runs was to verify that the transparent insulation model was predicting results that were reasonable using a simple test case. The winter design day was also modified in some runs to have a clearness of 1.0 so that the effect that solar radiation during winter-time conditions could be studied.

The Transparent Insulation material is conceived by applying a SurfaceControl:MoveableInsulation on the exterior. In the test cases, the TIM had the following thermal properties:

0.05, ! Thickness {m}
 0.90, ! Solar transmittance at normal incidence
 0.031, ! Solar reflectance at normal incidence: front side
 0.031, ! Solar reflectance at normal incidence: back side
 0.90, ! Visible transmittance at normal incidence
 0.05, ! Visible reflectance at normal incidence: front side
 0.05, ! Visible reflectance at normal incidence: back side
 0.0, ! IR transmittance at normal incidence
 0.84, ! IR emissivity: front side
 0.84, ! IR emissivity: back side
 0.04; ! Conductivity {W/m-K}

The Wall Construction is defined as an EXTWALL80 composed of 1" Stucco, 4" Common Brick and ¾" Plaster or Gypboard.

The following two tables shows data for two series of runs. The first "summer table" illustrates the execution of a summer design day. The second "winter table" shows winter conditions with clearness = 0 (the typical default for a winter design day) and clearness = 1 (to illustrate solar radiation with other winter conditions). Test cases included no movable insulation, moveable opaque insulation, and TIM on the exterior (south wall unless otherwise noted). Savings reported are heating and cooling loads for the design days only. The results showed that the TIM model was performing reasonably well and was producing results that were within expectations.

Table 3.13: TIM with Summer Conditions

3.10 Surface Heat Balances With Moveable Insulation

In EnergyPlus, moveable insulation can be present either on the interior or exterior side of a particular construction. Different heat balances are impacted depending on the location of the moveable insulation. Having moveable insulation on the interior side results in a modified form of the inside surface heat balance equation. Having moveable insulation on the exterior side results in different cases for the outside surface heat balance. Information on the modeling equations for each of these types of moveable insulation are shown in the next several sections.

3.10.1 Inside Heat Balance with Interior Moveable Insulation

There are two different heat balances which must be maintained to model interior moveable insulation. At both the interface between the zone air and the moveable insulation and the interface between the moveable insulation and the surface (wall, roof, etc.), the following general heat balance must be maintained:

$$\text{Conductive} + \text{Convective} + \text{Radiative} = 0 \quad (3.176)$$

One significant complication of the inside heat balance is the fact that surfaces within the same zone can interact with each other radiatively. This means that a solution for all surface temperatures must be done at the same time to maintain a radiation heat balance among the surfaces. This requires some iteration of the inside surface heat balance as will be seen in the equations that are shown later in this subsection.

Another complication of the inside heat balance relates to the presense of moveable insulation. When moveable insulation is present, a second heat balance equation is required to determine the temperature at both the air-moveable insulation interface as well as the moveable insulation-surface interface. This sets up a system of two equations with two unknowns: the temperatures at the air-moveable insulation interface and the moveable insulation-surface interface.

Applying the basic steady state heat balance equation at each of these interfaces results in the following two equations:

$$H_c \cdot (T_a - T_{mi}) + Q_{lw} + H_{mi} \cdot (T_i - T_{mi}) + I_t \cdot (T_{old} - T_{mi}) = 0 \quad (3.177)$$

$$H_{mi} \cdot (T_{mi} - T_i) + Q_{sw} + Q_{cond} = 0 \quad (3.178)$$

where:

H_c is the convective heat transfer coefficient between the moveable insulation and the air

T_a is the zone air temperature

T_{mi} is the temperature at the interface between the air and the moveable insulation

Q_{lw} is the long wavelength radiation incident on the interface between the air and the moveable insulation

H_{mi} is the U-value of the moveable insulation material

T_i is the temperature at the interface between the moveable insulation and the surface

I_t is a damping constant for iterating to achieve a stable radiant exchange between zone surfaces

T_{old} is the previous surface temperature at the last solution iteration

Q_{sw} is the short wavelength radiation incident on the interface between the moveable insulation and the surface

Q_{cond} is the conduction heat transfer through the surface.

Equation 3.177 is the heat balance at the air-moveable insulation interface and can be rearranged to solve for the temperature at this interface, T_{mi} . Equation 3.178 is the heat balance at the moveable insulation-surface interface and provides a second equation for T_{mi} . Both equations leave T_{mi} as a function of T_i and other known quantities as shown below.

It should be noted that there are some assumptions built into these equations. First, all long wavelength radiation whether from other surfaces or other elements (such as heat sources which add radiation to the zone) is all assumed to be incident at and influence the air-moveable insulation interface. This also means that no long wavelength radiation is transmitted through the moveable insulation to the moveable insulation-surface interface. Second, all short wavelength radiation is assumed to be transmitted through the moveable insulation to the moveable-insulation interface. This is a simplification that is consistent with transparent insulation and assumes that the moveable insulation material itself does not absorb any short wavelength as it passes through it. Third, the term Q_{cond} includes several terms that all relate to the method for calculating heat conduction through the actual surface to which the moveable insulation is attached. Finally, the moveable insulation material is sufficiently lightweight thermally that it has no thermal mass and it can be treated as an equivalent resistance.

Equation 3.177 can be rearranged to obtain:

$$(H_c + H_{mi} + I_t) \cdot T_m = H_c \cdot T_a + H_m \cdot T_i + Q_{lw} + I_t \cdot T_{old} \quad (3.179)$$

When Equation 3.178 is rearranged to solve for T_m and this is substituted back into Equation 3.179, one obtains a single equation that allows for the solution of T_i . This can then be used to solve for T_{mi} .

The C++ code that is used to solve for T_i and T_{mi} for cases where moveable insulation is present on the interior side is shown below.

construct.CTFCross(0) * TH11) / (HMOVInsul);

```

3.10.2 Outside Heat Balance Cases for Exterior Moveable Insulation

Just like at the inside surface-air interface, a heat balance must exist at the outside surface-air interface. The incoming conductive, convective, and radiative fluxes must sum up to zero as shown in Equation 3.176.

In contrast to the internal surface heat balance that treats all surfaces simultaneously, the external thermal balance for each surface is performed independent of all other surfaces. This implies that there is no direct interaction between the individual surfaces.

TARP includes four possible representations for the basic outside surface heat balance. The first two depend on which of the optimal surface conductance algorithms the user selects. The simple outside surface conductance that includes both the convective and thermal interchange between the surface and the environment in a single coefficient, is represented by the thermal network in Figure 3.24. Equation 3.176 can also be expressed as:

$$[KOP_t + Y_0 \cdot TI_t - X_0 \cdot TO_t] + [HO \cdot (T_a - TO_t)] + QSO = 0 \quad (3.180)$$

This can be solved for the outside surface temperature.

$$TO_t = \left[\frac{KOP_t + QSO + Y_0 \cdot TI_t + HO \cdot T_a}{X_0 + HO} \right] \quad (3.181)$$

The detailed outside surface conductance model considers convection and radiant interchange with the sky and with the ground as separate factors. Its use in the outside thermal balance is shown in Figure 3.25. In this case, Equation 3.176 can be expanded to give:

$$[KOP_t + Y_0 \cdot TI_t - X_0 \cdot TO_t] + [HA \cdot (T_a - TO_t) + HS \cdot (T_s - TO_t) + HG \cdot (T_g - TO_t)] + QSO = 0 \quad (3.182)$$

This can be solved for the outside surface temperature:

$$TO_t = \left[\frac{KOP_t + QSO + Y_0 \cdot TI_t + HA \cdot T_a + HS \cdot T_s + HG \cdot T_g}{X_0 + HA + HS + HG} \right] \quad (3.183)$$

The third and fourth representations occur when the outside surface has been covered with movable insulation. The insulation has a conductance of UM. The thermal network in Figure 3.26 represents this case. The insulation must be mass-less because it is not generally possible to perform a correct thermal balance at the juncture of two surfaces each modeled by CTF.

The equation for the thermal balance between the surface and the insulation is:

$$[KOP_t + Y_0 \cdot TI_t - X_0 \cdot TO_t + UM \cdot (TM - TO_t)] + QSO = 0 \quad (3.184)$$

Which can be rewritten to solve for TO:

$$TO_t = \left[\frac{KOP_t + QSO + Y_0 \cdot TI_t + UM \cdot TM}{X_0 + UM} \right] \quad (3.185)$$

Depending on whether or not the detailed or simple algorithm for surface conductance is being used, there are two expressions for TM, the outside temperature of the insulation. For the simple conductance:

$$TM = \left[\frac{QSM + UM \cdot TO_t + HO \cdot T_a}{UM + HO} \right] \quad (3.186)$$

For the detailed conductance:

$$TO_t = \left[\frac{QSM + UM \cdot TO_t + HA \cdot T_a + HS \cdot T_s + HG \cdot T_g}{UM + HA + HS + HG} \right] \quad (3.187)$$

In this case the values of HA, HS and HG must be found by using an estimated value of TM in place of TO.

Figure 3.24: Thermal Network for Simple Outside Surface Coefficient

3.10.3 Heat Balance Cases

TO_t and TI_t are related through the Y_0 CTF. However TI_t is also unknown. While it is possible to combine the outside and the inside surface heat balances to compute TO_t and TI_t simultaneously, TARP uses a simpler procedure where TO_t is based on a previous value of TI . When Y_0 is small, as occurs in well insulated or very massive surfaces, TI_t can be replaced by TI_{t-1} (which is known for the previous hour's heat balance) without significantly effecting the value of TO_t . When Y_0 is large, TO and TI can so strongly be coupled that separate outside and inside heat balances do not work because the environment and zone temperatures have negligible influence on the heat balances. The TARP uses the inside surface heat balance to couple TO_t with TZ and TR. These two temperatures are less strongly influenced by TO and allow a reasonable heat balance. On the first heat balance iteration, TZ and TR are the values at time t-1. The user may optionally require that TO_t be recomputed with every iteration of TI_t . In this case TZ and TR have values from the previous iteration and a true simultaneous solution is achieved. In most conventional constructions,

Figure 3.25: Thermal Network for Detailed Outside Surface Coefficient

Figure 3.26: Thermal Network for Outside Moveable Insulation

recomputing TO_t does not significantly change the computed zone loads and temperatures. The inside surface heat balance is given by:

$$TI_t = \left[\frac{KIP_t + QSI + HC \cdot TZ + HR \cdot TR + Y_0 \cdot TO}{Z_0 + HC + HR} \right] \quad (3.188)$$

The surface heat balances can be combined in eight ways according to conditions for calculations of the outside surface temperature:

$$F_1 = \left[\frac{Y_0}{Z_0 + HI + HR} \right] \quad (3.189)$$

$$F_2 = \left[\frac{UM}{UM + HO} \right] \quad (3.190)$$

$$F_3 = \left[\frac{UM}{UM + HA + HS + HG} \right] \quad (3.191)$$

3.10.3.1 Case1: Y_0 small, simple conductance, no movable insulation:

From Equation 3.181,

$$TO_t = \left[\frac{KOP_t + QSO + Y_0 \cdot TI_{t-1} + HO \cdot T_a}{X_0 + HO} \right] \quad (3.192)$$

3.10.3.2 Case2: Y_0 not small, simple conductance, no movable insulation:

From Equations 3.181 and 3.188:

$$TO_t = \left[\frac{KOP_t + QSO + HO \cdot T_a + F_1 \cdot (KIP_t + QSI + HI \cdot TZ + HR \cdot TR)}{X_0 + HO - F_1 \cdot Y_0} \right] \quad (3.193)$$

3.10.3.3 Case3: Y_0 small, detailed conductance, no movable insulation:

From Equation 3.182:

$$TO_t = \left[\frac{KOP_t + QSO + Y_0 \cdot TI_{t-1} + HA \cdot T_a + HS \cdot T_s + HG \cdot T_g}{X_0 + HA + HS + HG} \right] \quad (3.194)$$

3.10.3.4 Case4: Y_0 not small, detailed conductance, no movable insulation:

From Equations 3.182 and 3.188:

$$TO_t = \left[\frac{KOP_t + QSO + HA \cdot T_a + HS \cdot T_s + HG \cdot T_g + F_1 \cdot (KIP_t + QSI + HI \cdot TZ + HR \cdot TR)}{X_0 + HA + HS + HG - F_1 \cdot Y_0} \right] \quad (3.195)$$

3.10.3.5 Case5: Y_0 small, simple conductance, with movable insulation:

From Equations 3.185 and 3.186:

$$TO_t = \left[\frac{KOP_t + QSO + Y_0 \cdot TI_{t-1} + F_2 \cdot (QSM + HO \cdot TM)}{X_0 + UM - F_2 \cdot UM} \right] \quad (3.196)$$

3.10.3.6 Case6: Y_0 not small, simple conductance, with movable insulation:

From Equations 3.185, 3.186 and 3.188:

$$TO_t = \left[\frac{KOP_t + QSO + F_2 \cdot (QSM + HO \cdot T_a) + F_1 \cdot (KIP_t + QSI + HI \cdot TZ + HR \cdot TR)}{X_0 + UM - F_2 \cdot UM - F_1 \cdot Y_0} \right] \quad (3.197)$$

3.10.3.7 Case7: Y_0 small, detailed conductance, with movable insulation:

From Equations 3.185 and 3.187:

$$TO_t = \left[\frac{KOP_t + QSO + Y_0 \cdot TI_{t-1} + F_3 (QSM + HA \cdot T_a + HS \cdot T_s + HG \cdot T_g)}{X_0 + UM - F_3 \cdot UM} \right] \quad (3.198)$$

3.10.3.8 Case8: Y_0 not small, detailed conductance, with movable insulation:

From Equations 3.185, 3.187 and 3.188:

$$TO_t = \left[\frac{KOP_t + QSO + F_1 \cdot (KIP_t + QSI + HI \cdot TZ + HR \cdot TR) + F_3 (QSM + HA \cdot T_a + HS \cdot T_s + HG \cdot T_g)}{X_0 + UM - F_3 \cdot UM - F_1 \cdot Y_0} \right] \quad (3.199)$$

3.10.4 C++ Algorithm Examples

These C++ code snippets show the implementation of these different cases.

3.10.4.1 Case5: Y_0 small, simple conductance, with movable insulation:

From Equation 3.196:

```
// Outside heat balance case: Movable insulation, slow conduction, simple convection
F2 = HMovInsul / (HMOVINSUL + HEXTSURF(SurfNum) );
TH(1, 1, SurfNum) = (-SurfCTFConstOutPart(SurfNum) + SurfOpaqQRadSWOutAbs(SurfNum) + construct.
CTFCross(0) * SurfTempIn(SurfNum) +
F2 * (SurfQRadSWOutMvIns(SurfNum) + (HEXTSURF(SurfNum)) * TempExt) /
(construct.CTFOutside(0) + HMOVINSUL - F2 * HMOVINSUL);
```

3.10.4.2 Case6: Y_0 not small, simple conductance, with movable insulation:

From Equation 3.197:

```
// Outside heat balance case: Movable insulation, quick conduction, simple convection
F1 = construct.CTFCross(0) / (construct.CTFInside(0) + HConvIn(SurfNum));
F2 = HMovInsul / (HMOVInsul + HExtSurf(SurfNum));
TH(1, 1, SurfNum) = (-SurfCTFConstOutPart(SurfNum) + SurfOpaqQRadSWOutAbs(SurfNum) +
    SurfQRadLWOutSrdSurfs(SurfNum) +
        F1 * (SurfCTFConstInPart(SurfNum) + SurfOpaqQRadSWInAbs(SurfNum) +
            SurfQRadThermInAbs(SurfNum) +
                HConvIn(SurfNum) * MAT(ZoneNum) + SurfNetLWRadToSurf(SurfNum)) +
        F2 * (SurfQRadSWOutMvIns(SurfNum) + (HExtSurf(SurfNum)) * TempExt) /
    (construct.CTFOutside(0) + HMOVInsul - F2 * HMOVInsul - F1 * construct.CTFCross(0))
;
```

3.10.4.3 Case7: Y_0 small, detailed conductance, with movable insulation:

From Equation 3.198:

```
// Outside heat balance case: Movable insulation, slow conduction, detailed convection
F2 = HMOVInsul / (HMOVInsul + SurfHcExt(SurfNum) + SurfHAirExt(SurfNum) + SurfHSkyExt(SurfNum) +
    SurfHGrdExt(SurfNum));
TH(1, 1, SurfNum) = (-SurfCTFConstOutPart(SurfNum) + SurfOpaqQRadSWOutAbs(SurfNum) +
    SurfQRadLWOutSrdSurfs(SurfNum) + construct.CTFCross(0) * SurfTempIn(SurfNum) +
        F2 * (SurfQRadSWOutMvIns(SurfNum) + (SurfHcExt(SurfNum) + SurfHAirExt(SurfNum)) *
            TempExt + QAdditionalHeatSourceOutside(SurfNum) +
            SurfHSkyExt(SurfNum) * TSky + SurfHGrdExt(SurfNum) * TGround)) /
    (construct.CTFOutside(0) + HMOVInsul - F2 * HMOVInsul);
```

3.10.4.4 Case8: Y_0 not small, detailed conductance, with movable insulation:

From Equation 3.199:

```
// Outside heat balance case: Movable insulation, quick conduction, detailed convection
F1 = construct.CTFCross(0) / (construct.CTFInside(0) + HConvIn(SurfNum));
F2 = HMOVInsul / (HMOVInsul + SurfHcExt(SurfNum) + SurfHAirExt(SurfNum) + SurfHSkyExt(SurfNum) +
    SurfHGrdExt(SurfNum));
TH(1, 1, SurfNum) = (-SurfCTFConstOutPart(SurfNum) + SurfOpaqQRadSWOutAbs(SurfNum) +
    SurfQRadLWOutSrdSurfs(SurfNum) +
        F1 * (SurfCTFConstInPart(SurfNum) + SurfOpaqQRadSWInAbs(SurfNum) +
            SurfQRadThermInAbs(SurfNum) +
                HConvIn(SurfNum) * MAT(ZoneNum) + SurfNetLWRadToSurf(SurfNum)) +
        F2 * (SurfQRadSWOutMvIns(SurfNum) + (SurfHcExt(SurfNum) + SurfHAirExt(SurfNum)) *
            TempExt + QAdditionalHeatSourceOutside(SurfNum) +
            SurfHSkyExt(SurfNum) * TSky + SurfHGrdExt(SurfNum) * TGround)) /
    (construct.CTFOutside(0) + HMOVInsul - F2 * HMOVInsul - F1 * construct.CTFCross(0))
);
```

3.10.5 C++ Variable Descriptions

Table 3.15: C++ Variables and Descriptions

C++ Variable	Description	Tarp Variable	Units	Description
TH(1, 1, SurfNum)	Temperature History(SurfNum,HistTerm,In/Out), where: HistTerm (1 = Current Time, 2 = MaxCTFTerms = previous times), In/Out (1 = Outside, 2 = Inside)	TO	C	Temperature of outside of surface I at time t
Construct(ConstrNum).CTFCross(0)	Cross or Y term of the CTF equation	Y0	W/m K	Cross CTF term
Construct(ConstrNum).CTFInside(0)	Inside or Z terms of the CTF equation	Z0	W/m K	Inside CTF term
Construct(ConstrNum).CTFOutside(0)	Outside or X terms of the CTF equation	X0	W/m K	Outside CTF term
SurfCTFConstInPart(SurfNum)	Constant inside portion of the CTF calculation	KIP	W/m	Portion of inward conductive flux based on previous temperature and flux history terms
SurfCTFConstOutPart(SurfNum)	Constant Outside portion of the CTF calculation	KOP	W/m	Portion of outward conductive flux based on previous temperature and flux history terms
F1, F2, F3	Intermediate calculation variables	F1, F2, F3		Radiation interchange factor between surfaces
GroundTemp	Ground surface temperature	T	C	Temperature of ground at the surface exposed to the outside environment
HConvIn(SurfNum)	Inside convection coefficient	HI	W/m K	Inside convection coefficient
HExtSurf(SurfNum)	Outside Convection Coefficient	HO, HA	W/m K	Overall outside surface conductance
HGround	Radiant exchange (linearized) coefficient	HG	W/m K	Radiative conductance (outside surface to ground temperature)
HmovInsul	Conductance or "h" value of movable insulation	UM	W/m K	Conductance of Movable insulation
HSky	Radiant exchange (linearized) coefficient	HS	W/m K	Radiative conductance (outside surface to sky radiant temperature)
MAT(ZoneNum)	Zone temperature	TZ	C	Temperature of zone air
SurfNetLWRadToSurf(SurfNum)	Net interior longwave radiation to a surface from other surfaces	HR*TR	W/m	Net surface to surface radiant exchange
SurfOpaqQRadSWInAbs(SurfNum)	Short-wave radiation absorbed on inside of opaque surface	QSI	W/m	Short wave radiant flux absorbed at inside of surface
SurfOpaqQRadSWOutAbs(SurfNum)	Short wave radiation absorbed on outside opaque surface	QSO	W/m	Short wave radiant flux absorbed at outside of surface
SurfQRadSWOutMvIns(SurfNum)	Short wave radiation absorbed on outside of movable insulation	QSM	W/m	Short wave radiant flux absorbed at surface of movable insulation
SurfQRadThermInAbs(SurfNum)	Thermal Radiation absorbed on inside surfaces		W/m	Longwave radiant flux from internal gains
SkyTemp	Sky temperature	T	C	Sky temp

Table 3.15: C++ Variables and Descriptions

C++ Variable	Description	Tarp Variable	Units	Description
TempExt	Exterior surface temperature or exterior air temperature	TM, T	C	Temperature of external surface of movable insulation or outside ambient air temperature
SurfTempIn(SurfNum)	Temperature of inside surface for each heat transfer surface	TI	C	Temperature of inside of surface I at time t-1

3.11 Ground Heat Transfer Calculations using Foundation:Kiva

KivaTM is an open source foundation heat transfer calculation tool developed by Big Ladder Software.

<http://bigladdersoftware.com/projects/kiva/>

Kiva is the product of Neal Kruis’s dissertation where he demonstrated that accurate foundation heat transfer calculations can be performed quickly (on the order of 5 seconds) without any noticeable loss of accuracy relative to a mesh-independent, fully three-dimensional simulation.

3.11.1 Approach

Within EnergyPlus, Kiva is used to perform two-dimensional finite difference heat transfer calculations. Each foundation is represented by a single floor and wall in Kiva, meaning that individual walls in EnergyPlus are mapped to a single representative wall in the two-dimensional context using an area weighted average for any non-uniform boundary conditions among the walls.

Kiva uses the boundary conditions from EnergyPlus:

- weather data,
- solar position, and
- zone temperatures (from previous timestep),
- zone radiation (solar, IR, etc.)

to calculate the resulting convective heat gains and surface temperatures for the floor and wall surfaces associated with a single Foundation:Kiva object. Because Kiva performs multi-dimensional finite difference calculations, the associated surfaces do not use the same HeatBalanceAlgorithm (e.g., Conduction Transfer Functions) as the rest of the model.

3.11.2 Two-dimensional Approximation

The two-dimensional approximation method employed by Kiva relies on knowing the footprint shape, area, and exposed perimeter of each instance. The appropriate footprint shape, area, and

exposed perimeter for each instance will be defined within the context of the overall geometry of the Foundation surfaces.

The general method is to define the width of the floor (the distance from the symmetry plane to the wall interior), w in the two-dimensional context as:

$$A/P_{exp} \quad (3.200)$$

where A is the area of the foundation footprint, and P_{exp} is the exposed perimeter of the foundation (See `SurfaceProperty:ExposedFoundationPerimeter`).

Kiva also has the capability to adjust this width to account for concave foundation footprint shapes (Note: this also relies on detailed input of the exposed foundation perimeter for each segment of the footprint polygon). This adjustment is based on the boundary layer adjustment method described by Kruis and Krarti (2017). The approach adjusts the exposed perimeter to account for interactions in heat flow within concave corners and narrow gaps between two exposed edges.

This approach allows for accurate representation of building foundation heat transfer without performing three-dimensional calculations. Because the two-dimensional context is symmetric, the domain can be divided in half to further reduce the number of calculations.

3.11.3 Numerical Calculations

Kiva automatically discretizes the two-dimensional domain into rectangular cells. The size of each cell is defined by the `Foundation:Kiva:Settings` object's "Minimum Cell Dimension" and "Maximum Cell Growth Coefficient". The "Minimum Cell Dimension" defines the smallest possible dimension of a cell within the domain. Cells along a block boundary start at this size and grow geometrically away from the boundary according to the "Maximum Cell Growth Coefficient". This is evident from Figures 3.27 and 3.28 which show the discretization for a single foundation at close and far perspectives, respectively.

The discretized partial differential equations are solved using the Alternating Direction Implicit (ADI) finite difference time stepping scheme. This scheme provides relatively fast calculations with stable results as demonstrated by Kruis and Krarti (2015).

3.11.4 Boundary Conditions

Symmetry Plane: Zero heat flux in the horizontal direction.

Wall Top: Zero heat flux in the vertical direction (assumes heat transfer through the exterior wall above is one-dimensional in the horizontal direction).

Deep Ground: Either constant temperature or zero vertical heat flux, depending on user input. Deep ground depth may be automatically calculated based on water table estimates using a method defined by Williams and Williamson (1989).

Far-Field: Zero heat flux in the horizontal direction. If this boundary is sufficiently far from the building, this will result in an undisturbed ground temperature profile.

Interior Surfaces:

- Convection is calculated according to the TARP method (see `SurfaceConvectionAlgorithm:Inside`).

Figure 3.27: Example generated discretization near foundation perimeter

Figure 3.28: Example generated discretization of full domain

Figure 3.29: Boundary conditions in Kiva's two-dimensional context

- Long and short wave radiation is passed from EnergyPlus radiant exchange and interior solar distribution algorithms. Note: Kiva uses area weighted averages to define the radiation incident on walls in the two-dimensional context.

Exterior Surfaces:

- Convection is calculated according to the DOE-2 method (see SurfaceConvectionAlgorithm:Outside). Wind speeds along the exterior grade are calculated at the roughness height.
- Exterior long wave radiation is calculated using the same algorithms used for other EnergyPlus surfaces. Note: there is no explicit radiant exchange between the ground and building surfaces.
- Exterior solar incidence is uniform along the exterior grade surfaces. No shading is taken into account. Solar incidence along the wall exterior

3.11.5 Multiple Kiva Instances

In some cases, a single Foundation boundary condition might require multiple Kiva instances:

Multiple Zones: If the surfaces in several zones reference the same Foundation:Kiva object, each zone will be calculated using separate Kiva instances.

Walk-Out Basements: Walkout basements are defined by using walls of different heights all referencing the same Foundation:Kiva object.

Figure 3.30: Walkout basement surfaces (in gray) all reference the same Foundation:Kiva object

Figure 3.31: Walkout basement Kiva instances (one for each wall height)

A separate Kiva instance will be run for any walls with different heights associated with the same Foundation:Kiva object. Figure 3.30 shows how the grouping of walls by height based on the basement in Figure 3.31, including the portion that is only a slab.

The resulting five two-dimensional contexts will look like Figures 3.32 - 3.36.

Each Kiva instance with a different wall height will calculate different heat fluxes, convective coefficients and surface temperatures for both the wall and the floor. The heat flux through the associated floor will be weighted according to the fraction of the total exposed perimeter, $P_{exp,tot}$, represented by each segment of different height. The total heat flux through the walkout basement floor is:

$$\dot{q} = \sum_i^{N_{segs}} \frac{P_{exp,i}}{P_{exp,tot}} \cdot h_i (T_\infty - T_{floor,i}) \quad (3.201)$$

The weighted average convective coefficient for the walkout basement floor surface is:

$$\bar{h} = \sum_i^{N_{wall,segs}} \frac{P_{exp,i}}{P_{exp,tot}} \cdot h_i \quad (3.202)$$

Figure 3.32: Group 1 Kiva context

Figure 3.33: Group 2 Kiva context

Figure 3.34: Group 3 Kiva context

Figure 3.35: Group 4 Kiva context

Figure 3.36: Group 5 Kiva context

Figure 3.37: Core zone (no exposed perimeter)

The weighted average temperature for the floor surface is:

$$\bar{T}_{floor} = T_{\infty} - \dot{q}/\bar{h} \quad (3.203)$$

Multiple Floor Surfaces: If a floor has multiple constructions (e.g., carpeted and bare) each surface must reference a separate Foundation:Kiva object, or be combined into a single equivalent construction.

3.11.6 Core Zone Slabs

Because core zones have no exposed perimeter, they are assumed to exchange heat only with the deep ground boundary condition. This is calculated using a one-dimensional finite difference formulation. The associated Kiva instance will use only the description of the slab and the deep ground boundary condition to define the heat flux through the surface.

3.11.7 Warm-Up

The traditional “warm-up” period in EnergyPlus (of repeating a single day) presents several challenges for foundation heat transfer calculations:

- As the ground can have time constants on the order of years, a single day is simply not long enough to adequately capture the thermal history of the ground.

Figure 3.38: Core zone one-dimensional context

- Any repetition of a single day would erase any pre-calculated thermal history and likely take much longer to converge.

Instead, Kiva instances are initialized independently from the rest of the simulation using the accelerated initialization method developed by Kruis (2015). This method looks back in the weather file and simulates long timestep (on the order of weeks or months) calculations using an implicit numerical scheme. These long timesteps allow Kiva to capture a long term history of the ground without running the entire building model.

The initialization of the ground relies on assumptions of indoor air temperatures (as they are not yet calculated by EnergyPlus). When a thermostat is assigned to a zone with Kiva foundation surfaces, the assumed temperature is equal to the setpoint (or a weighted average of heating and cooling setpoints depending on outdoor temperature). For zones without thermostats, a constant 22 °C indoor temperature is assumed.

3.11.8 Validation

Kiva has been tested against the BESTEST Ground coupled cases with accuracy within 3% of the reference solutions (Kruis and Krarti, 2015).

3.12 Ground Heat Transfer Calculations using C and F Factor Constructions

Building energy code and standards like ASHRAE 90.1, 90.2 and California Title 24 require the underground wall constructions and slabs-on-grade or underground floors not to exceed certain maximum values of C-factor and F-factor, which do not specify detailed layer-by-layer materials for the constructions. If using the normal approach (layer by layer) of ground constructions with EnergyPlus, users would need to create a pseudo wall or floor construction to match the thermal performance such as thermal mass effect and U-factor, and rely on the EnergyPlus Basement and Slabs tools to generate the monthly ground temperatures.

A simplified approach is introduced to create equivalent constructions and model the ground heat transfer through underground walls and ground floors for the building energy code compliance calculations. The approach is to create constructions based on the user defined C or F factor with two layers: one concrete layer (0.15 m thick) with thermal mass, and one fictitious insulation layer with no thermal mass.

Three objects are used in the C and F factor calculations:

- Construction:CfactorUndergroundWall
- Construction:FfactorGroundFloor
- Site:GroundTemperature:FCfactorMethod

Site:GroundTemperature:FCfactorMethod is used only by the underground walls or slabs-on-grade or underground floors defined with C-factor (Construction:CfactorUndergroundWall) and F-factor (Construction:FfactorGroundFloor) method for code compliance calculations where detailed construction layers are unknown. Only one such ground temperature object can be included. The monthly ground temperatures for this object are close to the monthly outside air temperatures delayed by three months. If user does not input this object in the IDF file, it will be defaulted to the 0.5m set of monthly ground temperatures from the weather file if they are available.

Detailed description of the three objects is in the Input Output Reference document. The following section describes how the equivalent material layers are created based on the C-factor and F-factor.

3.12.0.1 Slab-on-grade and Underground Floors Defined with F-factors

The steady state heat transfer through the floor is calculated as,

$$Q = \text{Area} \cdot U_{eff} \cdot (T_{air,out} - T_{air,in}) = (T_{air,out} - T_{air,in}) \cdot (P_{exp} \cdot \text{F-factor}) \quad (3.204)$$

Where,

Q is the steady state heat transfer through the floor in Watt

Area is the area of the floor in m^2

U_{eff} is the effective heat transfer coefficient including the floor construction, the soil, and the thermal resistance of the interior and exterior air films.

$T_{air,in}$ is the indoor air temperature in $^{\circ}\text{C}$

$T_{air,out}$ is the outside air temperature in $^{\circ}\text{C}$

P_{exp} is the exposed perimeter of the floor in m

F-Factor is the heat transfer through the floor, induced by a unit temperature difference between the outside and inside air temperature, on the per linear length of the exposed perimeter of the floor. The unit is $\text{W/m} \cdot \text{K}$.

Therefore,

$$U_{eff} = (P_{exp} \cdot \text{F-factor}) / \text{Area} \quad (3.205)$$

$$1/U_{eff} = R_{eff} + R_{film,in} + R_{film,out} \quad (3.206)$$

$$R_{eff} = \text{Area} / (P_{exp} \cdot \text{F-factor}) - R_{film,in} - R_{film,out} \quad (3.207)$$

Where,

R_{eff} is the effective thermal resistance in $\text{m}^2 \cdot \text{K/W}$, including the soil and the floor construction

$R_{film,in}$ and $R_{film,out}$ are the air film resistance of the inside and outside surfaces, respectively.

The outside air film resistance $R_{film,out} = 0.03 \text{ m}^2 \cdot \text{K/W}$. The inside air film resistance $R_{film,in} = 0.125 \text{ m}^2 \cdot \text{K/W}$, which is the average of the $0.14 \text{ m}^2 \cdot \text{K/W}$ for heat flow up and $0.11 \text{ m}^2 \cdot \text{K/W}$ for heat flow down.

Approximate the thermal mass of the floor construction with a 6-inch (0.15 m) heavy concrete, and use a fictitious insulation layer with no thermal mass to match the thermal resistance of the construction.

We have,

$$R_{fic} = R_{eff} - R_{con} \quad (3.208)$$

Where,

R_{fic} is the thermal resistance of the fictitious insulation layer in $\text{m}^2 \cdot \text{K/W}$.

R_{con} is the thermal resistance of the concrete layer in $\text{m}^2 \cdot \text{K/W}$.

Properties of the concrete layer are:

Thickness = 0.15 m

Conductivity = $1.95 \text{ W/m} \cdot \text{K}$

Density = 2240 kg/m^3

Specific heat = $900 \text{ J/kg} \cdot \text{K}$

$R_{con} = 0.15 / 1.95 = 0.077 \text{ m}^2 \cdot \text{K/W}$

Finally,

$$R_{fic} = R_{eff} - 0.077 \quad (3.209)$$

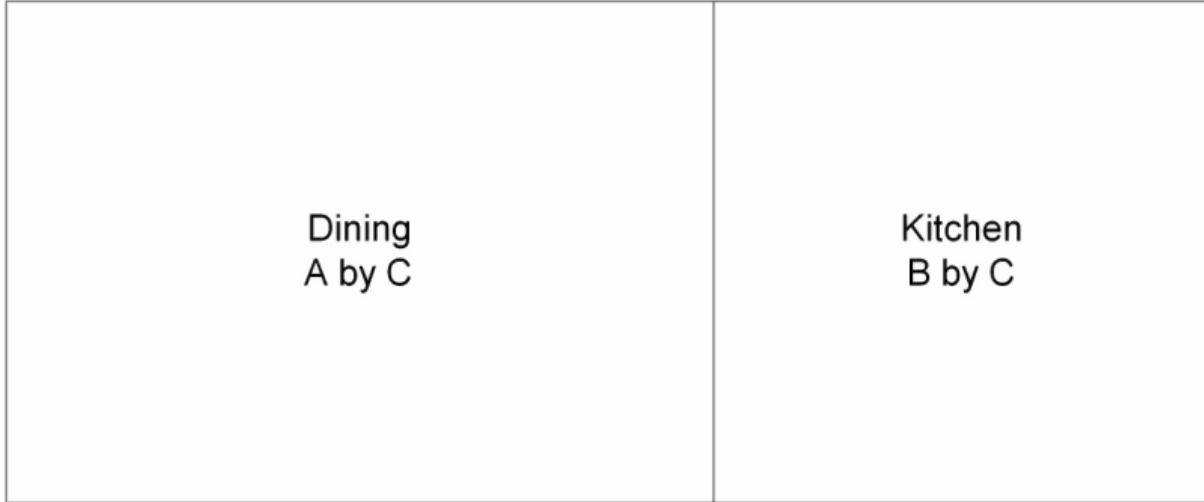

Figure 3.39: Schematic for Slab on Grade - Two Spaces

For slabs-on-grade as shown in the figure above, the exposed perimeter is $(2A + C)$ for the Dining area, and $(2B + C)$ for the Kitchen area. For underground floors with no exposed perimeter, the R_{eff} can be assumed a big value such as $1000 \text{ hr} \cdot \text{ft}^2 \cdot ^\circ\text{F}/\text{Btu}$ ($177 \text{ m}^2 \cdot \text{K}/\text{W}$).

Underground Walls Defined with C-Factors

The steady state heat transfer through the underground wall is calculated as,

$$Q = Area * U_{eff} * (T_{air,out} - T_{air,in}) \quad (3.210)$$

$$1/U_{eff} = R_{eff} + R_{film,out} + R_{film,in} \quad (3.211)$$

Where,

Q is the heat transfer through the wall in Watt

Area is the area of the wall in m^2

U_{eff} is the effective heat transfer coefficient including the wall construction, the soil, and the thermal resistance of the interior and exterior air films.

R_{eff} is the effective thermal resistance in $\text{m}^2 \cdot \text{K}/\text{W}$, including the soil and the wall construction

$R_{film,in}$ and $R_{film,out}$ are the air film resistance of the inside and outside surfaces, respectively.

C-factor is the time rate of steady-state heat flow through unit area of the construction, induced by a unit temperature difference between the body surfaces. The C-Factor unit is $\text{W}/\text{m}^2 \cdot \text{K}$. The C-factor does not include soil or air films.

$$R_{eff} = 1/C - factor + R_{soil} \quad (3.212)$$

R_{soil} is the effective R-value of the soil. Reference values from Table C6.10.1 of the SI version of the ASHRAE Standard 90.1-2010 are as follows:

A fairly good linear regression ($R^2 = 0.9967$) for the above data is,

$$R_{soil} = 0.0607 + 0.3479 * Depth \quad (3.213)$$

TABLE C6.10.1 Effective R-Value of Soil for Below-Grade Walls	
Depth, m	$R_{\text{soil}}, \text{m}^2 \cdot \text{k/W}$
0.25	0.12
0.50	0.23
0.75	0.33
1.0	0.42
1.25	0.52
1.50	0.59
1.75	0.68
2.00	0.75
2.25	0.83
2.50	0.92

Figure 3.40: Effective R-Value of Soil for Below-Grade Walls

Approximate the thermal mass of the wall construction with a 6-inch (0.15 m) heavy concrete, and use a fictitious insulation layer with no thermal mass to match the thermal resistance of the construction. Then we have the thermal resistance of the insulation layer,

$$R_{fic} = R_{eff} - R_{con} \quad (3.214)$$

Where,

R_{fic} is the thermal resistance of the fictitious insulation layer

R_{con} is the thermal resistance of the concrete layer in $\text{m}^2 \cdot \text{K/W}$.

Properties of the concrete layer are:

Thickness = 0.15 m

Conductivity = $1.95 \text{ W/m} \cdot \text{K}$

Density = 2240 kg/m^3

Specific heat = $900 \text{ J/kg} \cdot \text{K}$

$R_{con} = 0.15/1.95 = 0.077 \text{ m}^2 \cdot \text{K/W}$

3.13 Ground Heat Transfer Calculations using Site:GroundDomain:Slab

In order to simulate heat transfer with horizontal building surfaces in contact with the ground, a general finite difference ground model has been implemented. The model simulates heat transfer with the horizontal building surfaces through the ground domain. The domain can simulate heat transfer for slab-in-grade or slab-on-grade scenarios. In all scenarios, the ground domain must interact with the zone through an OthersideConditionsModel as the horizontal surface's outside boundary condition.

3.13.0.1 Approach

This model is generalized to be able to handle a number of different slab and insulation configurations. It uses an implicit finite difference formulation to solve for the ground temperatures. As a result the simulation is stable for all timesteps and grid sizes, but an iteration loop must be employed to converge the temperatures in the domain for each domain timestep.

Multiple horizontal surfaces can be coupled to each ground domain object. The model determines which surfaces are coupled to the ground domain and creates a surface of equivalent surface area within the ground domain as a representation of the horizontal surfaces coupled to the ground domain. This surface then interacts with the ground providing updated other side conditions model temperatures to the coupled surfaces for use in their surface heat balance calculations.

3.13.0.2 Boundary Conditions

At the interface surface, the average surface conduction heat flux from all surfaces connected to the ground domain is imposed as a GroundDomain boundary condition at the Surface/GroundDomain interface cells. Heat flux to each cell is weighted as was recommended by Pinel & Beausoleil-Morrison 2012 which is shown in Equation 3.215.

$$q_{out,i} = q_{out,1-D} \frac{T_{zone} - T_{out,i}}{T_{zone} - T_{out,avg}} \quad (3.215)$$

Far-field temperatures are applied as boundary temperature at the GroundDomain sides and lower surface. The ground temperature profile at the domain sides and lower surface are taken from Kusuda & Achenbach 1965. The correlation requires annual ground surface temperature data.

Ground surface cells are treated as a heat balance, where long and short wave radiation, conduction, and convection are considered. Evapotranspiration is also considered. The evapotranspiration rate is calculated as a moisture loss by using the Allen et al. (2005) model, and translated into a heat loss by multiplication with the density and latent heat of evaporation of water. The evapotranspiration rate is dependent on the type of vegetation at the surface; the user can vary the surface vegetation from anywhere between a concrete surface and a fairly tall grass (about 7").

Once the ground model has run, the updated cells with zone surface boundary conditions will update the OtherSideConditionsModel temperatures which are the used at the next timestep in the surface heat balance calculations.

3.13.0.3 Simulation Methodology

The ground domain is updated at each zone timestep, or hourly as specified by the user. For situations when the ground domain is updated at each timestep, the domain is simulated by applying the surface heat flux boundary conditions from the previous timestep and calculating a new OtherSideConditionsModeltemperature. At this point, the surface heat balance algorithms can then take the new outside surface temperatures to update their surface heat fluxes. For situations when the user has elected to have the domain update on an hourly basis, the surface heat balance for each coupled surface is aggregated and passed to the domain as an average surface heat flux from the previous hour, which will then update the outside surface temperatures for the surface heat balance's next iteration.

Both in-grade and on-grade scenarios are simulated with the GroundDomain object. The key difference being that for in-grade situations, the slab and horizontal insulation are simulated by

the ground domain, whereas for the on-grade situations the slab and horizontal insulation must be included in the floor construction object. All possible insulation/slab configurations are seen in Table 3.16.

Table 3.16: Possible insulation/slab configurations for Site:GroundDomain model.

Situations	Vert. Ins.	Horiz Ins. (Full)	Horiz Ins. (Perim)
In-Grade	1	X	
In-Grade	2	X	X
In-Grade	3	X	
In-Grade	4		X
In-Grade	5		X
In-Grade	6		X
On-Grade	7	X	
On-Grade	8*	X	X
On-Grade	9		
On-Grade	10*		X

* Horizontal insulation must be included in the floor construction

For the slab-in-grade scenarios, a thin surface layer must be included in the floor construction. This can be a very thin layer of the slab or other floor covering materials above the slab. This provides a zone boundary condition for the GroundDomain while still allowing 3-dimensional heat transfer effects to occur within the slab.

3.14 Ground Heat Transfer Calculations using Site:GroundDomain:Basement

Basement heat transfer calculations are performed by the same model used by Site:GroundDomain:Slab to simulate zone-ground coupled surfaces. To simulate basements, the previous model is extended to situations where surfaces are below ground.

3.14.0.1 Approach

This model is generalized to be able to handle several basement surface and insulation configurations. An implicit finite difference formulation is used to solve for the ground temperatures. As a result the simulation is stable for all timesteps and grid sizes, but an iteration loop must be employed to converge the temperatures in the domain for each domain timestep.

Multiple basement zones can be coupled to each basement domain object. The model determines which floor surfaces are coupled to the basement domain and creates a floor surface of equivalent surface area within the basement domain as a representation of the horizontal surfaces coupled to the domain. The user defined aspect ratio, which is the ratio of basement width to length, along with the total surface area of all surfaces connected to this basement floor will define the size and shape of the basement ground domain.

Vertical basement depth below the ground surface of the domain is user specified. For situations when the ground surface is lower than the first above ground level a separate surface should be employed to bridge the space between the ground domain, and the first above-ground level.

Basement wall and floor surfaces are created normally using the `BuildingSurface:Detailed` objects, with the outside boundary condition being the `OtherSideConditionsModel` used for the walls and floor of the basement domain. The interface between the basement walls and floors occurs at the outside surface of the walls and floor. Outside underground insulation is simulated by the ground domain, and therefore should not be included in the basement wall and floor construction objects.

3.14.0.2 Boundary Conditions

At the zone interface surfaces, the average surface conduction heat flux from all surfaces connected to the ground domain is imposed as a boundary condition at the `Surface/Domain` interface cells. Far-field temperatures are applied as boundary temperature at the domain sides and lower surface. The ground temperature profile at the domain sides and lower surface are taken from Kusuda & Achenbach 1965. The correlation requires annual ground surface temperature data. Ground surface temperature data can be determined by using the `CalcSoilSurfTemp` preprocessor; or, if the user has average monthly ground surface temperature data available, they can use the `Site:GroundTemperature:Shallow` object to provide the model monthly ground surface temperatures. From that, the model can then determine the ground temperature model parameters for the Kusuda & Achenbach (1965) ground temperature model.

Ground surface cells are treated as a heat balance, where long and short wave radiation, conduction, and convection are considered. Evapotranspiration is also considered. The evapotranspiration rate is calculated as a moisture loss by using the Allen et al. (2005) model, and translated into a heat loss by multiplication with the density and latent heat of evaporation of water. The evapotranspiration rate is dependent on the type of vegetation at the surface; the user can vary the surface vegetation from anywhere between a concrete surface and a fairly tall grass (about 7"). The model can be sensitive to variations in this parameter, especially in hot dry climates.

Once the basement model has run, the updated cells with zone surface boundary conditions will update the `OtherSideConditionsModel` temperatures which are then used at the next timestep in the surface heat balance calculations.

3.14.0.3 Simulation Methodology

The ground domain is updated at each zone timestep, or hourly as specified by the user. For situations when the ground domain is updated at each timestep, the domain is simulated by applying the surface heat flux boundary conditions from the previous timestep and calculating a new `OtherSideConditionsModel` temperature. At this point, the surface heat balance algorithms can then take the new outside surface temperatures to update their surface heat fluxes. For situations when the user has elected to have the domain update on an hourly basis, the surface heat flux for each coupled surface is aggregated and passed to the domain as an average surface heat flux from the previous hour, which will then update the outside surface temperatures for the surface heat balance's next iteration.

The basement floor and walls are simulated by standard surface heat balance models within `EnergyPlus` (CTF, finite difference). The horizontal and vertical insulation are simulated by the ground domain finite difference solver. This is shown in Figure 3.41 below where the dotted red line defines the `OtherSideConditionsModel` interface separating the two solution domains. This methodology applies to the basement floor and walls.

3.15 Undisturbed Ground Temperature Model: Finite Difference

3.15.0.1 Approach

This model uses a 1D implicit finite difference heat transfer model to determine the steady-periodic annual ground temperature. The model, which uses a daily timestep, is run through an annual simulation using the user provided weather file to determine daily averages for global horizontal radiation, air temperature, relative humidity, and wind speed. Once the steady-periodic ground temperature has been determined, the temperatures are cached for use later in the simulation. The basis for the model was taken from Xing, 2014, however, the numerical methods were adapted from those described in Lee, 2013; the latter uses an implicit numerically stable finite difference method, whereas the former utilized an explicit, conditionally stable method.

Surface heat balance boundary conditions are similar what is described in Herb et al., 2008. Evapotranspiration is considered as described by Allen et al., 1998. Soil freezing given the assumed stagnant soil moisture content is also considered.

3.15.0.2 Limitations

The model does not consider the effects of vegetative canopy layers, snow cover, ground water flow, ground moisture transport, or surface runoff.

Figure 3.41: Example surface construction.

3.16 Undisturbed Ground Temperature Model: Kusuda-Achenbach

3.16.0.1 Approach

The model uses the correlation developed by Kusuda & Achenbach, 1965 which is shown below. The average soil surface temperature, amplitude of the soil surface temperature, and day of minimum surface temperature are all required inputs. These can be determined by using the CalcSoilSurfTemp preprocessor. They can also automatically be generated by leaving the parameters blank and including a Site:GroundTemperature:Shallow object in the input file.

$$T(z, t) = \bar{T}_s - \Delta\bar{T}_s \cdot e^{-z \cdot \sqrt{\frac{\pi}{\alpha\tau}}} \cdot \cos\left(\frac{2\pi t}{\tau} - \theta\right) \quad (3.216)$$

Where:

$T(z, t)$ is the undisturbed ground temperature as a function of time and depth

\bar{T}_s is the average annual soil surface temperature, in deg C

$\Delta\bar{T}_s$ is the amplitude of the soil temperature change throughout the year, in deg C

θ is the phase shift, or day of minimum surface temperature

α is the thermal diffusivity of the ground

τ is time constant, 365.

3.17 Undisturbed Ground Temperature Model: Xing

3.17.0.1 Approach

This model uses the correlation developed by Xing, 2014 to predict undisturbed ground temperature. The correlation parameters for 4000+ international locations can be found in Xing, 2014. The parameters were first determined by creating and validating a finite difference numerical model

which used local weather data for boundary conditions. From the numerical model, the correlation parameters were determined to provide for this simplified design model.

$$T(z, t) = \bar{T}_s - \sum_{n=1}^2 \Delta \bar{T}_{s,n} \cdot e^{-z \cdot \sqrt{\frac{n\pi}{\alpha\tau}}} \cdot \cos \left[\frac{2\pi n}{\tau} (t - \theta_n) - z \sqrt{\frac{n\pi}{\alpha\tau}} \right] \quad (3.217)$$

$T(z, t)$ is the undisturbed ground temperature as a function of time and depth

\bar{T}_s is the average annual soil surface temperature, in deg C

$\Delta \bar{T}_{s,n}$ is the n-th amplitude of the soil temperature change throughout the year, in deg C

θ_n is the n-th phase shift, or day of minimum surface temperature

α is the thermal diffusivity of the ground

τ is time constant, 365.

Chapter 4

Advanced Surface Concepts

4.1 Exterior Naturally Vented Cavity

The input object “SurfaceProperty:ExteriorNaturalVentedCavity” allows modeling a special case for the outside boundary conditions of heat transfer surfaces with a multi-skin exterior that is opaque. From the thermal envelope’s point of view, the presence of a vented cavity on the outside of the surface modifies the conditions experienced by the underlying heat transfer surfaces. This exterior cavity acts as a radiation and convection baffle situated between the exterior environment and the outside face of the underlying heat transfer surface. The actual outer surface is referred to as the “baffle”. The modeling here assumes that the heat capacity in the outer baffle can be neglected since it is much lower than the underlying mass surface. This object is used with the BuildingSurface:Detailed object where the heat transfer surfaces are referred to as the underlying surfaces. The constructions and materials for the heat transfer surfaces should reflect the construction of just the underlying surface. The SurfaceProperty:ExteriorNaturalVentedCavity object is used to describe the detached layer, or baffle, and the characteristics of the cavity and openings for natural ventilation. This model uses the SurfaceProperty:OtherSideConditionsModel object to pass boundary conditions to the heat transfer modeling for the underlying surfaces.

4.1.1 Baffle Heat Balance

The baffle is assumed to be sufficiently thin and high-conductivity so that it can be modeled using a single temperature (for both sides and along its area). This temperature $T_{s,baff}$ is determined by formulating a heat balance on a control volume that just encapsulates the baffle surface. The baffle is assumed to completely cover the underlying surface such that it is opaque to shortwave and longwave radiation. This assumption means that even though the baffle will have some open area for ventilation, no solar energy passes through these openings. The heat balance is diagrammed in the following figure.

The heat balance on the baffle surface’s control volume is:

$$q''_{\alpha sol} + q''_{LWR,Env} + q''_{conv,Env} + q''_{LWR,cav} + q''_{conv,cav} + q''_{source} = 0 \quad (4.1)$$

where:

$q''_{\alpha sol}$ is absorbed direct and diffuse solar (short wavelength) radiation heat flux.

$q''_{LWR,Env}$ is net long wavelength (thermal) radiation flux exchange with the air and surroundings.

Figure 4.1: Baffle Surface Heat Balance

$q''_{conv,Env}$ = surface convection flux exchange with outside air.

$q''_{LWR,cav}$ is net long wavelength (thermal) radiation flux exchange with the outside face of the underlying surface(s).

$q''_{conv,cav}$ = surface convection flux exchange with cavity air.

q''_{source} is a source/sink term that accounts for energy exported out of the control volume when the baffle is a hybrid device such as a photovoltaic panel.

All terms are positive for net flux to the baffle. Each of these heat balance components is introduced briefly below.

4.1.1.1 External SW Radiation

$q''_{\alpha sol}$ is calculated using procedures presented elsewhere in this manual and includes both direct and diffuse incident solar radiation absorbed by the surface face. This is influenced by location, surface facing angle and tilt, shading surfaces, surface face material properties, weather conditions, etc. The baffle blocks all shortwave radiation from reaching the underlying surface.

4.1.1.2 External LW Radiation

$q''_{LWR,Env}$ is a standard radiation exchange formulation between the surface, the sky, the ground, and the atmosphere. The radiation heat flux is calculated from the surface absorptivity, surface temperature, sky, air, and ground temperatures, and sky and ground view factors. Radiation is modeled using linearized coefficients. The baffle blocks all longwave radiation.

4.1.1.3 External Convection

$q''_{conv,env}$ is modeled using the classical formulation: $q''_{conv} = h_{co}(T_{air} - T_o)$ where h_{co} , is the convection coefficient. The h_{co} is treated in the same way as an outside face with ExteriorEnvironment conditions. In addition, when it is raining outside, we assume the baffle gets wet and model the enhanced surface heat transfer using a large value for h_{co} .

4.1.1.4 Cavity LW Radiation

$q''_{LWR,cav}$ is a standard radiation exchange formulation between the baffle surface and the underlying heat transfer surface located across the cavity. Radiation is modeled using linearized coefficients.

4.1.1.5 Cavity Convection

$q''_{conv,cav}$ is modeled using the classical formulation: $q''_{conv} = h_{cp}(T_{air} - T_o)$ where h_{cp} , is the convection coefficient. The value for h_{cp} is obtained from correlations used for window gaps from ISO (2003) standard 15099.

Substituting models into Equation 4.1 and solving for $T_{s,baff}$ yields the following equation:

$$T_{s,baff} = \frac{(I_s \alpha + h_{co} T_{amb} + h_{r,atm} T_{amb} + h_{r,sky} T_{sky} + h_{r,gnd} T_{amb} + h_{r,cav} T_{so} + h_{c,cav} T_{a,cav} + q''_{source})}{(h_{co} + h_{r,air} + h_{r,sky} + h_{r,gnd} + h_{r,cav} + h_{c,cav})} \quad (4.2)$$

where,

I_s is the incident solar radiation of all types [W/m²],

α is the solar absorptivity of the baffle [dimensionless],
 $h_{r,atm}$ is the linearized radiation coefficient for the surrounding atmosphere [$\text{W}/\text{m}^2 \cdot \text{K}$],
 T_{amb} is the outdoor drybulb from the weather data, also assumed for ground surface [$^{\circ}\text{C}$],
 $h_{r,sky}$ is the linearized radiation coefficient for the sky [$\text{W}/\text{m}^2 \cdot \text{K}$],
 T_{sky} is the effective sky temperature [$^{\circ}\text{C}$],
 $h_{r,gnd}$ is the linearized radiation coefficient for the ground [$\text{W}/\text{m}^2 \cdot \text{K}$],
 $h_{r,cav}$ is the linearized radiation coefficient for the underlying surface [$\text{W}/\text{m}^2 \cdot \text{K}$],
 T_{so} is the temperature of the outside face of the underlying heat transfer surface [$^{\circ}\text{C}$],
 h_{co} is the convection coefficient for the outdoor environment [$\text{W}/\text{m}^2 \cdot \text{K}$],
 $h_{c,cav}$ is the convection coefficient for the surfaces facing the plenum [$\text{W}/\text{m}^2 \cdot \text{K}$], and
 $T_{a,cav}$ is the drybulb temperature for air in the cavity [$^{\circ}\text{C}$].

4.1.2 Cavity Heat Balance

The *cavity* is the volume of air located between the baffle and the underlying heat transfer surface. The cavity air is modeled as well-mixed. The uniform temperature of the cavity air, $T_{a,cav}$, is determined by formulating a heat balance on a control volume of air as diagrammed below.

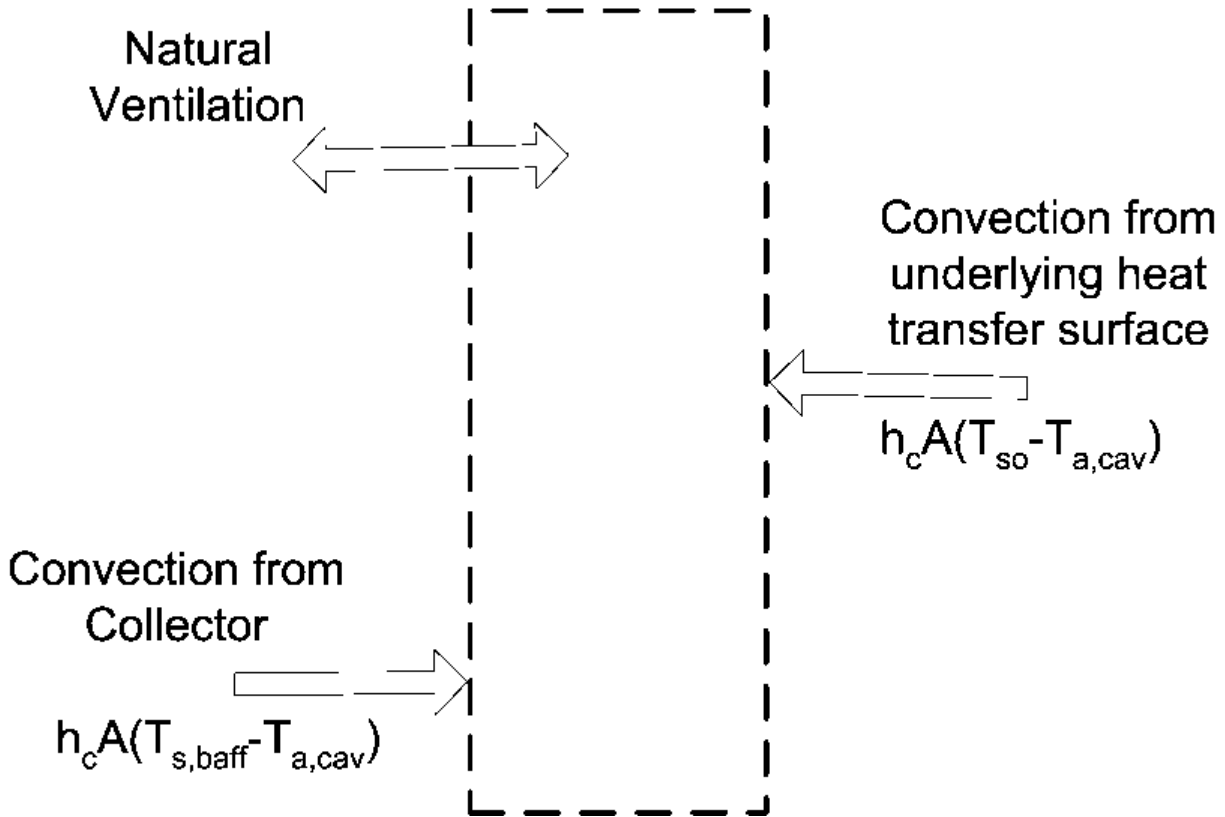

Figure 4.2: Cavity Air Heat Balance

The heat balance on the cavity air control volume is:

$$\dot{Q}_{vent} + \dot{Q}_{co} + \dot{Q}_{c,baff} = 0 \quad (4.3)$$

where,

\dot{Q}_{vent} is the net rate of energy added from natural ventilation – where outdoor ambient air exchanges with the cavity air.

\dot{Q}_{co} is the net rate of energy added by surface convection heat transfer with the underlying surface.

$\dot{Q}_{c,baff}$ is the net rate of energy added by surface convection heat transfer with the collector.

And substituting into Equation 4.3 yields the following equation:

$$T_{a,cav} = \frac{(h_{c,cav}A T_{so} + \dot{m}_{vent}c_p T_{amb} + h_{c,cav}A T_{s,baff})}{(h_{c,cav}A + \dot{m}_{vent}c_p + h_{c,cav}A)} \quad (4.4)$$

where,

\dot{m}_{vent} is the air mass flow from natural forces [kg/s]

Modeling natural ventilation air exchanges in a general way is challenging. Simplistic engineering models are used to model \dot{m}_{vent} resulting from natural buoyancy and wind forces. Reasoning that the configuration is similar to single-side natural ventilation, we elect to use correlations for natural ventilation presented as equations (29) and (30) in Chapter 26 of ASHRAE Handbook of Fundamentals (2001).

$$\dot{m}_{vent} = \rho \dot{V}_{tot} \quad (4.5)$$

where,

ρ is the density of air [kg/m³], and

$\dot{V}_{tot} = \dot{V}_{wind} + \dot{V}_{thermal}$ is the total volumetric flow rate of air ventilating in and out of the cavity.

$\dot{V}_{wind} = C_v A_{in} U_{\infty}$

$\dot{V}_{thermal} = C_D A_{in} \sqrt{2g\Delta H_{NPL} (T_{a,cav} - T_{amb}) / T_{a,cav}}$ (if $T_{a,cav} > T_{amb}$)

$\dot{V}_{thermal} = C_D A_{in} \sqrt{2g\Delta H_{NPL} (T_{amb} - T_{a,cav}) / T_{amb}}$ (if $T_{amb} > T_{a,cav}$ and baffle is vertical)

C_v is the effectiveness of the openings that depends on opening geometry and the orientation with respect to the wind. ASHRAE HoF (2001) indicates values ranging from 0.25 to 0.6. This value is available for user input.

C_D is the discharge coefficient for the opening and depends on opening geometry. This value is available for user input.

Mass continuity arguments lead to modeling the area of the openings as one half of the total area of the openings, so we have:

$$A_{in} = \frac{A}{2} \quad (4.6)$$

g is the gravitational constant taken as 9.81 [m/s²].

ΔH_{NPL} is the height from midpoint of lower opening to the Neutral Pressure Level. This is value is available for user input.

If the cavity is horizontal and $T_{amb} > T_{a,cav}$ then $\dot{V}_{thermal} = 0$ because this is a stable situation.

4.1.3 Underlying Heat Transfer Surface

The exterior baffle and cavity are applied to the outside of a heat transfer surface. This surface is modeled using the usual EnergyPlus methods for handling heat capacity and transients – typically the CTF method. These native EnergyPlus heat balance routines are used to calculate T_{so} . The exterior baffle and cavity system is coupled to the underlying surface using the SurfaceProperty:OtherSideConditionsModel mechanism. The exterior naturally vented cavity model provides

values for $h_{r,cav}$, $T_{s,baff}$, $h_{c,cav}$, and $T_{a,cav}$ for use with the heat balance model calculations for the outside face of the underlying surface (described elsewhere in this manual).

4.1.4 Solar and Shading Calculations

The exterior vented cavity model uses standard EnergyPlus surfaces in order to take advantage of the detailed solar and shading calculations. Solar radiation incident on the surface includes beam and diffuse radiation, as well as radiation reflected from the ground and adjacent surfaces. Shading of the collector by other surfaces, such as nearby buildings or trees, is also taken into account.

4.1.5 Local Wind Speed Calculations

The outdoor wind speed affects terms used in modeling. The wind speed in the weather file is assumed to be measured at a meteorological station located in an open field at a height of 10 m. To adjust for different terrain at the building site and differences in the height of building surfaces, the local wind speed is calculated for each surface.

The wind speed is modified from the measured meteorological wind speed by the equation (ASHRAE 2001):

$$U_{\infty} = V_{met} \left(\frac{\delta_{met}}{z_{met}} \right)^{a_{met}} \left(\frac{z}{\delta} \right)^a \quad (4.7)$$

where z is the height of the centroid of the system, z_{met} is the height of the standard meteorological wind speed measurement, and a and δ are terrain-dependent coefficients. δ is the boundary layer thickness for the given terrain type. The values of a and δ are shown in the following table:

Table 4.1: Terrain-Dependent Coefficients (ASHRAE 2001).

Terrain	Description	Exponent, a	Layer Thickness, δ (m)
1	Flat, open country	0.14	270
2	Rough, wooded country	0.22	370
3	Towns and cities	0.33	460
4	Ocean	0.10	210
5	Urban, industrial, forest	0.22	370

The exterior vented cavity can be defined such that it has multiple underlying heat transfer surfaces. The centroid heights for each surface are area-weighted to determine the average height for use in the local wind calculation.

4.1.6 Convection Coefficients

Exterior cavity modeling requires calculating up to three different coefficients for surface convection heat transfer. These coefficients are defined in the classic way by:

$$h_c = \frac{T_{air} - T_{surf}}{q''_{conv}} \quad (4.8)$$

First, h_{co} is the convection coefficient for the baffle surface facing the outdoors. It is modeled in exactly the same way as elsewhere in EnergyPlus and will depend on the user setting for Outside Convection Algorithm – Outside Surface Heat Balance entry elsewhere in this document.

Second, $h_{c,cav}$ is the convection coefficient for baffle surfaces facing the cavity. This coefficient is applied to both the baffle and the underlying surface. The convection coefficient is modeled in the same way used in EnergyPlus to model air gaps in windows. These correlations vary by Rayleigh number and surface tilt and are based on the work of various research including Hollands et. al., Elsherbiny et. al., Wright, and Arnold. The formulations are documented in ISO (2003) standard 15099. The routines were adapted from Subroutine NusseltNumber in WindowManager.f90 (by F. Winkelmann), which itself was derived from Window5 subroutine “nusselt”.

4.1.7 Radiation Coefficients

Exterior vented cavity modeling requires calculating up to four different linearized coefficients for radiation heat transfer. Whereas radiation calculations usually use temperature raised to the fourth power, this greatly complicates solving heat balance equations for a single temperature. Linearized radiation coefficients have the same units and are used in the same manner as surface convection coefficients and introduce very little error for the temperature levels involved.

The radiation coefficient, $h_{r,cav}$, is used to model thermal radiation between the collector surface and the outside face of the underlying heat transfer surface. We assume a view factor of unity. It is calculated using:

$$h_{r,cav} = \sigma_{SB} e_{baff} e_{so} \frac{(T_{s,baff}^4 - T_{so}^4)}{(T_{s,baff} - T_{so})} \quad (4.9)$$

where,

all temperatures are converted to Kelvin,

σ_{SB} is the Stefan-Boltzmann constant,

e_{baff} is the longwave thermal emittance of the baffle, and

e_{so} is the longwave thermal emittance of the underlying heat transfer surface.

The three other coefficients, $h_{r,atm}$, $h_{r,sky}$, and $h_{r,gnd}$ are used elsewhere in EnergyPlus for the outside face surface heat balance and are calculated in the same manner as Equation 4.9. [This is accomplished by calling subroutine InitExteriorConvectionCoeffs in the file HeatBalanceConvectionCoeffs.f90.]

4.2 Green Roof Model (EcoRoof)

4.2.1 Overview

The input object `Material:RoofVegetation` provides a model for green roofs (aka ecoroofs or vegetated roofs) that are becoming increasingly common for both new and retrofit buildings. There is widespread recognition and a growing literature of measured data that suggest green roofs can reduce building energy consumption. Currently, however, there are few design tools available to assist developers and architects in assessing the likely magnitude of energy savings associated with various implementation options (e.g., soil type/depth, irrigation options, plant type). As a result there is a significant need for a quantitative and physically-based building energy simulation tool that represents the effects of green roof constructions. Such a tool would facilitate more rapid spread of green roof technologies and make it possible to account for green roof benefits in state energy codes and related energy efficiency standards such as LEED.

In response to the need for green roof design tools a computational model of the heat transfer processes involved on a vegetated roof has been developed. This model accounts for:

- long wave and short wave radiative exchange within the plant canopy,
- plant canopy effects on convective heat transfer,
- evapotranspiration from the soil and plants, and
- heat conduction (and storage) in the soil layer

The ability to track moisture-dependent thermal properties is not implemented yet due to stability issues in the Conduction Transfer Function (CTF) scheme. Finite difference solution scheme currently is not supported in EnergyPlus Green Roof (EcoRoof) Model.

As implemented in EnergyPlus the green roof module allows the user to specify “ecorooft” as the outer layer of a rooftop construction using a “`Material:RoofVegetation`” object. The user can then specify various aspects of the green roof construction including growing media depth, thermal properties, plant canopy density, plant height, stomatal conductance (ability to transpire moisture), and soil moisture conditions (including irrigation).

The model formulation includes the following:

- simplified moisture balance that allows precipitation, irrigation, and moisture transport between two soil layers (top and root zone).
- soil and plant canopy energy balance based on the Army Corps of Engineers’ FASST vegetation models (Frankenstein and Koenig), drawing heavily from BATS (Dickenson et al.) and SiB (Sellers et al.).
- soil surface (T_g) and foliage (T_f) temperature equations are solved simultaneously each time step, inverting the CTF to extract heat flux information for the energy balance calculation.

The detailed energy balance analysis and resulting equations, being rather complicated, are summarized here. The interested reader is referred to the FASST documentation cited herein for the complete development. The end result is a set of two simultaneous equations for temperature—one for the soil surface and the other for the foliage.

4.2.2 Green Roof Model Description

As with a traditional roof, the energy balance of a green roof is dominated by radiative forcing from the sun. This solar radiation is balanced by sensible (convection) and latent (evaporative) heat flux from soil and plant surfaces combined with conduction of heat into the soil substrate. This energy balance is illustrated in Figure 4.3. The variables introduced in this figure are defined in the equations that follow.

Figure 4.3: The Energy Balance for a Green Roof.

The energy budget analysis follows the Fast All Season Soil Strength (FASST) model developed by Frankenstein and Koenig for the US Army Corps of Engineers. FASST was developed, in part, to determine the ability of soils to support manned and unmanned vehicles and personnel movement. In order to accomplish this, however, FASST tracks the energy and moisture balance (including ice and snow) within a vegetated soil. It is a one-dimensional model that draws heavily from other plant canopy models including BATS (Dickinson et al.) and SiB (Sellers et al.). We have implemented FASST here with only a few modifications to adapt it for use with a relatively thin soil layer. The sign convention used assumes all heat fluxes are positive when energy is absorbed into the layer.

In the following discussion this energy budget is divided into a budget for the foliage layer (F_f) and a budget for the ground surface (F_g). The various parameterizations for latent and sensible heat flux are described in some detail and then the equation set is reduced to the simultaneous solution of two equations involving the temperatures of the foliage and ground surface.

4.2.2.1 Energy budget in the foliage layer

The foliage energy balance is given by:

$$F_f = \sigma_f [I_S^\downarrow(1 - \alpha_f) + \varepsilon_f I_{ir}^\downarrow - \varepsilon_f \sigma T_f^4] + \frac{\sigma_f \varepsilon_g \varepsilon_f \sigma}{\varepsilon_1} (T_g^4 - T_f^4) + H_f + L_f \quad (4.10)$$

Where σ_f is calculated as a function of Leaf-Area-Index (LAI):

$$\sigma_f = 0.9 - 0.7 \exp -0.75 LAI \quad (4.11)$$

In addition to convective and sensible heat transfer this equation accounts for both the short and longwave radiation absorbed by the vegetation, including the effects of multiple reflections. The sensible and latent heat flux terms (H_f and L_f) are somewhat complicated and therefore discussed in some detail below.

4.2.2.1.1 Sensible heat flux in the foliage layer

The sensible heat transfer between the leaf surface and near-canopy air (H_f) is influenced by the temperature difference between them, wind speed, and Leaf Area Index (LAI). The Leaf Area Index is the dimensionless ratio of the projected leaf area for a unit ground area (Oke). In contrast fractional vegetative cover (s_f) is the ratio of shaded ground surface to total ground surface area. The sensible heat flux is given by:

$$H_f = (1.1 * LAI \rho_{af} C_{p,a} C_f W_{af}) * (T_{af} - T_f) \quad (4.12)$$

In this equation the constant 1.1 accounts for heat transfer from the stems, twigs and limbs (Deardorff). The properties of air near the foliage are modeled using the average from the foliage and instrument conditions:

$$\rho_{af} = 0.5(\rho_a + \rho_f) \quad (4.13)$$

where ρ_a is the density of air at the instrument height and ρ_f is the density of air at the leaf temperature. The air temperature within the foliage is estimated by:

$$T_{af} = (1 - \sigma_f)(T_a) + \sigma_f (0.3T_a + 0.6T_f + 0.1T_g) \quad (4.14)$$

where, T_a is the air temperature at the instrument height in Kelvin T_f , is leaf temperature in Kelvin and T_g , is the ground surface temperature in Kelvin. The foliage wind speed is estimated as:

$$W_{af} = 0.83\sigma_f W \sqrt{C_{hn}^f} + (1 - \sigma_f)W \quad (4.15)$$

Here W is the larger of 2.0 m/s or the actual wind speed above the canopy (Hughes et al.) and C_{hn}^f is the transfer coefficient at near-neutral atmospheric stability conditions:

$$C_{hn}^f = K_v^2 \cdot \left(\ln \left(\frac{Z_a - Z_d}{Z_o^f} \right) \right)^{-2} \quad (4.16)$$

where K_v , is von Karmen's constant (0.4), Z_a is the instrument height, Z_d is the zero displacement height in meters (height above soil within which the wind speed is effectively zero), and Z_o^f is the

foliage roughness length scale (m). The formulations for zero displacement height, roughness length are based on Balick et al.:

$$Z_d = 0.701 Z_f^{0.979} \quad (4.17)$$

$$Z_o = 0.131 Z_f^{0.997} \quad (4.18)$$

Finally, the bulk transfer coefficient as defined by Deardorff is given by:

$$C_f = 0.01 * \left(1 + \frac{0.3(m/s)}{W_{af}(m/s)} \right) \quad (4.19)$$

4.2.2.1.2 Latent heat flux in the foliage layer

The process of water loss through plant respiration is known as transpiration. It is controlled by the closing and opening of stomata - the intercellular openings between to epidermal (guard) cells (Gates). The resistance to the diffusion of water vapor from these spaces into the atmosphere is called stomatal resistance. It depends on factors such as light intensity, soil moisture content and vapor pressure difference between inside leaf and the outside atmosphere. It is measured in units of s/m and is formulated as:

$$r_s = \frac{r_{s,min}}{LAI} \cdot f_1 \cdot f_2 \cdot f_3 \quad (4.20)$$

Here, $r_{s,min}$ is the minimum stomatal resistance. The actual stomatal resistance at any time is proportional to this minimum resistance and inversely proportional to LAI. The stomatal resistance is further modified by fractional multiplying factors that relate to incoming solar radiation and atmospheric moisture. As found in Frankenstein and Koenig the inverses of the multiplying factors f_1 , f_2 , and f_3 are given by:

$$\begin{aligned} \frac{1}{f_1} &= \min \left[1, \frac{0.004 * I_s^\downarrow + 0.005}{0.81 * (0.004 * I_s^\downarrow + 1)} \right] \\ \frac{1}{f_2} &= \begin{cases} 0 & \text{when } \theta_r > \bar{\theta} \\ \frac{\bar{\theta} - \theta_r}{\theta_{max} - \theta_r} & \text{when } \theta_r \leq \bar{\theta} \leq \theta_{max} \end{cases} \\ \frac{1}{f_3} &= \exp [-g_d(e_{f,sat} - e_a)] \end{aligned} \quad (4.21)$$

Here, Q_r , is the residual moisture content (defined as the amount of moisture in soil when plants begin to wilt), Q_{max} is the maximum moisture content (defined as the maximum amount of moisture a particular type of soil can hold and above which run off occurs), and $\bar{\theta}$ is the average soil moisture in the root zone. The residual moisture content is typically around $0.01 \text{ m}^3/\text{m}^3$ (Frankenstein and Koenig). The maximum moisture content depends upon the soil, but generally varies from 0.3 to $0.6 \text{ m}^3/\text{m}^3$ (Guymon et al.). In the expression for f_3 , g_d is a plant specific characteristic that is only non-zero for trees, $e_{f,sat}$ is the saturated vapor pressure at the leaf temperature, and e_a is the air vapor pressure.

Resistance to moisture exchange offered by the boundary layer formed on the leaf surface is known as aerodynamic resistance. It is measured in units of (s/m) and is influenced by wind speed, surface roughness and stability of the atmosphere (Oke). It is formulated as:

$$r_a = \frac{1}{c_f W_{af}} \quad (4.22)$$

The combined effect of aerodynamic and stomatal resistances to vapor diffusion is integrated into a foliage surface wetness factor:

$$r'' = \frac{r_a}{r_a + r_s} \quad (4.23)$$

This surface wetness factor is simply a ratio of the aerodynamic resistance to the total resistance. When the aerodynamic resistance is small the wetness factor approaches zero (leaf surfaces remain dry as surface moisture is readily evaporated). As the aerodynamic resistance increases in importance relative to stomatal resistance the wetness factor approaches 1.0 (moisture readily travels to the leaf surfaces, but is not easily evaporated).

The latent heat flux is then given by:

$$L_f = l_f * LAI \rho_{af} C_f W_{af} r'' (q_{af} - q_{f,sat}) \quad (4.24)$$

Here l_f , is the latent heat of vaporization (J/kg), $q_{f,sat}$ is the saturation mixing ratio at the leaf surface temperature, and q_{af} is the mixing ratio of the air within the canopy. As developed in Frankenstein and Koenig the mixing ratio within the canopy can be determined from:

$$q_{af} = \left[\frac{(1 - \sigma_f) q_a + \sigma_f (0.3 q_a + 0.6 q_{f,sat} r'' + 0.1 q_{f,sat} M_g)}{1 - \sigma_f [0.6 (1 - r'') + 0.1 (1 - M_g)]} \right] \quad (4.25)$$

where the factor M_g (ranging from 0 to 1) is the ratio of volumetric moisture content to the porosity of the soil (Koenig). The latent heat of vaporization (l_f) is the amount of energy required to convert a unit mass of water to vapor. It is measured in units of J/kg and is inversely proportional to the temperature. From Henderson-Sellers it is estimated as:

$$l_f = 1.91846 * 10^6 \left[\frac{T_f}{T_f - 33.91} \right]^2 \quad (4.26)$$

4.2.2.2 Soil Energy budget

The energy budget at the soil surface is mainly influenced by the soil thermal properties, the amount of foliage coverage (s_f) and the amount of moisture in the soil. If the soil surface is densely covered the diurnal range of surface temperature is small. In the soil energy budget the heat released or gained due to phase changes of soil water, precipitation heat flux and heat flux due to vertical transport of water in the soil are ignored. Future refinements to this model will incorporate these phenomena. The sign convention followed here is the same as above (heat flux into the soil is positive). The overall energy balance at the soil surface (as given in Frankenstein and Koenig) is:

$$F_g = (1 - \sigma_f) \left[I_s^\downarrow (1 - \alpha_g) + \varepsilon_g I_{ir}^\downarrow - \varepsilon_g T_g^4 \right] - \frac{\sigma_f \varepsilon_g \varepsilon_f \sigma}{\varepsilon_1} (T_g^4 - T_f^4) + H_g + L_g + K * \frac{\partial T_g}{\partial z} \quad (4.27)$$

As with the energy equation for the foliage this equation represents sensible heat flux (H_g), latent heat flux (L_g) and the multiple reflections associated with long and short wave radiation. The final term on the right side gives the conduction of heat into the soil substrate.

4.2.2.2.1 Sensible heat flux in the soil layer

Sensible heat flux between the soil surface and air in its vicinity is dependent on the temperature difference between them and the wind speed within the canopy. It is given as

$$H_g = \rho_{ag} C_{p,a} C_h^g W_{af} (T_{af} - T_g) \quad (4.28)$$

where C_h^g is the bulk transfer coefficient and ρ_{ag} is the density of air near the soil surface (kg/m^3) given by:

$$\rho_{ag} = \frac{\rho_a + \rho_g}{2} \quad (4.29)$$

Here ρ_g is the density of air at the ground surface temperature

The bulk transfer coefficient is given as the linear combination of bulk transfer coefficient near ground (C_{hn}^f) and near foliage-atmosphere interface (C_{hn}^g) multiplied by the stability factor (Γ_h) and is formulated as:

$$C_h^g = \Gamma_h \left[(1 - \sigma_f) C_{hn}^g + \sigma_f C_{hn}^f \right] \quad (4.30)$$

The ground and foliage bulk transfer coefficients, in turn, are given by:

$$C_{hn}^g = r_{ch}^{-1} \left[\frac{K_v}{\ln \left(\frac{Z_a}{Z_o^g} \right)} \right]^2 \quad (4.31)$$

And

$$C_{hn}^f = \left[\frac{K_v}{\ln \left(\frac{Z_a - Z_d}{Z_o^f} \right)} \right]^2 \quad (4.32)$$

where Z_o^g and Z_o^f are the ground and foliage roughness lengths, r_{ch} is turbulent Schmidt number (0.63), and K_v is the von Karman constant (0.4).

The condition of the atmosphere (Γ_h) is determined as stable or unstable based on the sign of the bulk Richardson number:

$$R_{ib} = \frac{2gZ_a(T_{af} - T_g)}{(T_{af} + T_g)W_{af}^2} \quad (4.33)$$

The atmospheric stability factor is then given by Businger and Lumley and Panofsky as:

$$\Gamma_h = \begin{cases} \frac{1.0}{(1.0 - 16.0R_{ib})^{0.5}} & \text{for } R_{ib} < 0 \\ \frac{1.0}{(1.0 - 5.0R_{ib})} & \text{for } R_{ib} > 0 \end{cases} \quad (4.34)$$

4.2.2.2.2 Latent heat flux in the soil layer

Removal of water vapor from the soil surface depends on the difference between the mixing ratio of the soil surface and air and the wind speed within the canopy. The resulting latent heat flux is then given by:

$$L_R = C_e l_g W_{af} \rho_{ag} (q_{af} - q_g) \quad (4.35)$$

Here C_e^g is the bulk transfer coefficient, l_g is the latent heat of vaporization at the ground surface temperature, q_{af} is the mixing ratio at the foliage-atmosphere interface, and q_f is the mixing ratio at the ground surface, given by:

$$q_g = M_g q_{g,sat} + (1 - M_g) q_{af} \quad (4.36)$$

The bulk transfer coefficient for latent heat exchange is analogous to that for sensible heat exchange and is given by:

$$C_e^g = \Gamma_e \left[(1 - \sigma_f) C_{en}^g + \sigma_f C_{hn}^f \right] \quad (4.37)$$

where C_{en}^g is the near ground bulk transfer coefficient for Latent heat flux and G_e is the latent heat exchange stability correction factor (assumed to be the same as G_h).

4.2.3 Linearization

In order to solve the foliage and soil heat budget equations, the 4th order terms T_f^4 and T_g^4 and mixing ratio terms $q_{g,sat}$ and $q_{f,sat}$ are linearized as given by Deardorff:

$$\left[T_f^{(n+1)} \right]^4 = \left[T_f^n \right]^4 + 4 \left[T_f^n \right]^3 \left[T_f^{n+1} - T_f^n \right] \quad (4.38)$$

$$\left[T_g^{(n+1)} \right]^4 = \left[T_g^n \right]^4 + 4 \left[T_g^n \right]^3 \left[T_g^{n+1} - T_g^n \right] \quad (4.39)$$

Here T_f^{n+1} and T_g^{n+1} are the current time step leaf and ground surface temperatures in Kelvin. T_f^n and T_g^n are the corresponding temperatures at the previous time step.

The saturation mixing ratio at the ground and leaf surface temperatures are given as:

$$q_{g,sat} (T_g^{n+1}) = q_{sat} (T_g^n) + \left(\frac{\partial q_{sat}}{\partial T} \right)_{T_g^n} * (T_g^{n+1} - T_g^n) \quad (4.40)$$

$$q_{f,sat} (T_f^{n+1}) = q_{sat} (T_f^n) + \left(\frac{\partial q_{sat}}{\partial T} \right)_{T_f^n} * (T_f^{n+1} - T_f^n) \quad (4.41)$$

where $q_{sat}(T_g^n)$ is the saturation mixing ratio at the previous time step and is formulated as given in Garratt:

$$q_{sat} (T_g^n) = \frac{0.622 e^* (T_g^n)}{P - e^* (T_g^n)} \quad (4.42)$$

Here the saturation vapor pressure e^* (Pa) is evaluated at the ground temperature from the previous time step (T_g^n) as:

$$e^* = 611.2 \exp \left[17.67 \left(\frac{T_g^n - 273.15}{T_g^n - 29.65} \right) \right] \quad (4.43)$$

The derivative of saturation mixing ratio at the previous time step is given by:

$$\frac{dq^*}{dT_g^n} = \left[\frac{0.622 * P}{(P - 0.378 * e^*)^2} \right] \left(\frac{de^*}{dT_g^n} \right) \quad (4.44)$$

Here, the derivative of the saturation vapor pressure can be calculated from the Clausius-Clapeyron equation:

$$\frac{de^*}{dT_g^n} = \frac{l_g * e^*(T_g^n)}{(R_v * (T_g^n)^2)} \quad (4.45)$$

Where R_v is the gas constant for water vapor and l_g is the latent heat of vaporization at the soil surface temperature.

The corresponding saturation mixing ratio relations for the leaf surfaces can be obtained by replacing T_g with T_f in the above relations.

4.2.4 Final Equations

After linearization the final equations are of the form:

$$C_1^f + C_2^f T_g + C_3^f T_f = 0 \quad (4.46)$$

$$C_1^g + C_2^g T_g + C_3^g T_f = 0 \quad (4.47)$$

The coefficients in these equations result from the direct combination of the equations from the above development. The interested reader is directed to the papers by Frankenstein and Koenig for the complete and somewhat complicated expressions.

This final set of equations is then solved simultaneously to obtain T_g and T_f . One key difference in our implementation of the FASST algorithm is that the conduction terms in the equations for C_1^g and C_2^g are solved by inverting the Conduction Transfer Functions (CTF) within the EnergyPlus solution scheme.

4.2.5 Green Roof Nomenclature

C_1, C_2, C_3	=	coefficients in linearized temperature equations
C_e^g	=	latent heat flux bulk transfer coefficient at ground layer
C_f	=	bulk heat transfer coefficient
C_h^g	=	sensible heat flux bulk transfer coefficient at ground layer
C_{hn}^f	=	near-neutral transfer coefficient at foliage layer
C_{hn}^g	=	near-neutral transfer coefficient at ground layer
$C_{p,a}$	=	specific heat of air at constant pressure (1005.6 J/kg k)
e^*	=	saturation vapor pressure (Pa)
f_1	=	multiplying factor for radiation effect on stomatal resistance
f_2	=	multiplying factor for moisture effect on stomatal resistance
f_3	=	additional multiplying factor for stomatal resistance
F_f	=	net heat flux to foliage layer (W/m ²)
F_g	=	net heat flux to ground surface (W/m ²)
g_d	=	plant specific characteristic related to stomatal resistance
H_f	=	foliage sensible heat flux (W/m ²)
H_g	=	ground sensible heat flux (W/m ²)
I_s^\downarrow	=	total incoming short wave radiation (W/m ²)

$I_{i\gamma}^{\downarrow}$	=	total incoming longwave radiation (W/m ²)
K_v	=	von Karmen constant (0.4)
l_f	=	latent heat of vaporization at foliage temperature (J/kg)
l_g	=	latent heat of vaporization at ground temperature (J/kg)
L_f	=	foliage latent heat flux (W/m ²)
L_g	=	ground latent heat flux (W/m ²)
LAI	=	leaf area index (m ² /m ²)
M_g	=	moisture saturation factor
q_a	=	mixing ratio for air
q_{af}	=	mixing ratio for air within foliage canopy
$q_{f,sat}$	=	saturation mixing ratio at foliage temperature
$q_{g,sat}$	=	saturation mixing ratio at ground temperature
r_a	=	aerodynamic resistance to transpiration (s/m)
r_s	=	foliage leaf stomatal resistance (s/m)
$r_{s,min}$	=	minimal leaf stomatal resistance (s/m)
r''	=	surface wetness factor
R_{ib}	=	bulk Richardson number
R_v	=	gas constant for water vapor (461.53 J/kgK)
T_a	=	the air temperature at the instrument height (Kelvin)
T_{af}	=	air temperature with in the canopy (Kelvin)
T_f	=	leaf temperature (Kelvin)
T_g	=	ground surface temperature (Kelvin)
W	=	wind speed above canopy (m/s)
W_{af}	=	wind speed with in the canopy (m/s)
z	=	height or depth (m)
Z_a	=	instrument height (m)
Z_d	=	displacement height (m)
Z_o^f	=	foliage roughness length scale (m)

4.2.5.1 Greek letters

α_f	=	albedo (short wave reflectivity) of the canopy
α_g	=	albedo (short wave reflectivity) of ground surface
ε_1	=	$\varepsilon_g + \varepsilon_f - \varepsilon_f \varepsilon_g$
ε_f	=	emissivity of canopy
ε_g	=	emissivity of the ground surface
Γ_h	=	stability factor
ρ_a	=	density of air at instrument height (kg/m ³)
ρ_f	=	density of air at foliage temperature (kg/m ³)
ρ_{af}	=	density of air at foliage temperature (kg/m ³)
ρ_{ag}	=	density of air at ground surface temperature (kg/m ³)
σ	=	the Stefan-Boltzmann constant (5.699*10 ⁸ W/m ² °K ⁴)
σ_f	=	fractional vegetation coverage

4.2.5.2 Subscripts and superscripts

a	=	air
af	=	air within the foliage layer
e	=	latent heat flux term
f	=	foliage surface
g	=	ground surface
h	=	sensible heat flux term
n	=	current time step
n+1	=	future time step
ir	=	infrared (or long-wave)
sat	=	saturation value
S	=	short-wave

4.3 Underwater Surface Boundary Condition

4.3.1 Overview

The input object `SurfaceProperty:Underwater` provides a model for applying a water boundary condition to a surface. This boundary condition captures the convective heat transfer to the free stream water. The convection may be forced if a velocity is applied to the free stream relative to the surface, or buoyant for slow or non-moving flow.

The model assumes the convective boundary layer is developed along a nearly flat plate, and that this surface is centered at a user-specified distance from the leading edge of the boundary layer. The model also assumes free stream flow beyond the boundary layer.

The model uses a standard flat plate mixed convection Reynolds number correlation to determine a local Reynolds number and therefore a local convection coefficient. Once the convection coefficient is calculated, the convection heat transfer can be imposed on the surface outside heat balance.

Chapter 5

Climate, Sky and Solar/Shading Calculations

5.1 Climate Calculations

The location of the facility under analysis is critical for the determination of energy consumption, heating/cooling loads, daylighting potential, and a host of other calculations. In EnergyPlus, both external (i.e., weather files supplied from others) and internal (i.e., solar position, design day temperature/humidity/solar profiles) data is used during simulations.

The “Site:Location” input object includes parameters (Latitude, Longitude, Elevation, Time-zone) that allow EnergyPlus to calculate the solar position (using Latitude, Longitude and Time-zone) for any day of the year as well as supply the standard barometric pressure (using elevation). Solar position modeling is discussed in more detail in both the Sky Radiance and Shading Calculation sections that directly follow this section.

Weather files have hourly or sub-hourly data for each of the critical elements needed during the calculations (i.e., Dry-Bulb Temperature, Dew-Point Temperature, Relative Humidity, Barometric Pressure, Direct Normal Radiation, Diffuse Horizontal Radiation, Total & Opaque Sky Cover, Wind Direction, Wind Speed) as well as some auxiliary data such as Rain or Snow that assist in certain calculational aspects. Weather file excerpts such as might be used in sizing calculations also have this breadth of data. The input object “SizingPeriod:DesignDay” describes design days (meant to mimic ASHRAE design conditions but in a whole day profile) using certain characteristics for the day and then EnergyPlus supplies the remaining portions to complete outdoor conditions needed for program execution. SizingPeriod:DesignDay are perhaps the best objects for sizing equipment as the ASHRAE specified design conditions can be input AND weather files may or may not have the conditions necessary to size equipment properly.

Two other objects, however, can be used at times: SizingPeriod:WeatherFileDays and SizingPeriod:WeatherFileConditionType. With the first of these, one specifies a set of weather file days similar to a RunPeriod (but will be used for the Sizing calculations). In the second, the extreme or typical conditions that are calculated for the weather file during processing can be used by name. Of course, either of these can be used as a measure of usage over small periods.

The ASHRAE Handbook of Fundamentals describes their criteria in creating design condition synopses. “Design data based on dry-bulb temperature represent peak occurrences of the sensible component of ambient outdoor conditions. Design values based on wet-bulb temperature are related to the enthalpy of the outdoor air. Conditions based on dewpoint relate to the peaks of the humidity

ratio. The designer, engineer, or other user must decide which set(s) of conditions and probability of occurrence apply to the design situation under consideration.”

5.1.1 EnergyPlus Design Day Temperature Calculations

In EnergyPlus, the typical design day input includes a “high” and a “low” dry-bulb temperature for the day. As these two temperatures are insufficient to represent a full 24 hour period, the program uses a “range multiplier” profile to represent the full day’s temperatures:

Figure 5.1: Default Daily Temperature Range Profile

The multipliers are taken from the ASHRAE 2009 HOF, Table # 6, p. 14.11.. More explicitly, EnergyPlus creates an air temperature for each timestep by using the entered maximum dry-bulb temperature in conjunction with the entered daily range and the above multiplier values. The actual equation used is shown below:

$$T_{current} = T_{Max} - T_{range} \cdot T_{Multiplier} \quad (5.1)$$

where

$T_{current}$ = Air temperature of current Hour of Day

T_{Max} = User supplied Max Dry-bulb Temperature

T_{range} = User supplied Daily Temperature Range

$T_{Multiplier}$ = Range multiplier as shown on the above graph

The range multiplier values represent typical conditions of diurnal temperatures (i.e. the low temperature for the day occurring about 5:00 AM and the maximum temperature for the day occurring about 3:00 PM. Note that EnergyPlus does not shift the profile based on the time of solar noon as is optionally allowed by ASHRAE procedures.

ASHRAE research indicates that dry-bulb and wet-bulb temperatures typically follow the same profile, so EnergyPlus can use the default daily temperature profile to generate humidity conditions based on maximum and range of wet-bulb temperature.

Since this default temperature profile may not be applicable to all locations, the user can give a different profile as part of the design day definition.

5.1.2 Sky Radiation Modeling

EnergyPlus calculates the Horizontal Infrared Radiation Intensity (IR_H), if it is missing in the weather file or for design days, from the Dry Bulb Temperature, Dewpoint Temperature or Partial Pressure of Water Vapor, and Opaque Cloud Cover as described below. Regardless of whether or not IR_H is present in the weather file, it can be specified in the **WeatherProperty:SkyTemperature** object to ignore the reported value of IR_H and instead calculate it from the specified sky emissivity model as described below.

IR_H is defined as the rate of infrared radiation emitted from the sky falling on a horizontal upward-facing surface, in W/m^2 .

$$IR_H = \sigma T_{sky}^4 \quad (5.2)$$

where:

σ = Stefan-Boltzmann constant = $5.6697 \times 10^{-8} \text{ W}/(\text{m}^2 \text{ K}^4)$

T_{sky} = Effective mean sky temperature, or sky radiative temperature, K.

Over the years authors have proposed a fictitious quantity called the Sky Emissivity (ϵ_{sky}) such that the following energy balance is satisfied:

$$IR_H = \epsilon_{sky} \cdot \sigma \cdot T_{db}^4 \quad (5.3)$$

ϵ_{sky} = sky emissivity

T_{db} = drybulb temperature, K

Four correlations for ϵ_{sky} under clear-sky conditions, proposed by four sets of authors, are available in EnergyPlus. The default correlation is from Clark & Allen (1978):

Author	$\epsilon_{sky,clear}$
Clark & Allen	$= 0.787 + 0.764 \ln (T_{dp}/273)$
Martin & Berdahl	$= 0.758 + 0.521 (T_{dp}/100) + 0.625 (T_{dp}/100)^2$
Brunt	$= 0.618 + 0.056 (P_{wv})^{0.5}$
Idso	$= 0.685 + 3.2 \times 10^{-5} (P_{wv}) e^{1699/T_{db}}$

where:

$\epsilon_{sky,clear} = \epsilon_{sky}$ under clear-sky conditions

T_{dp} = dewpoint temperature, in K for Clark & Allen, in $^{\circ}\text{C}$ for Martin & Berdahl

P_{wv} = partial pressure of water vapor, in hPa

The clear sky emissivity is modified for partially-cloudy conditions using the correlation from Walton (1983) which uses the opaque cloud cover fraction:

$$\epsilon_{sky} = \epsilon_{sky,clear} (1 + 0.0224N - 0.0035N^2 + 0.00028N^3) \quad (5.4)$$

where:

N = opaque sky cover, in tenths.

Example:

Clear sky ($N = 0$), $T_{db} = 20 + 273.15 = 293.15$ K, $T_{dp} = 10 + 273.15 = 283.15$ K

$$\epsilon_{sky} = (0.787 + 0.764 \ln(283.15/273)) (1 + 0.0224N - 0.0035N^2 + 0.00028N^3) = 0.815$$

$$IR_H = 0.8155.6697E - 8293.15^4 = 341.2 \text{ W/m}^2$$

References for these calculations are contained in the references section at the end of this list of fields. (Walton, 1983) (Clark & Allen, 1978), (Li et al, 2017).

5.1.3 EnergyPlus Sky Temperature Calculation

By default the Sky Temperature (T_{sky}) is calculated from the Horizontal Infrared Radiation Intensity (IR_H):

$$T_{sky} = (IR_H/\sigma)^{0.25} - 273.15 \quad (5.5)$$

where:

T_{sky} = Effective mean sky temperature, or sky radiative temperature, in °C.

IR_H = rate of infrared radiation emitted from the sky falling on a horizontal upward-facing surface, in W/m².

$$\sigma = \text{Stefan-Boltzmann constant} = 5.6697 \times 10^{-8} \text{ W/(m}^2 \text{ K}^4)$$

(Note: $T\{\text{°C}\} = T\{\text{K}\} - 273.15$)

The Sky Temperature can also be set by the user from several options using the **Weather-Property:SkyTemperature** object.

5.1.4 EnergyPlus Design Day Solar Radiation Calculations

Similarly, calculating solar irradiance (solar modeling) is one of the important effects to be accomplished. Several solar models exist with varying complexity.

5.1.4.1 ASHRAE Clear Sky Solar Model

The default model used is the ASHRAE Clear Sky model. The ASHRAE clear sky model described in ASHRAE HOF 2005 Chapter 31 can be used to estimate hourly clear-day solar radiation for any month of the year in U.S. or similar temperate climates in the northern hemisphere. EnergyPlus calculations extend the clear sky application to both northern and southern hemispheres. Note that the Clear Sky model has been updated in the ASHRAE HOF 2009 (see ASHRAE Revised Clear Sky Model below).

At the earth's surface on a clear day, direct normal irradiation is represented by

$$\text{Direct Normal Irradiation} = \frac{A}{\exp\left(\frac{B}{\sin \beta}\right)} \quad (5.6)$$

where

A = apparent solar irradiation at air mass $m = 0$ (Table 5.1)

B = atmospheric extinction coefficient Table 5.1)

Values of A and B vary during the year because of seasonal changes in the dust and water vapor content of the atmosphere and because of the changing earth-sun distance. Equation 5.6 does not give the maximum value of direct normal irradiation that can occur in each month but yields values that are representative of conditions on cloudless days for a relatively dry and clear atmosphere. For very clear atmospheres, direct normal irradiation can be 15% higher than indicated by Equation 5.6, using values of A and B in Table 5.1 below.

Table 5.1: Extraterrestrial Solar Irradiance and Related Data Note: Data are for 21st day of each month during the base year of 1964.

	$I_o\{\text{W/m}^2\}$	Equation of Time {minutes}	Declination {degrees}	A {W/m ² }	B {}	C {}
Jan	1416	-11.2	-20.0	1202	0.141	0.103
Feb	1401	-13.9	-10.8	1187	0.142	0.104
Mar	1381	-7.5	0.0	1164	0.149	0.109
Apr	1356	1.1	11.6	1130	0.164	0.120
May	1336	3.3	20.0	1106	0.177	0.130
Jun	1336	-1.4	23.45	1092	0.185	0.137
Jul	1336	-6.2	20.6	1093	0.186	0.138
Aug	1338	-2.4	12.3	1107	0.182	0.134
Sep	1359	7.5	0.0	1136	0.165	0.121
Oct	1380	15.4	-10.5	1166	0.152	0.111
Nov	1405	13.8	-19.8	1190	0.144	0.106
Dec	1417	1.6	-23.45	1204	0.141	0.103

For locations where clear, dry skies predominate (e.g., at high elevations) or, conversely, where hazy and humid conditions are frequent, values found by using Equation 5.6 and Table 5.1 should be multiplied by the clearness numbers in Threlkeld and Jordan (1958), reproduced as Figure 5 in Chapter 33 of the 2007 ASHRAE Handbook—HVAC Applications.

The Clear Sky model usually over estimates the amount of solar radiation available to the building.

5.1.4.2 ASHRAE Revised Clear Sky Model (“Tau Model”)

The ASHRAE 2009 HOF introduced a revised clear sky model based on location-specific optical depths for direct and diffuse radiation. These values are tabulated by month for all 5564 locations in the ASHRAE design data that accompanies the 2009 HOF.

The model requires relative air mass, m , calculated as follows:

$$m = 1 / [\sin \beta + 0.50572 \cdot (6.07995 + \beta)^{-1.6364}] \quad (5.7)$$

where β = solar altitude, degrees.

Direct and diffuse irradiance are determined with the following relationships,

$$E_b = E_o \cdot \exp [-\tau_b \cdot m^{ab}] \quad (5.8)$$

$$E_d = E_o \cdot \exp [-\tau_d \cdot m^{ad}] \quad (5.9)$$

where:

E_b = beam normal irradiance, W/m²

E_d = diffuse horizontal irradiance,

E_o = extraterrestrial normal irradiance,

m = relative air mass

τ_b and τ_d = beam and diffuse optical depths (from ASHRAE climatic design data)

ab and ad = beam and diffuse air mass exponents (see below)

Values of τ_b and τ_d are location-specific and vary during the year. They embody the dependence of clear sky solar radiation upon local conditions, such as elevation, precipitable water content, and aerosols.

The air mass exponents ab and ad were correlated to τ_b and τ_d through the following empirical relationships. If solar model indicator selected is ASHRAETau, then the τ_b and τ_d values and the empirical equations coefficients should be based on the 2009 ASHRAE HOF as shown below:

$$ab = 1.219 - 0.043 \cdot \tau_b - 0.151 \cdot \tau_d - 0.204 \cdot \tau_b \cdot \tau_d \quad (5.10)$$

$$ad = 0.202 + 0.852 \cdot \tau_b - 0.007 \cdot \tau_d - 0.357 \cdot \tau_b \cdot \tau_d \quad (5.11)$$

Else if solar model indicator selected is ASHRAETau2017, then the τ_b and τ_d values and the empirical equations coefficients should be based on the 2017 ASHRAE HOF as shown below:

$$ab = 1.454 - 0.406 \cdot \tau_b - 0.268 \cdot \tau_d + 0.021 \cdot \tau_b \cdot \tau_d \quad (5.12)$$

$$ad = 0.507 + 0.205 \cdot \tau_b - 0.080 \cdot \tau_d - 0.190 \cdot \tau_b \cdot \tau_d \quad (5.13)$$

The empirical equations coefficients of the 2017 ASHRAE HOF are also valid for the 2013 ASHRAE HOF hence the τ_b and τ_d values from the 2013 ASHRAE HOF can be used with ASHRAE-Tau2017 solar model indicator if needed.

Studies done as part of ASHRAE research projects show that the revised tau model produces more physically plausible irradiance values than does the traditional clear sky model. In particular, diffuse irradiance values are more realistic.

5.1.4.3 Zhang-Huang Solar Model

The Zhang-Huang solar model was developed for initial use in modeling typical meteorological years for China weather sites. This model seems to be good for other locations as well. Using total cloud cover, dry-bulb temperature, relative humidity, and wind speed as the independent variables, the total (global horizontal) solar radiation is estimated by:

$$I = \frac{[I_0 \cdot \sin(h) \cdot (c_0 + c_1 \cdot CC + c_2 \cdot CC^2 + c_3 (T_n - T_{n-3}) + c_4 \cdot \varphi + c_5 \cdot V_w) + d]}{k} \quad (5.14)$$

Where

I = estimated hourly solar radiation, W/m²

I_0 = global solar constant, 1355 W/m²

h = solar altitude angle, i.e, the angle between the horizontal and the line to the sun

CC = cloud cover

φ = relative humidity, %

T_n, T_{n-3} = dry-bulb temperature at hours n (current) and $n-3$, respectively

V_w = Wind speed, m/s

$c_0, c_1, c_2, c_3, c_4, c_5, d, k$ = regression coefficients

The constants were determined by analysis from measured data and are as follows:

$c_0 = .5598, c_1 = .4982, c_2 = -.6762, c_3 = .02842, c_4 = -.00317, c_5 = .014, d = -17.853, k = .843$.

This is the same model used to estimate the global solar radiation value (when it is absent from the source data) in the Weather Converter. References given in the reference section for this model include Watanabe, Urano and Hayashi(1983) and Zhang and Huang (2002).

5.1.5 Perez Direct/Diffuse Splitting Model

Splitting from global calculated (EnergyPlus) or entered values (WeatherConverter) into direct normal and diffuse horizontal components are done using the Perez direct/diffuse split. References shown in the reference section include Perez et al. (1990 and 1992).

5.1.6 Weather File Solar Interpolation

The solar values on the weather file are average values over the hour. For interpolation of hourly weather data (i.e., when the specified timestep is greater than 1), the average value is assumed to be the value at the midpoint of the hour. The reported values in the output are totals for each reporting period. So, hourly reported values will not match the original values in the weather file, but the total solar for a day should agree. A reference for this model is Ellis, Liesen and Pedersen (2003).

5.1.7 Variable Location and Orientation

EnergyPlus allows for a user to specify that the building is not static for the entire simulation. Use of the “Site:VariableLocation” object allows for specifying a scheduled building location (by latitude and longitude) and orientation. Varying the orientation transforms the vertex locations during a simulation to allow appropriate incident solar on the rotated surfaces. Varying the location adjusts the solar calculation terms to account for the changed location.

5.2 Design Week Specification

A design week (or longer) may be specified in EnergyPlus by selecting a RunPeriod of one week. One-week custom weather files may be constructed if extreme design week conditions are desired or one can use the specific dates from the EPW weather files that designate the extreme conditions on the weather file. The design week simulation requires that the simulation reach a ‘steady-periodic’ state for the one week time period. This is achieved manually by increasing the ‘number of years of simulation’ until the weekly profile does not change from one year to the next. The ‘steady-periodic’ output for the last week of the simulation represents the design week simulation results.

Using the SizingPeriod:WeatherFileDays object, one could size equipment from a longer period.

5.3 Sky Radiance Model

In EnergyPlus the calculation of diffuse solar radiation from the sky incident on an exterior surface takes into account the anisotropic radiance distribution of the sky. For this distribution, the diffuse

sky irradiance on a surface is given by:

$$AnisoSkyMultiplier_{surface} \cdot DiffuseSolarIrradiance \quad (5.15)$$

Where

Diffuse Solar Irradiance is the diffuse solar irradiance from the sky on the ground.
surface is the surface being analyzed.

AnisoSkyMultiplier is determined by surface orientation and sky radiance distribution, and accounts for the effects of shading of sky diffuse radiation by shadowing surfaces such as overhangs. It does not account for *reflection* of sky diffuse radiation from shadowing surfaces.

The sky radiance distribution is based on an empirical model based on radiance measurements of real skies, as described in Perez et al., 1990. In this model the radiance of the sky is determined by three distributions that are superimposed (see Figure 5.2)

- (1) An isotropic distribution that covers the entire sky dome;
- (2) A circumsolar brightening centered at the position of the sun;
- (3) A horizon brightening.

Figure 5.2: Schematic view of sky showing solar radiance distribution as a superposition of three components: dome with isotropic radiance, circumsolar brightening represented as a point source at the sun, and horizon brightening represented as a line source at the horizon.

The proportions of these distributions depend on the sky condition, which is characterized by two quantities, *clearness factor* and *brightness factor*, defined below, which are determined from sun position and solar quantities from the weather file.

The *circumsolar brightening* is assumed to be concentrated at a point source at the center of the sun although this region actually begins at the periphery of the solar disk and falls off in intensity with increasing angular distance from the periphery.

The *horizon brightening* is assumed to be a linear source at the horizon and to be independent of azimuth. In actuality, for clear skies, the horizon brightening is highest at the horizon and decreases in intensity away from the horizon. For overcast skies the horizon brightening has a negative value since for such skies the sky radiance increases rather than decreases away from the horizon.

Table 5.2: Variables in Anisotropic Sky Model and Shadowing of Sky Diffuse Radiation

Mathematical variable	Description	Units	C++ variable
I_{sky}	Solar irradiance on surface from sky	W/m ²	-
$I_{horizon}$	Solar irradiance on surface from sky horizon	W/m ²	-
I_{dome}	Solar irradiance on surface from sky dome	W/m ²	-
$I_{circumsolar}$	Solar irradiance on surface from circumsolar region	W/m ²	-
I_h	Diffuse horizontal solar irradiance	W/m ²	-
S	Surface tilt	radians	Surface(SurfNum)%Tilt*DegToRadians
a, b	intermediate variables	-	-
F_1, F_2	Circumsolar and horizon brightening coefficients	-	F1, F2
α	Incidence angle of sun on surface	radians	IncAng
Z	Solar zenith angle	radians	ZenithAng
Δ	Sky brightness factor	-	Delta
ε	Sky clearness factor	-	Epsilon
m	relative optical air mass	-	AirMass
I_o	Extraterrestrial solar irradiance	W/m ²	-
I	Direct normal solar irradiance	W/m ²	Material%Thickness
κ	constant = 1.041 for Z in radians	radians	-
F_{ij}	Brightening coefficient factors	-	F11R, F12R, etc.
$R_{circumsolar}$	Shadowing factor for circumsolar radiation	-	SunLitFrac
R_{dome}	Shadowing factor for sky dome radiation	-	DifShdgRatioIsoSky
$R_{horizon}$	Shadowing factor for horizon radiation	-	DifShdgRatioHoriz
E	Sky radiance	W/m ²	-

Table 5.2: Variables in Anisotropic Sky Model and Shadowing of Sky Diffuse Radiation

Mathematical variable	Description	Units	C++ variable
θ	Azimuth angle of point in sky	radians	Theta
φ	Altitude angle of point in sky	radians	Phi
I_i	Irradiance on surface from a horizon element	W/m ²	-

I'	Sky solar irradiance on surface with shadowing	W/m ²	-

5.3.1 Sky Diffuse Solar Radiation on a Tilted Surface

The following calculations are done in subroutine AnisoSkyViewFactors in the SolarShading module.

In the absence of shadowing, the sky formulation described above gives the following expression for sky diffuse irradiance, I_{sky} , on a tilted surface:

$$I_{sky} = I_{horizon} + I_{dome} + I_{circumsolar} \quad (5.16)$$

where

$$\begin{aligned}
 I_{horizon} &= \text{irradiance on surface from sky horizon} &= I_h F_2 \sin S \\
 I_{dome} &= \text{irradiance on surface from sky dome} &= I_h (1 - F_1)(1 + \cos S)/2 \\
 I_{circumsolar} &= \text{irradiance on surface from circumsolar region} &= I_h F_1 a/b
 \end{aligned} \quad (5.17)$$

AnisoSkyMult is then $I_{sky}/\text{DifSolarRad}$.

In the above equations:

$I_{horizon}$ = horizontal solar irradiance (W/m²)

S = surface tilt (radians)

$a = \max(0, \cos \alpha)$

$b = \max(0.087, \cos Z)$

F_1 = circumsolar brightening coefficient

F_2 = horizon brightening coefficient

where

α = incidence angle of sun on the surface (radians)

Z = solar zenith angle (radians).

The brightening coefficients are a function of sky conditions; they are given by:

$$\begin{aligned} F_1 &= F_{11}(\varepsilon) + F_{12}(\varepsilon)\Delta + F_{13}(\varepsilon)Z \\ F_2 &= F_{21}(\varepsilon) + F_{22}(\varepsilon)\Delta + F_{23}(\varepsilon)Z \end{aligned} \quad (5.18)$$

Here the sky brightness factor is:

$$\Delta = I_h m / I_o \quad (5.19)$$

where

m = relative optical air mass

I_o = extraterrestrial irradiance (taken to have an average annual value of 1353 W/m²);

and the sky *clearness factor* is

$$\varepsilon = \frac{(I_h + I)/I_h + \kappa Z^3}{1 + \kappa Z^3} \quad (5.20)$$

where

I = direct normal solar irradiance

κ = 1.041 for Z in radians

The factors F_{ij} are shown in the following table. The F_{ij} values in this table were provided by R. Perez, private communication, 5/21/99. These values have higher precision than those listed in Table 6 of Perez et al., 1990.

Table 5.3: F_{ij} Factors as a Function of Sky Clearness Range

ε Range	1.000-1.065	1.065-1.230	1.230-1.500	1.500-1.950	1.950-2.800	2.800-4.500	4.500-6.200	> 6.200

5.3.2 Shadowing of Sky Diffuse Solar Radiation

Sky diffuse solar shadowing on an exterior surface is calculated as follows in subroutine SkyDifSolarShading in the SolarShading module. The sky is assumed to be a superposition of the three Perez sky components described above.

For the horizon source the following ratio is calculated by dividing the horizon line into 24 intervals of equal length:

$$R_{horiz} = \frac{\text{Irradiance from horizon with obstructions}}{\text{Irradiance from horizon without obstructions}} = \frac{\sum_{i=1}^{24} I_i S F_i}{\sum_{i=1}^{24} I_i} \quad (5.21)$$

where I_i is the unobstructed irradiance on the surface from the i^{th} interval, SF_i is the sunlit fraction from radiation coming from the i^{th} interval, and the sums are over intervals whose center

lies in front of the surface. SF_i is calculated using the beam solar shadowing method as though the sun were located at the i^{th} horizon point. Here:

$$I_i = E(\theta_i)d\theta \cos \alpha_i \quad (5.22)$$

where

$E(\theta_i)$ = radiance of horizon band (independent of θ)

$d\theta = 2\pi/24$ = azimuthal extent of horizon interval (radians)

$\theta_i = 0^\circ, 15^\circ, \dots, 345^\circ$

α_i = incidence angle on surface of radiation from θ_i

The corresponding ratio for the isotropic sky dome is given by:

$$R_{dome} = \frac{\text{Irradiance from dome with obstructions}}{\text{Irradiance from dome without obstructions}} = \frac{\sum_{i=1}^{24} \sum_{j=1}^6 I_{ij} SF_{ij}}{\sum_{i=1}^{24} \sum_{j=1}^6 I_{ij}} \quad (5.23)$$

where (i,j) is a grid of 144 points (6 in altitude by 24 in azimuth) covering the sky dome, I_{ij} is the unobstructed irradiance on the surface from the sky element at the ij^{th} point, SF_{ij} is the sunlit fraction for radiation coming from the ij^{th} element, and the sum is over points lying in front of the surface. Here:

$$I_{ij} = E(\theta_i, \phi_j) \cos \phi_j d\theta d\phi \cos \alpha_{ij} \quad (5.24)$$

where

$E(\theta_i, \phi_j)$ = sky radiance (independent of θ and ϕ for isotropic dome)

$d\theta = 2\pi/24$ = azimuthal extent of sky element (radians)

$d\phi = (\pi/2)/6$ = altitude extent of sky element (radians)

$\theta_i = 0^\circ, 15^\circ, \dots, 345^\circ$

$\phi_j = 7.5^\circ, 22.5^\circ, \dots, 82.5^\circ$

α_j = incidence angle on surface of radiation from (θ_i, ϕ_j)

Because the circumsolar region is assumed to be concentrated at the solar disk, the circumsolar ratio is:

$$R_{circumsolar} = \frac{\text{Irradiance from circumsolar region with obstructions}}{\text{Irradiance from circumsolar without obstructions}} = SF_{sun} \quad (5.25)$$

where SF_{sun} is the beam sunlit fraction. The total sky diffuse irradiance on the surface with shadowing is then:

$$I'_{sky} = R_{horizon} I_{horizon} + R_{dome} I_{dome} + R_{circumsolar} I_{circumsolar} \quad (5.26)$$

If the Sky Diffuse Modeling Algorithm (ShadowCalculation object) is set to SimpleSkyDiffuseModeling, then $R_{horizon}$ and R_{dome} are calculated once for each surface since they are independent of sun position, or else if the Sky Diffuse Modeling Algorithm is set to DetailedSkyDiffuseModeling, then $R_{horizon}$ and R_{dome} are calculated every timestep for each surface.

With shadowing we then have:

$$\text{AnisoSkyMult} = I'_{sky} / \text{DifSolarRad}.$$

5.3.3 Shadowing of Sky Long-Wave Radiation

EnergyPlus calculates the sky long-wave radiation incident on exterior surfaces assuming that the sky long-wave radiance distribution is isotropic. If obstructions such as overhangs are present the sky long-wave incident on a surface is multiplied by the isotropic shading factor, R_{dome} , described above. The long-wave radiation from these obstructions is added to the long-wave radiation from the ground; in this calculation both obstructions and ground are assumed to be at the outside air temperature and to have an emissivity of 0.9.

5.4 Shading Module

5.4.1 Shading and Sunlit Area Calculations

When assessing heat gains in buildings due to solar radiation, it is necessary to know how much of each part of the building is shaded and how much is in direct sunlight. As an example, the figure below shows a flat roofed, L-shaped structure with a window in each of the visible sides. The sun is to the right so that walls 1 and 3 and windows a and c are completely shaded, and wall 4 and window d are completely sunlit. Wall 2 and window b are partially shaded. The sunlit area of each surface changes as the position of the sun changes during the day. The purpose of the EnergyPlus shadow algorithms is to compute these **sunlit areas**. Predecessors to the EnergyPlus shadowing concepts include the BLAST and TARP shadowing algorithms.

Figure 5.3: Overall Shadowing Scheme Depiction

5.4.2 Solar Position

Current solar position is described in terms of three direction cosines that are convenient for determining the angle of incidence of the sun's rays on a building surface. The following procedure is used to determine the direction cosines. The values of the solar declination angle, δ , and the equation of time, ε , are based on *Astronomical Algorithms*, Meeus. Solar declination is a function of local/site latitude.

The fractional year is calculated, in radians:

$$\gamma = \frac{2\pi}{366}(\text{day of year}) \quad (5.27)$$

From this fractional year, the equation of time and solar declination angle are calculated. For each time step (time value = fractional hour), the hour angle is calculated from:

$$\text{HourAngle} = (15 \cdot (12 - (\text{TimeValue} + \text{EquationOfTime})) + (\text{TimeZoneMeridian} - \text{Longitude})) \quad (5.28)$$

TimeZoneMeridian is the standard meridian for the location's time zone {GMT +/-}.

Solar HourAngle (H) gives the apparent solar time for the current time period (degrees); HourAngle is positive before noon, negative after noon. It is common astronomical practice to express the hour angle in hours, minutes and seconds of time rather than in degrees. You can convert the hour angle displayed from EnergyPlus to time by dividing by 15. (Note that 1 hour is equivalent to 15 degrees; 360° of the Earth's rotation takes place every 24 hours.) The relationship of angles in degrees to time is shown in the following table:

Table 5.4: Relationship of Angles (degrees) to Time

Unit of Angle	Equivalent time
1 radian	3.819719 hours
1 degree	4 minutes
1 arcmin	4 seconds
1 arcsec	0.066667 seconds

The Solar Altitude Angle (β) is the angle of the sun above the horizontal (degrees). The Solar Azimuth Angle (ϕ) is measured from the North (clockwise) and is expressed in degrees. This is shown more clearly in the following figure.

5.4.3 Surface Geometry

Shadow calculations first require that the building surfaces be described geometrically. Surfaces are described by the coordinates of their vertices in a three dimensional Cartesian coordinate system. This Right-hand coordinate system has the X-axis pointing east, the Y-axis pointing north, and the Z-axis pointing up (see figure below). The azimuth angle (ψ) of a surface is the angle from the north axis to the projection onto the X-Y plane of a normal to the surface (clockwise positive). The surface tilt angle (ϕ) is the angle between the Z-axis and the normal to the surface. The vertices

Figure 5.4: Solar Position Illustration

are recorded in counter-clockwise sequence (as the surface is viewed from outside its zone).

During surface entry, surfaces are checked for convex or non-convex shape. If non-convex and inappropriate (used as a receiving surface) then a severe error is produced telling the user that shadowing calculations may be inaccurate.

Similarly collinear points (or as noted below, points within 1 mm distance) are removed unless removing would make an illegal surface (less than 3 points). But degenerate collinear surfaces *should* be removed – they make the shadowing routines do extra work which takes extra time.

Collinear – points that essentially form a “line” rather than a surface shape.

Figure 5.5: EnergyPlus Coordinate System

The GlobalGeometryRules object specifies to EnergyPlus how the surface vertices will be presented in the input file. Of pertinent interest here is that the user may specify the vertices in either “relative” or “world” coordinates. Regardless of input specifications, when vertices are reported, they are reported in world coordinates, starting at the upper-left-corner (4-sided surface) and are listed counter-clockwise.

5.4.3.1 Relative Coordinate Transformation

When vertices are specified in “relative” coordinates, there can be a “building” north axis as well as a “zone” north axis. The building north axis/coordinate system is a rotation of ψ_b degrees from the global/world coordinate system. The global coordinates of zone origins are related to the building relative coordinates by:

$$X_{zo} = X_{br} \cdot \cos \psi_b - Y_{br} \cdot \sin \psi_b \quad (5.29)$$

$$Y_{zo} = Y_{br} \cdot \sin \psi_b + X_{br} \cdot \cos \psi_b \quad (5.30)$$

$$Z_{zo} = Z_{br} \quad (5.31)$$

Where

zo – represents Zone Origin

br – represents the Zone Origin as input (relative to building origin)

The zone may also be rotated ψ_z degrees relative to the building coordinates. Origins of zone surfaces are then given relative to the zone coordinate system. The global coordinates of the surface origins are calculated by:

$$X_{so} = X_{zo} + X_{zr} \cdot \cos \psi_z - Y_{zr} \cdot \sin \psi_z \quad (5.32)$$

$$Y_{so} = Y_{zo} + X_{zr} \cdot \sin \psi_z - Y_{zr} \cdot \cos \psi_z \quad (5.33)$$

$$X_{so} = X_{zo} + X_{zr} \cdot \cos \psi_z - Y_{zr} \cdot \sin \psi_z \quad (5.34)$$

A surface azimuth angle relative to the zone coordinate system (ψ_s) is converted to a global azimuth by:

$$\psi = \psi_s + \psi_z + \psi_b \quad (5.35)$$

The surface tilt angle (ϕ) is not changed by these rotations about the Z-axis.

The coordinates of the surface vertices are given in a coordinate system in the plane of the surface relative to the second vertex as shown for surfaces in Figure 5.5. The X-axis of the surface coordinate system is a horizontal line through the second vertex. The global coordinates of the surface vertices are given by:

$$X = X_{so} + X_{sr} \cdot \cos \psi - Y_{sr} \cdot \sin \psi \cdot \cos \phi \quad (5.36)$$

$$Y = Y_{so} + X_{sr} \cdot \sin \psi - Y_{sr} \cdot \cos \psi \cdot \cos \phi \quad (5.37)$$

$$Z = Z_{so} + Y_{sr} \cdot \sin \phi \quad (5.38)$$

5.4.3.2 World Coordinates to Relative Coordinates

Vertices in the global coordinate system can be transformed to the coordinate system relative to a given surface by

$$X' = X - X_{so} \quad (5.39)$$

$$Y' = Y - Y_{so} \quad (5.40)$$

$$Z' = Z - Z_{so} \quad (5.41)$$

$$X_{sr} = -X' \cdot \cos \psi + Y' \cdot \sin \psi \quad (5.42)$$

$$Y_{sr} = -X' \cdot \sin \psi \cdot \cos \phi + Y' \cdot \cos \psi \cdot \cos \phi + Z' \cdot \sin \phi \quad (5.43)$$

$$Z_{sr} = -X' \cdot \sin \psi \cdot \sin \phi + Y' \cdot \cos \psi \cdot \sin \phi + Z' \cdot \cos \phi \quad (5.44)$$

5.4.4 Shadow Projection

Using the **ShadowCalculation** object, you can set how often the shadowing calculations are performed. Calculating them every timestep (Timestep frequency option) is obviously the most accurate but is also be the most time consuming. Using a greater length of time (number of days) before calculating again can yield speedier results. For lengths of time greater than one day, the solar position values (e.g. equation of time, sun position angles) are averaged over that time period for the shadowing calculations. For dynamic shading, Timestep frequency is required to capture changes in shading transmittance.

EnergyPlus provides four methods for calculating sunlit fractions:

1. Polygon Clipping: The shadow algorithm is based on coordinate transformation methods similar to Groth and Lokmanhekim and the shadow overlap method of Walton.
2. Pixel Counting: GPU-rendering based calculations based on the method developed by Jones et al 2011.
3. Scheduled: Pre-calculated sunlit fractions are input through a schedule in the **SurfaceProperty:LocalEnvironment** object.
4. Imported: Pre-calculated sunlit fractions are input through a **Schedule:File:Shading** object.

5.4.5 Polygon Clipping

All architectural forms are represented by plane polygons. This can give good accuracy even for curved surfaces: a sphere can be approximated by the 20 nodes of an icosahedron with only 3 percent error in the shadow area cast by the sphere. Consider how a solid object, which is composed of a set of enclosing plane polygons, casts a shadow. Figure 5.6 shows a box shaped structure on a horizontal surface. The structure consists of a top (surface 1) and four vertical surfaces (2 and 3 visible to the observer and 4 and 5 not visible). The sun is positioned behind and to the right of the structure and a shadow is cast onto the horizontal surface (the ground).

Surfaces 1, 4, and 5 are in sunlight; 2 and 3 are in shade. It is possible to think of the structure's shadow as the combination of shadows cast by surfaces 1, 2, 3, 4 and 5 or by 1, 4 and 5, or by surfaces 2 and 3. This last combination of shadow casting surfaces is the simplest. In the EnergyPlus shadow algorithm every surface is considered to be one of the surfaces that enclose a solid, and only those surfaces that are not sunlit at a given hour are considered shadowing surfaces.

The expressions in Equation 5.44 are the direction cosines of the surface:

$$CW_1 = \sin \psi \cdot \cos \phi \quad (5.45)$$

$$CW_2 = \cos \psi \cdot \sin \phi \quad (5.46)$$

Figure 5.6: Basic shadowing concept structure

$$CW_3 = \cos \phi \quad (5.47)$$

The cosine of the angle of incidence of the sun's rays on the surface are given by the dot product of surface and sun direction cosines.

$$\cos \theta = CS_1 \cdot CW_1 + CS_2 \cdot CW_2 + CS_3 \cdot CW_3 \quad (5.48)$$

If $\cos \theta$ is less than zero, the sun is behind the surface.

A shadow is projected from the vertices of the shadowing polygon (SP) along the direction of the sun's rays to the plane of the shadow receiving polygon (RP). If any vertices of the SP are below the plane of the RP ($z < 0$), a false shadow is cast as in Figure 5.7. The "submerged" portion of the SP must be clipped off before projection.

Figure 5.7: Illustration of Shadow Clipping

This is done by finding, through linear interpolation, the points on the perimeter of the SP, which intersect the plane of the RP. These points become new vertices of the SP, which together with the other positive vertices define a clipped SP that casts only a real shadow.

A vertex located at (x, y, z) relative to the RP coordinate system casts a shadow to a point in the plane of the RP given by

$$x' = x - \frac{z \cdot a}{\cos \theta} \quad (5.49)$$

$$y' = y - \frac{z \cdot b}{\cos \theta} \quad (5.50)$$

where

$$a = \sin \psi \cdot CS_1 - \cos \psi \cdot CS_2 \quad (5.51)$$

and

$$b = -\cos \psi \cdot \cos \phi \cdot CS_1 - \sin \psi \cdot \cos \phi \cdot CS_2 + \sin \phi \cdot CS_3 \quad (5.52)$$

More explicitly, a casting surface – a shadow casting surface or general casting surface – is one that casts a shadow on other surfaces. A receiving surface – a shadow receiving surface – is one that receives shadows from other surfaces (i.e. casting surfaces). A back surface – an inside surface – is one that may be partially sunlit/receive solar transmission for interior solar distribution.

Note that the resolution on surfaces/shadowing is 1 mm – using resolution beyond that will result in truncation of the shadowing.

5.4.5.1 Homogeneous Coordinates

Two-dimensional homogeneous coordinate techniques are used to determine the vertices of shadow overlaps. In homogeneous coordinates, points and lines are represented by a single form that allows simple vector operations between those forms [Newman-Sproul]. A point (X, Y) is represented by a three element vector (x, y, w) where $x = w \cdot X$, $y = w \cdot Y$, and w is any real number except zero. A line is also represented by a three element vector (a, b, c). The directed line (a, b, c) from point (x₁, y₁, w₁) to point (x₂, y₂, w₂) is given by:

$$(a, b, c) = (x_1, y_1, z_1) \otimes (x_2, y_2, z_2) \quad (5.53)$$

The sequence in the cross product is a convention to determine sign. The condition that a point (x, y, w) lie on a line (a, b, c) is that

$$(a, b, c) \bullet (x, y, w) = 0 \quad (5.54)$$

The point is normalized by dividing by w. Then if

$$(a, b, c) \bullet (x/w, y/w, 1) > 0 \quad (5.55)$$

the point is to the left of the line. If it is less than zero, the point is to the right of the line. The intercept (x, y, w) of line (a₁, b₁, c₁) and line (a₂, b₂, c₂) is given by:

$$(x, y, w) = (a_1, b_1, c_1) \otimes (a_2, b_2, c_2) \quad (5.56)$$

Note that the use of homogeneous coordinates as outlined above provides a consistent method and notation for defining points and lines, for determining intercepts, and for determining whether a point lies to the left, to the right, or on a line. Normalization provides the means for transforming to and from homogeneous notation and Cartesian coordinates. Thus, if (X, Y) is a Cartesian coordinate pair, its homogeneous coordinates are (X, Y, 1). Similarly, the homogeneous coordinates (x, y, w) can be transformed to the Cartesian point with coordinates (x/w, y/w).

5.4.5.2 Polygon Clipping Algorithms

Three methods for polygon clipping (treating of overlapping shadows) are currently in use in EnergyPlus.

- Convex Weiler-Atherton
- Sutherland-Hodgman
- Slater-Barsky (for rectangular surfaces only)

The original EnergyPlus method for polygon clipping is a special version of the Weiler-Atherton model (Weiler, Atherton, 1977). It was developed to be sufficiently general to clip concave polygons with holes. The implementation in the current version of EnergyPlus, however, does not support concave shadowing surfaces or holes. The relative computational complexity is preserved – the algorithm is carried out in four steps. For example, if A and B are polygons (see Figure 5.8).

- 1) A call to INCLOS determines which vertices of X lie within Y.
- 2) A second call determines which vertices of Y lie within X.
- 3) If neither polygon is contained completely within the other, INTCPT is called to collect points of intersection between X and Y.
- 4) Since the points are usually gathered out of order, they must then be oriented.

The Sutherland-Hodgman algorithm (Sutherland, Hodgman, 1974) is less complex compared to the Weiler-Atherton method and is well-suited to clipping convex polygons. In actuality, only convex shading surfaces are currently supported by EnergyPlus. Let X be a polygon called the “subject polygon” (SP) and Y be a polygon called the “clipping polygon” (CP). The method performs the computation by iterating over the edges of the CP and removing points from the SP that fall in the clipping plane, i.e. points that fall to the left of the edge of the CP. Intersections between the clip edge and the edges of the SP are added appropriately, and points falling outside of the clipping plane, i.e. to the right of the edge of the CP, are added the output polygon as well. This resultant polygon is stored and the process is repeated for the rest of the clip edges in CP. The process is analogous to cutting off pieces of the SP one-by-one with respect to each edge of the CP. The result is ordered and identical to the polygon produced by the Weiler-Atherton method.

The Slater-Barsky algorithm (Slater, M., Barsky, B.A., 1994) can also be chosen for clipping surfaces which are rectangular. The algorithm further saves computational cost. It relies on converting the line segment to be clipped into a parametric equation. Below is the general form for the x- and y- components of a parametric line:

$$x = x_0 + t\Delta x \quad (5.57)$$

$$y = y_0 + t\Delta y \quad (5.58)$$

Letting our subject line be starting at (x_0, y_0) and ending at (x_1, y_1) :

$$\Delta x = x_1 - x_0 \quad (5.59)$$

$$\Delta y = y_1 - y_0 \quad (5.60)$$

Distances from the endpoints to the edges of the clipping rectangle that collide with the line are used to obtain two values of t that parameterize the equation, representing the pair of new endpoints.

Once we have the two values of t , t_1 and t_2 , we can calculate the clipped line endpoints (Note that $t_2 > t_1$).

$$x'_1 = x_0 + t_1 \Delta x \quad (5.61)$$

$$y'_1 = y_0 + t_1 \Delta y \quad (5.62)$$

$$x'_2 = x_0 + t_2 \Delta x \quad (5.63)$$

$$y'_2 = y_0 + t_2 \Delta y \quad (5.64)$$

The Slater-Barsky algorithm uses space subdivision to reduce the number of pre-emptive calculations. We break the plane into 9 parts, where region (4) is the clipping region.

6	7	8
3	4	5
0	1	2

With this method, calculating deltas and plugging in the final parametric equations can be skipped if the subject line obeys certain conditions. For example, if the line begins in region (0) and ends in region (6), then no new endpoints need to be calculated.

5.4.5.3 Overlapping Shadows

After transforming the shadows onto the plane of the receiving surface, the basic job of the shadow algorithm is to determine the area of the overlap between the polygons representing the shadows and the polygon representing the receiving surface. Concave surfaces are supported only for exterior wall heat transfer surfaces, when using SutherlandHodgman option. Concave shading devices are not supported by the this option. Neither concave shading devices nor concave exterior wall heat transfer surfaces are supported by the ConvexWeilerAtherton clipping routine.

When only convex shading devices are considered, this provides a great simplification. The overlap between two convex polygons (i.e. projections of shading devices via the direction of the sun) is another convex polygon. Coordinate and projection transformations of a convex polygon produce another convex polygon. Any non-convex polygon can be constructed as the union of convex ones.

For ConvexWeilerAtherton, there is considerable simplification if only convex (no interior angle $> 180^\circ$) polygons are considered. The overlap between two convex polygons is another convex polygon. Coordinate and projection transformations of a convex polygon produce another convex polygon. Any non-convex polygon can be constructed as a sum of convex ones.

The vertices that define the overlap between two convex polygons, A and B, consist of:

- the vertices of A enclosed by B
- the vertices of B enclosed by A
- and the intercepts of the sides of A with the sides of B

In Figure 5.8, point a is the result of rule 1, point c is the result of rule 2, and points b and d result from rule 3. The overlap of A and B is the polygon a-b-c-d. Figure 5.9 shows an overlap where all of the vertices of B are enclosed by A. Figure 5.10 shows an overlap defined only by the intercepts of A and B. Figure 5.11 shows a more complex overlap.

Figure 5.8: Point a – Vertex of A Enclosed by B

Coordinate transformation retains the order of the vertices of a polygon, while a projection reverses the order. The sequence of vertices of the receiving polygons should be reversed so it and all shadow polygons will have the same sequence.

A point is enclosed by a clockwise, convex polygon if the point lies to the right of all sides (or does not lie to the left of any side) of the polygon. The intercept of two sides may not lie beyond the ends of either side. These are “line segments” rather than “lines”. It is possible to tell if line segments A and B intercept within their end points by noting that the ends of A must lie on both sides of B, and the ends of B must lie on both sides of A. This should be done before the intercept is calculated.

Once the vertices are determined, they must be sorted into clockwise order for the area to be computed. Given a closed, planar polygon of n sequential vertices $(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)$, its **area** is given:

$$Area = \frac{1}{2} \sum_{i=1}^n (x_i y_{i+1} - x_{i+1} y_i) \quad (5.65)$$

where $(x_{n+1}, y_{n+1}) = (x_1, y_1)$

Figure 5.9: Surface A Totally Overlaps Surface B.

Figure 5.10: Figure Formed from Intercept Overlaps Between A and B

The area is positive if the vertices are counter-clockwise and negative if they are clockwise.

Figure 5.11: Complex Overlapping Condition

If two shadows overlap the receiving surface, they may also overlap each other as in Figure 5.12. The vertices of this overlap can be computed. The areas of all overlaps can be computed. The total sunlit area can be expressed as the sum of all polygon areas given a proper sign on each of the areas.

The following convention was adopted:

Table 5.5: Surface / Area Characteristic / Convention

Surface Characteristic	Area Convention
receiving surface	positive (A)
overlap between shadow and receiving	negative (B & C)
overlap between two shadows	positive (D)

and so on through multiple overlaps where the sign of the overlap area is the product of the signs of the overlapping areas.

Partially transparent shadowing surfaces can also be modeled by giving a transparency (τ) to every shadowing polygon. Let τ of the receiving polygon be one. Then the τ of every overlap of polygons i and j is the product of τ_i and τ_j . The shaded area is then computed by summing $A_i \cdot (1 - \tau_i)$ for all overlap polygons.

It is easy to determine the sunlit area of a window once all the shadow and overlap vertices

Figure 5.12: Multiple Shadow Overlaps

on the wall have been computed. Consider wall 2 of Figure 5.3. First, the wall is considered a simple rectangle and the window on it is ignored. The shadow overlapping is performed and the sunlit portion of the gross wall area is computed. Then the window rectangle is overlapped with the shadow to determine its sunlit area. The sunlit area of the window is subtracted from the gross wall sunlit area to determine the net wall sunlit area. During this calculation it is not necessary to recompute the shadows, because they were precisely determined on the wall.

When the SutherlandHodgman option is selected, the overlap is computed using the Sutherland-Hodgman algorithm for polygon clipping when. Let X be a polygon called the “subject polygon” (SP) and Y be a polygon called the “clipping polygon” (CP). The method performs the computation by iterating over the edges of the CP and removing points from the SP that fall in the clipping plane, i.e. points that fall to the left of the edge of the CP. If it is to the left of any edge, it the point does not overlap with the CP. Intersections between the clip edge and the edges of the SP are added appropriately, and points falling outside of the clipping plane, i.e. to the right of the edge of the CP, are added the output polygon as well. This resultant polygon is stored and the process is repeated for the rest of the clip edges in CP. The process is analogous to cutting off pieces of the SP one-by-one with respect to each edge of the CP. Note that the SP may be concave, but the CP may not. This means that the exterior wall surfaces may be concave, while shading devices may not be concave.

5.4.6 Pixel Counting

Determination of surface shading is a common task performed by modern graphics processors. Digital graphic rendering generates a depth map for each pixel in a scene to determine the portion of each polygon that is visible within a single view of the scene. When a scene is rendered from the perspective of the sun along the direction of its beams, visible pixels represent the sunlit portions of a surface. This is the same technique used to determine and render shadows within video games and other graphics applications. The application of this technique was originally applied to building energy simulation by Jones et al (2011). They refer to the method as “Pixel Counting” because the number of pixels of a given surface is a proxy for the sunlit area of that surface:

$$A_s \approx \frac{N \cdot A_p}{\cos \theta} = \frac{PSSA}{\cos \theta} \quad (5.66)$$

Where, A_s = Sunlit area, N = Number of visible pixels, A_p = the projected area of a single pixel, θ = solar incidence angle of the surface, and $PSSA$ = Projected Sunlit Surface Area. The approximation is limited by the resolution of the rendering.

For more information on the Pixel Counting method, refer to Jones et al 2011.

5.4.7 Solar Gains

The total solar gain on any exterior surface is a combination of the absorption of direct and diffuse solar radiation given by

$$Q_{so} = \alpha \cdot \left(I_b \cdot \cos \theta \cdot \frac{S_s}{S} + I_s \cdot F_{ss} + I_g \cdot F_{sg} \right) \quad (5.67)$$

where

α = solar absorptance of the surface

A = angle of incidence of the sun's rays

S = area of the surface

S_s = sunlit area

I_b = intensity of beam (direct) radiation

I_s = intensity of sky diffuse radiation

I_g = intensity of ground reflected diffuse radiation

F_{ss} = angle factor between the surface and the sky

F_{sg} = angle factor between the surface and the ground

For the surface of a building located on a featureless plain

$$F_{ss} = \frac{1 + \cos \phi}{2} \quad (5.68)$$

and

$$F_{sg} = \frac{1 - \cos \phi}{2} \quad (5.69)$$

If the surface is shaded the program modifies F_{ss} by a correction factor that takes into account the radiance distribution of the sky (see “Shadowing of Sky Diffuse Solar Radiation”).

Shading of ground diffuse solar radiation is not calculated by the program. It is up to the user to estimate the effect of this shading and modify the input value of F_{sg} accordingly.

5.4.8 Solar Distribution

As discussed in the Input Output Reference (Object: Building), the field Solar Distribution, in the “Building” input object, determines how EnergyPlus will treat beam solar radiation entering a zone through exterior windows. There are five choices: **MinimalShadowing**, **FullExterior**, **FullInteriorAndExterior**, **FullExteriorWithReflections**, and **FullInteriorAndExteriorWithReflections**.

5.4.8.1 MinimalShadowing

In this case, there is no exterior shadowing except from window and door reveals. All beam solar radiation entering the zone is assumed to fall on the floor, where it is absorbed according to the floor's solar absorptance. Any reflected by the floor is added to the transmitted diffuse radiation, which is assumed to be uniformly distributed on all interior surfaces. If no floor is present in the zone, the incident beam solar radiation is absorbed on all interior surfaces according to their absorptances. The zone heat balance is then applied at each surface and on the zone's air with the absorbed radiation being treated as a flux on the surface.

5.4.8.2 FullExterior

In this case, shadow patterns on exterior surfaces caused by detached shading, wings, overhangs, and exterior surfaces of all zones are computed. As for MinimalShadowing, shadowing by window and door reveals is also calculated. Beam solar radiation entering the zone is treated as for MinimalShadowing.

5.4.8.3 FullExteriorWithReflections

This case is the same interior distribution as the preceding option but uses exterior reflections as well (see the section Solar Radiation Reflected from Exterior Surfaces for further explanation).

5.4.8.4 FullInteriorAndExterior

This is the same as FullExterior except that instead of assuming all transmitted beam solar falls on the floor the program calculates the amount of beam radiation falling on each surface in the zone, including floor, walls and windows, by projecting the sun's rays through the exterior windows, taking into account the effect of exterior shadowing surfaces and window shading devices.

If this option is used, you should be sure that the surfaces of the zone totally enclose a space. This can be determined by viewing the **eplusout.dxf** file with a program like AutoDesk's Volo View Express. You should also be sure that the zone is **convex**. Examples of convex and non-convex zones are shown in Figure 5.13. The most common non-convex zone is an L-shaped zone. (A formal definition of convex is that any straight line passing through the zone intercepts at most two surfaces.) If the zone's surfaces do not enclose a space or if the zone is not convex you should use Solar Distribution = **FullExterior** instead of **FullInteriorAndExterior**.

If you use **FullInteriorAndExterior** the program will calculate how much beam radiation falling on an interior window is absorbed by the window, how much is reflected back into the zone, and how much is transmitted into the adjacent zone. (Interior windows are assumed to have no shading device).

If you use **FullInteriorAndExterior** the program will also calculate how much beam radiation falling on the inside of an exterior window (from other windows in the zone) is absorbed by the window, how much is reflected back into the zone, and how much is transmitted to the outside. In this calculation the effect of an interior or exterior shading device, if present, is accounted for.

5.4.8.5 FullInteriorAndExteriorWithReflections

This case is the same interior distribution as the preceding option but uses exterior reflections as well (see Solar Radiation Reflected from Exterior Surfaces for further explanation).

5.4.9 Details of the Interior Solar Distribution Calculation

EnergyPlus calculates the distribution of short-wave radiation in the interior of each thermal zone. This radiation consists of beam solar radiation, diffuse solar radiation, and short-wave radiation from electric lights. The program determines the amount of this radiation that is (1) absorbed on the inside face of opaque surfaces, (2) absorbed in the glass and shading device layers of the zone's exterior and interior windows, (3) transmitted through the zone's interior windows to adjacent zones, and (4) transmitted back out of the exterior windows. The effects of movable shading devices on the exterior windows are taken into account; *the program does not allow shading devices on interior windows*. Most of this calculation is done in subroutine CalcInteriorSolarDistribution in the SolarShading module. EnergyPlus will use either Polygon Clipping or Pixel Counting—depending on the method of shading algorithm selected by the user—to determine interior solar distribution if full interior solar distribution is requested.

Figure 5.13: Illustration of Convex and Non-convex Zones

5.4.9.1 Initial Distribution of Diffuse Solar Transmitted through Exterior and Interior Windows

Diffuse solar (from sky and ground sources) transmitted through exterior windows is first distributed to the interior heat transfer surfaces in the zone containing the exterior windows. This initial distribution apportions the transmitted diffuse solar to interior surfaces using the approximate view factors described above in “LW Radiation Exchange Among Zone Surfaces.” The amount of this initially distributed diffuse solar absorbed by each interior surface, and each window material layer, is calculated and later added to the “short-wave radiation absorbed” values described below. The amount of this initially distributed diffuse solar that is reflected is accumulated for each zone and redistributed uniformly as part of the QD calculation described below. The amount of this initially distributed diffuse solar that is transmitted by interior windows to adjacent zones is initially distributed to the interior heat transfer surfaces in the adjacent zone in the same manner as just described.

This new treatment of diffuse solar is intended to more accurately account for the initial absorption, transmittance, and reflection of short-wave radiation prior to the uniform distribution described below.

5.4.9.2 Interior Solar Radiation Absorbed by Opaque Surfaces

The short-wave radiation absorbed on the inside face of an opaque surface (floor, wall or ceiling) is given by:

$$\begin{aligned} SurfOpqQRadSWInAbs(SurfNum) = & QS(ZoneNum) * AbsIntSurf(SurfNum) \\ & + AISurf(SurfNum) * BeamSolarRad[W/m^2] \end{aligned} \quad (5.70)$$

where

$SurfNum$ = surface number

$ZoneNum$ = number of zone that surface belongs to

$QS(ZoneNum)$ = short-wave diffuse irradiance in the zone [W/m²]

$AbsIntSurf(SurfNum)$ = inside solar absorptance of the surface

$AI_{Surf}(SurfNum)$ = inside beam solar irradiance factor for the surface [-]

$BeamSolarRad$ = outside beam normal solar irradiance [W/m²]

5.4.9.2.1 Interior Diffuse Radiation

QS is assumed to be uniformly distributed throughout the zone. It is calculated as follows. Let Q_{sw} be the total diffuse short-wave radiation entering the zone or originating in the zone. Since Q_{sw} is ultimately absorbed or transmitted by zone heat transfer surfaces, summing over these surfaces gives the following energy balance equation:

$$\sum_{i=1}^{N_{surf}} QS(ZoneNum) * \alpha_i A_i = Q_{sw}(ZoneNum) \quad (5.71)$$

where

i = zone surface number counter

N_{surf} = number of heat transfer surfaces in zone

A_i = surface area [m²]

α_i = inside solar absorptance for an opaque surface, or, for a window, α_i = back diffuse transmittance plus back diffuse system absorptance of glass layers and shading device layers (if present)

Solving this equation for QS gives:

$$QS(ZoneNum) = \frac{Q_{sw}(ZoneNum)}{\sum_{i=1}^{N_{surf}} AbsIntSurf_i A_i} = Q_{sw}(ZoneNum) * VMULT(ZoneNum) \quad (5.72)$$

where

$$VMULT(ZoneNum) = \frac{1}{\sum_{i=1}^{N_{surf}} AbsIntSurf_i * A_i} [\text{m}^{-2}] \quad (5.73)$$

and Q_{sw} is given by:

$$Q_{sw} = QD(ZoneNum) + ZoneIntGain(ZoneNum)\%QLTSW + ZoneIntGain(ZoneNum)\%T_QLTSW [W] \quad (5.74)$$

where

$ZoneIntGain(ZoneNum)\%QLTSW$ = short-wave radiation into zone from general (overhead) electric lighting [W]

$ZoneIntGain(ZoneNum)\%T_QLTSW$ = short-wave radiation into zone from task electric lighting [W]

$QD(ZoneNum)$ = diffuse solar radiation entering or originating in zone [W]

$QD(ZoneNum)$ is given by:

$$QD(ZoneNum) = EnclSolDB(ZoneNum) * BeamSolarRad + InitialDifSolDistReflectedW(ZoneNum) \quad (5.75)$$

where

BeamSolarRad is the outside beam normal solar irradiance [W/m²]

EnclSolDB(ZoneNum) is the diffuse solar radiation originating from beam solar that passes through the exterior windows in the zone and reflects diffusely from inside zone surfaces plus beam solar entering the zone as diffuse radiation from windows with shading devices or diffusing glass (all divided by *BeamSolarRad*) [m²]

InitialDifSolDistReflectedW(ZoneNum) is the diffuse solar radiation originating from sky and sun related diffuse solar transmitted through the zone's exterior or interior windows into the zone, and reflected diffusely from inside zone surfaces.

EnclSolDB(ZoneNum) is calculated as:

$$EnclSolDB(ZoneNum) = BTOTZone - BABSZone[m^2] \quad (5.76)$$

where

BTOTZone = total beam solar incident on the zone's exterior windows that is transmitted as beam or diffuse.¹

BABSZone = total beam solar absorbed inside the zone.

BTOTZone is given by:

$$\begin{aligned} BTOTZone = & \sum_{i=1}^{N_{extwin}} TBmAll_i * SunlitFract_i * CosInc_i * Area_i * InOutprojSLFracMult_i \\ & + Diffuse\ entering\ zone\ from\ beam\ reflected\ by\ window\ inside\ reveal\ surfaces \\ & + Diffuse\ transmitted\ by\ windows\ from\ beam\ reflected\ by\ outside\ reveal\ surfaces \\ & - Beam\ absorbed\ by\ window\ inside\ reveal\ surfaces \end{aligned} \quad (5.77)$$

For more information on the diffuse entering the zone from beam reflected, see “Beam Solar Reflection from Window Reveal Surfaces.” In the above equation,

TBmAll = beam-to-beam plus beam-to-diffuse transmittance of window

SunlitFract = fraction of window irradiated by sun

CosInc = cosine of solar incidence angle on window

Area = glazed area of window [m²]

InOutProjSLFracMult = shadowing factor due to inside and outside projections of window frame and/or divider (= 1.0 if there is no frame or divider).

BABSZone is given by the following sum (see Figure 5.14):

¹For beam incident on an exterior window we have the following: For transparent glass with no shade or blind there is only beam-to-beam transmission. For diffusing glass, or if a window shade is in place, there is only beam-to-diffuse transmission. If a window blind is in place there is beam-to-diffuse transmission, and, depending on slat angle, solar profile angle, etc., there can also be beam-to-beam transmission.

$$\begin{aligned}
 BABSZone = & \text{Beam absorbed by opaque inside surfaces}^2 \\
 & + \text{Beam transmitted through the zone's interior windows} \\
 & + \text{Beam transmitted back out of the zone's exterior windows} \\
 & + \text{Beam absorbed by the zone's exterior and interior windows} \\
 & + \text{Beam absorbed by inside daylighting shelves}
 \end{aligned} \tag{5.78}$$

Figure 5.14: Vertical section through a two-zone building showing where transmitted beam solar falls. Some of the beam solar from exterior window EW is absorbed by the floor, D, interior wall, B, and interior window, IW. Some is transmitted by IW to the adjacent zone, Z2. Aoverlap is the irradiated area of a surface projected back onto the plane of EW. Beam reflected by D, B and IW contributes to the interior short-wave radiation flux in Z1.

If zone $ZoneNum$ shares interior windows with other zones, $QS(ZoneNum)$ is modified to take into account short-wave radiation received from the other zones through these windows:

$$\begin{aligned}
 QS(ZoneNum) \rightarrow & QS(ZoneNum) \\
 & + \sum_{otherZones} ZoneFractDifShortZtoZ(OtherZoneNum, ZoneNum) \\
 & * [QD(OtherZoneNum) + ZoneIntGain(OtherZoneNum)\%QLTSW \\
 & + ZoneIntGain(OtherZoneNum)\%T_QLTSW]
 \end{aligned} \tag{5.79}$$

where

$ZoneFractDifShortZtoZ(OtherZoneNum, ZoneNum)$ = “diffuse solar exchange factor” = fraction of short-wave radiation in $OtherZoneNum$ that is transmitted to $ZoneNum$. This factor is calculated in subroutine `ComputeDifSolExcZonesWIZWindows` taking into account multiple reflection between zones. For example, for two zones means that some of the radiation transmitted from Zone1 to Zone2 is reflected back to Zone1, and some of this is in turn reflected back to Zone2, etc.

5.4.9.2.2 Interior Beam Radiation

The inside beam solar irradiance factor³ in Equation 5.70 is given by:

$$AISurf(SurfNum) = \frac{AbsIntSurf(SurfNum)}{A(SurfNum)} \sum_{i=1}^{N_{extwin}} TBm_i * Aoverlap_i(SurfNum) * CosInc_i \quad (5.80)$$

where

i = exterior window number

N_{extwin} = number of exterior windows in zone

$CosInc_i$ = cosine of angle of incidence of beam on exterior window i

TBm_i = beam-to-beam transmittance of exterior window i at $CosInc_i$ ⁴

$Aoverlap_i(SurfNum)$ = beam solar irradiated area of surface $SurfNum$ projected back onto the plane of exterior window i (the $Aoverlap$'s for an exterior window sum up to the glazed area of the window). These overlap areas (Figure 5.14) are determined with the EnergyPlus shadowing routines by considering a zone's exterior window as a "sending" surface and the inside faces of the zone's other surfaces as "receiving" surfaces (see "Shading Module"). The overlap areas for a particular exterior window depend on the sun position, the geometry of the window, the geometry of the interior surfaces, and the location of the window with respect to the interior surfaces.

$AbsIntSurf(SurfNum)$ = inside face solar absorptance of surface $SurfNum$

$A(SurfNum)$ = area of surface $SurfNum$ [m²]

5.4.9.3 Interior Solar Radiation Absorbed by Windows

The interior short-wave radiation absorbed by layer l (glass, shade or blind) of a window is equal to:

$$QS(ZoneNum) * \alpha_{l,back}^{dif}(SurfNum) + BeamSolarRad * \frac{\alpha_{l,back}^{beam}(SurfNum)}{A(SurfNum)} \sum_{i=1}^{N_{extwin}} TBm_i * Aoverlap_i(SurfNum) * CosInc_i [W/m^2] \quad (5.81)$$

where

$\alpha_{l,back}^{dif}$ = the system diffuse solar absorptance of layer l for irradiance from the back side

$\alpha_{l,back}^{beam}$ = the system beam solar absorptance of layer l for irradiance from the back side

$A(SurfNum)$ = glazing area [m²]

Note that as of Version 2.1, the initially distributed diffuse solar absorbed by each surface (as described above under "Initial Distribution of Diffuse Solar Transmitted through Exterior and Interior Windows") is added to this uniformly distributed short-wave radiation.

³For the purposes of the surface heat balance calculation, any beam solar radiation absorbed by a surface is assumed to be uniformly distributed over the surface even though in reality it is likely to be concentrated in one or more discrete patches on the surface.

⁴ TBm_i is zero if the window has diffusing glass or a shade. TBm_i can be > 0 if a blind is present and the slat angle, solar profile angle, etc., are such that some beam passes between the slats.

5.4.9.4 Interior Solar Radiation Transmitted by Interior Windows

5.4.9.4.1 Interior Diffuse Radiation Transmitted by Interior Windows

The interior diffuse short-wave radiation transmitted by an interior window to the adjacent zone is given by

$$QS(ZoneNum) * \tau^{dif}(SurfNum) * A(SurfNum)[W] \quad (5.82)$$

where

$\tau^{dif}(SurfNum)$ = diffuse transmittance of the interior window

5.4.9.4.2 Interior Beam Radiation Transmitted by Interior Windows

The interior beam solar radiation transmitted by an interior window to the adjacent zone is

$$BeamSolarRad * \tau^{beam}(SurfNum) \sum_{i=1}^{N_{extwin}} TBm_i * Aoverlap_i(SurfNum) * CosInc_i[W] \quad (5.83)$$

where $\tau^{beam}(SurfNum)$ is the beam-to-beam transmittance of the interior window at the angle of incidence of beam solar from the exterior window on the interior window. The program does not track where this radiation falls in the adjacent zone: it is counted as diffuse radiation in that zone. Therefore,

$$QS(ZoneNum) \rightarrow QS(ZoneNum) + [beamsolarfromadjacentzones] * VMULT(ZoneNum) \quad (5.84)$$

5.4.10 Ground Reflectances

Ground reflectance values (Ref Object: Site:GroundReflectance) are used to calculate the ground reflected solar amount. This fractional amount (entered monthly) is used in the following equation:

$$GroundReflectedSolar = (BeamSolar * COS(SunZenithAngle) + DiffuseSolar) * GroundReflectance \quad (5.85)$$

Of course, the Ground Reflected Solar is never allowed to be negative. The Snow Ground Reflectance Modifier can further modify the ground reflectance when snow is on the ground. If the user enters 0.0 for each month, no ground reflected solar is used.

5.4.11 Ground Reflectances (Snow)

When snow is on the ground, ground reflectances may change. (Ref Object: Site:GroundReflectance:SnowModifier). This object allows the user to specify two values, Ground Reflected Solar Modifier and Daylighting Ground Reflected Solar Modifier.

Ground Reflected Solar Modifier is used to modified the basic monthly ground reflectance when snow is on the ground (from design day input or weather data values). Values can range from 0.0 to 1.0.

$$GroundReflectance_{used} = GroundReflectance * SolarModifier_{Snow} \quad (5.86)$$

Daylighting Ground Reflected Solar Modifier is used to modified the basic monthly ground reflectance when snow is on the ground (from design day input or weather data values). Values can range from 0.0 to 1.0.

$$\text{DaylightingGroundReflectance}_{\text{used}} = \text{GroundReflectance} \bullet \text{DaylightingModifier}_{\text{snow}} \quad (5.87)$$

Chapter 6

Solar Radiation Reflected from Exterior Surfaces

EnergyPlus has an option to calculate beam and sky solar radiation that is reflected from exterior surfaces and then strikes the building. This calculation occurs if “withReflections” is used on the SolarDistribution option in the Building object. For zones with detailed daylighting, these reflections are also considered in the daylight illuminance calculations.¹

The reflecting surfaces fall into three categories:

- **Shadowing surfaces.** These are surfaces like overhangs or neighboring buildings entered with objects Shading:Site:Detailed, Shading:Building:Detailed, or Shading:Zone:Detailed. Examples are shown in Figure 6.1.

These surfaces can have diffuse and/or specular (beam-to-beam) reflectance values that are specified with the ShadingProperty:Reflectance object.

- **Exterior building surfaces.** In this case one section of the building reflects solar radiation onto another section (and vice-versa). See Figure 6.2.

Opaque building surfaces (walls, for example) are assumed to be diffusely reflecting. Windows and glass doors are assumed to be specularly reflecting. The reflectance values for opaque surfaces are calculated by the program from the Solar Absorptance and Visible Absorptance values of the outer material layer of the surface’s construction. The reflectance values for windows and glass doors are calculated by the program from the reflectance properties of the individual glass layers that make up surface’s construction assuming no shading device is present and taking into account inter-reflections among the layers.

- **The ground surface.** Beam solar and sky solar reflection from the ground is calculated even if “withReflections” is not used (the default). But in this case the ground plane is considered unobstructed, i.e., the shadowing of the ground by the building itself or by obstructions such as neighboring buildings is ignored. This shadowing is taken into account only if “WithReflections” is used in the Solar Distribution field (in “Building” input object) (Figure 6.3). In this case the user-input value of ground view factor is not used.

¹A different method from that described here is used for calculating reflections from daylighting shelves (see “Daylighting Shelves”).

Figure 6.1: Examples of solar reflection from shadowing surfaces in the Shading series of input objects. Solid arrows are beam solar radiation; dashed arrows are diffuse solar radiation. (a) Diffuse reflection of beam solar radiation from the top of an overhang. (b) Diffuse reflection of sky solar radiation from the top of an overhang. (c) Beam-to-beam (specular) reflection from the facade of an adjacent highly-glazed building represented by a vertical shadowing surface.

Figure 6.2: Solar reflection from building surfaces onto other building surfaces. In this example beam solar reflects from a vertical section of the building onto a roof section. The reflection from the window is specular. The reflection from the wall is diffuse.

Figure 6.3: Shadowing by the building itself affects beam solar reflection from the ground. Beam-to-diffuse reflection from the ground onto the building occurs only for sunlit areas, A and C, not for shaded area, B. Shadowing by the building also affects sky solar reflection from ground (not shown).

6.1 Diffuse Reflection of Beam Solar and Sky Solar Radiation

A ray-tracing method is used to calculate beam solar and sky solar radiation that is diffusely reflected onto each of a building's exterior surfaces (walls, roofs, windows and doors), called here "receiving surfaces." The calculation begins by generating a set of rays proceeding into the outward hemisphere at each receiving point on a receiving surface. Then it determines whether each ray hits the sky, ground or an obstruction. The radiance at the hit point from reflection of incident beam or sky solar is determined and the contribution of this radiance to the receiving surface is calculated, added to the contribution from other hit points, and averaged over the receiving points. Separate calculations are done for beam-to-diffuse and sky solar reflection from all obstructions and beam-to-diffuse and sky solar reflection from the ground. (For beam-to-beam reflection see "Beam Solar Radiation Specularly Reflected from Obstructions," below.)

6.1.1 Receiving points

An N -sided surface is assigned N receiving points with the following coordinates, expressed in terms of the surface vertex coordinates:

$$P_{ij} = \sum_{k=1}^N a_{ki} v_{kj}, i = 1, 3; j = 1, 3 \quad (6.1)$$

where

P_{ij} = j^{th} coordinate of the i^{th} receiving point
 v_{kj} = j^{th} coordinate of the k^{th} surface vertex

If $N = 3$: $a_{kj} = 3/5$ if $k = i$; $a_{kj} = 1/5$ otherwise

If $N > 3$: $a_{kj} = \frac{N+1}{2N}$ if $k = i$; $a_{kj} = \frac{1}{2N}$ otherwise

For example, for a vertical 3m by 5m rectangle with vertices (0,0,3), (0,0,0), (5,0,0) and (5,0,3), this expression gives receiving points at (1.25,0,2.25), (1.25,0,0.75), (3.75,0,0.75) and (3.75,0,2.25), as shown in Figure 6.4.

Figure 6.4: Vertical rectangular exterior heat transfer surface showing location of receiving points for calculating incident solar radiation reflected from obstructions.

6.1.2 Rays

A total of 90 rays are sent out into the exterior hemisphere surrounding each receiving point. An upgoing ray may hit an obstruction or the sky. A downgoing ray may hit an obstruction or the ground. See Figure 6.5.

In subroutine InitSolRefRecSurf, the following is determined for each ray, i :

1. Unit vector in direction of ray
2. Cosine of angle between ray and plane of receiving surface ($\cos \alpha_i$)
3. Element of solid angle associated with ray ($d\Omega_i$)
4. If the ray hits one or more obstructions, the coordinates of the hit point on the obstruction nearest the receiving point
5. For the surface containing the hit point: the surface number, the solar reflectance ($\rho_{obs,i}$ if an obstruction), and the surface unit vector at the hit point pointing into the hemisphere containing the receiving point
6. If the ray is downgoing and hits the ground, the coordinates of the ground hit point
7. Distance from receiving point to hit point

6.1.3 Sky Solar Radiation Diffusely Reflected from Obstructions

The factor for reflection of sky radiation from obstructions onto a receiving surface is calculated in subroutine CalcSkySolDiffuseRefFactors. It is given by:

Figure 6.5: Two-dimensional schematic showing rays going outward from a point on a receiving surface. Rays 1-6 hit the ground, rays 7-11 hit an obstruction, and rays 12-15 hit the sky.

$$SurfReflFacSkySolObs(RecSurfNum) = \frac{1}{N_{rec}} \sum_{j=1}^{N_{rec}} \sum_{i=1}^{N_{ray}} Hit_{obs,i} ViewFacSky_{obs,i} DifShdgRatioIsoSky_{obs,i} \rho_{obs,i} \cos \alpha_i / \pi \quad (6.2)$$

where

$RecSurfNum$ is the receiving surface number,

N_{rec} is the number of receiving points,

N_{ray} is the number of rays,

obs, i denotes the obstruction hit by ray i ,

$Hit_{obs,i} = 1$ if ray i hits an obstruction, $= 0$ otherwise,

$ViewFacSky_{obs,i} = \text{unobstructed sky view factor of the obstruction} = (1 + \cos tilt_{obs})/2$,

$DifShdgRatioIsoSky_{obs,i} = (\text{obstructed sky irradiance on obstruction})/(\text{unobstructed sky irradiance on obstruction})$

In this equation, the product $ViewFacSky * DifShdgRatioIsoSky$ is the sky irradiance at the hit point divided by the horizontal sky irradiance taking into account shadowing of sky diffuse radiation on the obstruction by other obstructions, and assuming that the radiance of the sky is uniform. Note that we ignore secondary reflections here and in the following sections. In the present case this means that the irradiance at the hit point due to reflection of sky radiation from the ground or from other obstructions is not considered.

The above reflection factor is used in the timestep calculation to find the irradiance on a receiving surface due to sky radiation reflected from obstructions:

$$QRadSWOutIncSkyDifReflObs(RecSurfNum) = DifSolarRad * SurfReflFacSkySolObs(RecSurfNum) (W/m^2) \quad (6.3)$$

where $DifSolarRad$ is the horizontal sky irradiance on an unobstructed horizontal plane (W/m^2).

6.1.4 Sky Solar Radiation Diffusely Reflected from the Ground

If a downgoing ray from a receiving point hits the ground (for example, rays 1-6 in Figure 6.5), the program calculates the radiance at the ground hit point due to sky diffuse solar reaching that point. To do this, rays are sent upward from the ground hit point and it is determined which of these rays are unobstructed and so go to the sky (for example, rays 6-10 in Figure 6.6). For this calculation it is assumed that the radiance of the sky is uniform.

Figure 6.6: Two-dimensional schematic showing rays going upward from a ground hit point.

The factor for reflection of sky radiation from the ground onto a receiving surface is calculated in subroutine `CalcSkySolDiffuseReflFactors`. It is given by:

$$SurfReflFacSkySolGnd(RecSurfNum) = \frac{1}{N_{rec}} \sum_{i=1}^{N_{rec}} \sum_{j=1}^{N_{ray}} \left[(Hit_{gnd,i} d\Omega_i \cos \alpha_i / \pi) \sum_{j(i)}^{N_{ray}} Hit_{sky,j(i)} \cos \alpha_{j(i)} d\Omega_{j(i)} / \pi \right] \quad (6.4)$$

where

$j(i)$ denotes an upgoing ray from the ground point hit by ray i from the receiving point,

$Hit_{sky,j(i)} = 1$ if ray $j(i)$ hits the sky, $= 0$ otherwise,

$\alpha_{j(i)}$ is the angle of incidence of ray $j(i)$ with respect to the ground plane,

$d\Omega_{j(i)}$ is the solid angle element associated with ray $j(i)$.

This factor is used in the timestep calculation to find the irradiance on a receiving surface due to sky radiation reflected from the ground:

$$QRadSWOutIncSkyDiffReflGnd(RecSurfNum) = DifSolarRad * \rho_{gnd} * SurfReflFacSkySolGnd(RecSurfNum) \quad (W/m^2) \quad (6.5)$$

where ρ_{gnd} is the solar reflectance of the ground, which is assumed to be uniform over the ground plane but may vary monthly (because of snow cover, for example).

6.1.5 Beam Solar Radiation Diffusely Reflected from Obstructions

This calculation is similar to that for sky solar reflected from obstructions. However, to find the radiance at a hit point on an obstruction a line is drawn from the hit point to center of the sun. From this line it is determined (1) if there is an obstruction between the hit point and the sun, in which case it is assumed that no beam solar reaches the hit point; and (2) if beam solar does reach the hit point, what the the solar angle of incidence at that point is.

The calculation is done for the hourly sun positions on each of the design days. It is also done for hourly sun positions on selected days during the weather file run period (the same days for which the shadowing calculations are done).

The factor for diffuse reflection of beam solar radiation from obstructions onto a receiving surface is calculated in subroutine CalcBeamSolDiffuseReffFactors. It is given by:

$$SurfReflFacBmToDiffSolObs(RecSurfNum, IHr) = \frac{1}{N_{rec}} \sum_1^{N_{rec}} \sum_{i=1}^{N_{ray}} Hit_{obs,i} Hit_{obs,i,sun} d\Omega_i \cos \alpha_i \rho_{obs,i} \cos \alpha_{sun,obs,i} \quad (6.6)$$

where

IHr = hour number

$Hit_{obs,i}$ = 1 if ray i from the receiving point hits an obstruction, = 0 otherwise,

$Hit_{obs,i,sun}$ = 1 if the line from ray i 's hit point to the sun is unobstructed, = 0 otherwise,

$\alpha_{sun,obs,i}$ is the angle of incidence of the sun on the obstruction.

This factor is used in the timestep calculation to find the diffuse irradiance on a receiving surface due to beam solar diffusely reflected from obstructions:

$$\begin{aligned} QRadSWOutIncBmToDiffReflObs(RecSurfNum) = & BeamSolarRad \\ & * (WeightNow * SurfReflFacBmToDiffSolObs(RecSurfNum, HourOfDay) \\ & + WeightPreviousHour * SurfReflFacBmToDiffSolObs(RecSurfNum, PreviousHour)) \end{aligned} \quad (6.7)$$

where $BeamSolarRad$ is the timestep value of beam normal solar intensity W/m^2 , and $WeightNow$ and $WeightPreviousHour$ are time-averaging factors.

6.1.6 Beam Solar Radiation Diffusely Reflected from the Ground

This calculation is the same as that for beam solar diffusely reflected from obstructions except that only rays from a receiving point that hit the ground are considered. The factor for diffuse reflection of beam solar from the ground onto a receiving surface is calculated in subroutine CalcBeamSolDiffuseReffFactors. It is given by:

$$SurfReflFacBmToDiffSolGnd(RecSurfNum, IHr) = \frac{1}{N_{rec}} \sum_1^{N_{rec}} \sum_{i=1}^{N_{ray}} Hit_{gnd,i} Hit_{gnd,i,sun} d\Omega_i \cos \alpha_{gnd,i} \cos \alpha_{sun,gnd} \quad (6.8)$$

where

$Hit_{gnd,i}$ = 1 if ray i hits the ground, = 0 otherwise,

$Hit_{gnd,i,sun}$ = 1 if the line from ray i 's hit point to the sun is unobstructed, = 0 otherwise,

$\alpha_{sun,gnd}$ = angle of incidence of sun on ground (= solar zenith angle).

This factor is used in the timestep calculation to find the diffuse irradiance on a receiving surface due to beam solar diffusely reflected from the ground:

$$\begin{aligned}
 QRadSWOutIncBmToDiffReflGnd(RecSurfNum) = \\
 BeamSolarRad * \rho_{gnd} * (WeightNow * SurfReflFacBmToDiffSolGnd(RecSurfNum, HourOfDay) \\
 + WeightPreviousHour * SurfReflFacBmToDiffSolGnd(RecSurfNum, PreviousHour))
 \end{aligned}
 \tag{6.9}$$

6.1.7 Beam Solar Radiation Specularly Reflected from Obstructions

Figure 6.7 shows schematically how specular (beam-to-beam) reflection from an obstruction is calculated.²

Figure 6.7: Two-dimensional schematic showing specular reflection from an obstruction such as the glazed façade of a neighboring building. The receiving point receives specularly reflected beam solar radiation if (1) DB passes through specularly reflecting surface EF, (2) CD does not hit any obstructions (such as RS), and (3) AC does not hit any obstructions (such as PQ).

The calculation procedure is as follows:

1. Select receiving point D on receiving surface JK.
2. Select specularly reflecting surface EF.
3. Find the mirror image, B, of the sun with respect to the plane of EF and construct ray DB.
4. Check if DB passes through EF; if yes, find intersection point C and construct ray CD.
5. Check if CD is obstructed.
6. If no, construct ray AC and check if it is obstructed.
7. If no, find reflected beam irradiance (W/m^2) at D:

²The ground surface is assumed to be diffusely reflecting so there is no specular reflection from the ground. The program could be improved by adding a ground surface specular component, which could be important for snow-cover conditions.

$$I_{D,refl}^{bm} = BeamSolarRad * \rho_{spec}(\alpha_C) \cos \alpha_D \quad (6.10)$$

where

α_C = angle of incidence of beam solar at point C of the obstruction,

$\rho_{spec}(\alpha_C)$ = reflectance of obstruction as a function of the angle of incidence,

α_D = angle of incidence of ray CD on JK.

The factor for specular reflection of beam solar from obstruction onto a receiving surface is calculated in subroutine CalcBeamSolSpecularReflFactors. It is given by:

$$SurfReflFacBmToBmSolObs(RecSurfNum, IHr) = \sum_{\text{specularly reflecting surfaces}} \left[\frac{1}{N_{rec}} \sum_1^{N_{rec}} f_{C,glazed} \rho_{spec}(\alpha_C) \cos \alpha_D \right] \quad (6.11)$$

The program assumes that specular reflection from a surface is due to glazing. If the reflecting surface is a window belonging to the building itself (as in Figure 6.2), then $f_{C,glazed}$ is the fraction of the window that is glazed (which is 1.0 unless the window has dividers).

If the surface is a shading surface (that represents, for example, the glazed façade of a neighboring building) the surface reflection information is entered with the Shading Surface Reflectance object. This object contains values for:

1. Diffuse solar reflectance of the unglazed part of the shading surface
2. Diffuse visible reflectance of the unglazed part of the shading surface
3. Fraction of shading surface that is glazed
4. Name of glazing construction

In this case $f_{C,glazed}$ is “Fraction of shading surface that is glazed” and $\rho_{spec}(\alpha_C)$ is the front reflectance of the indicated glazing construction as a function of beam solar incidence angle.

The above specular reflection factor is used in the timestep calculation to find the beam irradiance on a receiving surface due to beam-beam reflection from obstructions:

$$\begin{aligned} QRadSWOutIncBmToBmReflObsRecSurfNum) = \\ BeamSolarRad * (WeightNow * SurfReflFacBmToBmSolObs(RecSurfNum, HourOfDay) \\ + WeightPreviousHour * SurfReflFacBmToBmSolObs(RecSurfNum, PreviousHour)) \end{aligned} \quad (6.12)$$

Chapter 7

Daylighting and Window Calculations

7.1 Daylighting Calculations

The EnergyPlus daylighting model using the SplitFlux method, in conjunction with the thermal analysis, determines the energy impact of daylighting strategies based on analysis of daylight availability, site conditions, window management in response to solar gain and glare, and various lighting control strategies.

The daylighting calculation has three main steps:

- (1) *Daylight factors*, which are ratios of interior illuminance or luminance to exterior horizontal illuminance, are calculated and stored. The user specifies the coordinates of one or more reference points in each daylit zone. EnergyPlus then integrates over the area of each exterior window in the zone (or enclosure) to obtain the contribution of direct light from the window to the illuminance at the reference points, and the contribution of light that reflects from the walls, floor and ceiling before reaching the reference points.

If a zone has surfaces with air boundaries (Construction:AirBoundary) then all of the surfaces within the grouped enclosure are included in the “zone”. Each daylighting control and reference point remains associated with a specific zone, but all windows (and other surfaces) within the grouped enclosure are seen by each reference point within the enclosure. For example if there is an air boundary between Zone A and Zone B, a daylighting reference point in Zone A will see all surfaces in both Zone A and Zone B directly.

Window luminance and window background luminance, which are used to determine glare, are also calculated. Taken into account are such factors as sky luminance distribution, window size and orientation, glazing transmittance, inside surface reflectances, sun control devices such as movable window shades, and external obstructions. Dividing daylight illuminance or luminance by exterior illuminance yields daylight factors. These factors are calculated for the hourly sun positions on sun-paths for representative days of the run period. To avoid the spikes of daylight and glare factors calculated during some sunrise and/or sunset hours when exterior horizontal illuminance is very low, the daylight and glare factors for those hours are reset to 0.

- (2) A daylighting calculation is performed each heat-balance time step when the sun is up. In this calculation the illuminance at the reference points in each zone is found by interpolating the stored daylight factors using the current time step’s sun position and sky condition, then

multiplying by the exterior horizontal illuminance. If glare control has been specified, the program will automatically deploy window shading, if available, to decrease glare below a specified comfort level. A similar option uses window shades to automatically control solar gain.

- (3) The electric lighting control system is simulated to determine the lighting energy needed to make up the difference between the daylighting illuminance level and the design illuminance. Finally, the zone lighting electric reduction factor is passed to the thermal calculation, which uses this factor to reduce the heat gain from lights.

The EnergyPlus daylighting calculation is derived from the daylighting calculation in DOE-2.1E, which is described in [Winkelmann, 1983] and [Winkelmann and Selkowitz, 1985]. There are two major differences between the two implementations:

- (1) In EnergyPlus daylight factors are calculated for four different sky types—clear, clear turbid, intermediate, and overcast; in DOE-2 only two sky types are used—clear and overcast.
- (2) In EnergyPlus the clear-sky daylight factors are calculated for hourly sun-path sun positions several times a year whereas in DOE-2 these daylight factors are calculated for a set of 20 sun positions that span the annual range of sun positions for a given geographical location.

7.2 Daylight Factor Calculation

The daylighting factor calculation using the SplitFlux daylighting method is described below.

Table 7.1: Variables in Daylighting Calculations

Mathematical Variable	Description	Units	Internal Variable
$E_{h,sky}$	Exterior horizontal illuminance due to light from the sky	lux	GILSK
$E_{h,sun}$	Exterior horizontal illuminance due to light from the sun	lux	GILSU
d_{sky}, d_{sun}	Interior illuminance factor due to sky, sun related light	—	DFACSK, DFACSU
w_{sky}, w_{sun}	Window luminance factor due to sky, sun related light	cd/lm	SFACSK, SFACSU
b_{sky}, b_{sun}	Window background luminance factor due to sky, sun related light	cd/lm	BFACSK, BFACSU
N	Number of exterior windows in a zone	—	NWD

Table 7.1: Variables in Daylighting Calculations

Mathematical Variable	Description	Units	Internal Variable
$\theta_{\text{sky}}, \varphi_{\text{sky}}$	Azimuth and altitude angles of a point in the sky	radians	THSKY, PHSKY
Ψ_{cs}	Clear sky luminance distribution	cd/m^2	—
Ψ_{ts}	Clear turbid sky luminance distribution	cd/m^2	—
Ψ_{is}	Intermediate sky luminance distribution	cd/m^2	—
Ψ_{os}	Overcast sky luminance distribution	cd/m^2	—
φ_{sun}	Altitude angle of the sun	radians or degrees	PHSUN
γ	Angle between point in the sky and the sun; or angle between vertical and ray from reference point to window element	radians	G
L_z	Sky zenith luminance	cd/m^2	ZENL
m	Optical air mass of the atmosphere	m	AM
h	Building altitude	m	ELEVATION
$E_{h,k}$	Exterior horizontal illuminance for sky type k	lux	—
N_θ, N_φ	Number of azimuth, altitude steps for sky integration	—	NTH, NPH
\vec{R}_{ref}	Vector from zone origin to reference point	m	RREF
\vec{R}_{win}	Vector from zone origin to window element	m	RWIN
$d\Omega$	Solid angle subtended by window element	steradians	DOMEGA
L_w	Luminance of a window element as seen from reference point	cd/m^2	WLUMSK, WLUMSU
$L_{w,shade}$	Luminance of window element with shade in place	cd/m^2	WLUMSK, WLUMSU

Table 7.1: Variables in Daylighting Calculations

Mathematical Variable	Description	Units	Internal Variable
dE_h	Horizontal illuminance at reference point from window element	lux	—
dx, dy	Size of window element	m	DWX, DWY
D	Distance from reference point to window element	m	DIS
B	Angle between window element's outward normal and ray from reference point to window element	radians	—
\hat{R}_{ray}	Unit vector from reference point to window element	—	RAY
\hat{W}_n	Unit vector normal to window element, pointing away from zone	—	WNORM
\hat{W}_{21}	Unit vector along window y-axis	—	W21
\hat{W}_{23}	Unit vector along window x-axis	—	W23
τ_{vis}	Glass visible transmittance	—	TVISB
L	Luminance of sky or obstruction	cd/m^2	ELUM, —
ϕ_{FW}	Downgoing luminous flux from a window	lm	FLFW —
ϕ_{CW}	Upgoing luminous flux from a window	lm	FLCW —
F_1	First-reflected flux	lm	-
ρ_{FW}	Area-weighted reflectance of floor and upper part of walls	—	SurfaceWindow%RhoFloorWall
ρ_{CW}	Area-weighted reflectance of ceiling and upper part of walls	—	SurfaceWindow%RhoCeilingWall
E_r	Average internally-reflected illuminance	lux	EINTSK, EINTSU
A	Total inside surface area of a zone	m^2	ATOT

Table 7.1: Variables in Daylighting Calculations

Mathematical Variable	Description	Units	Internal Variable
ρ	Area-weighted average reflectance of zone interior surfaces	—	ZoneDaylight%AveVisDiffREffect
θ, φ	Azimuth and altitude angle of a sky or ground element	radians	TH, PH
$L(\theta, \varphi)$	Luminance of sky or ground element at (θ, φ)	cd/m^2	HitPointLum—
A_w	Area of glazed part of window	m^2	Surface%Area
β	Angle of incidence, at center of window, of light from a sky or ground element	radians	—
$T(\beta)$	Glazing visible transmittance at incidence angle β	—	TVISBR
$d\phi_{inc}$	Luminous flux incident on window from sky or ground element	lm	—
$d\phi$	Luminous flux from sky or ground element transmitted through window	lm	—
$d\phi_{FW}, d\phi_{CW}$	Luminous flux from sky or ground element transmitted through window and going downward, upward	lm	-
$\theta_{min}, \theta_{max}$	Azimuth angle integration limits	radians	THMIN, THMAX
φ_w	Window normal altitude angle	radians	-
ϕ_{sh}, ϕ_{unsh}	Transmitted flux through window and shade, without shade	lm	—
$\phi_{CW,sh}, \phi_{FW,sh}$	Upgoing and downgoing portions of transmitted flux through window with shade	lm	—

E_s	Illuminance setpoint	lm	IllumSetPoint
G_I	Glare Index	—	GLINDX

7.2.1 Overview

There are three types of daylight factors: interior illuminance factors, window luminance factors, and window background luminance factors. To calculate these factors the following steps are carried out for each hourly sun position on the sun paths for the design days and for representative days¹ during the simulation run period:

1. Calculate exterior horizontal daylight illuminance from sky and sun for standard (CIE) clear and overcast skies.
2. Calculate interior illuminance, window luminance and window background luminance for each window/reference-point combination, for bare and for shaded window conditions (if a shading device has been specified), for overcast sky and for standard clear sky.
3. Divide by exterior horizontal illuminance to obtain daylight factors.

7.2.2 Interior Illuminance Components

To calculate daylight factors, daylight incident on a window is separated into two components: (1) light that originates from the *sky* and reaches the window directly or by reflection from exterior surfaces; and (2) light that originates from the *sun* and reaches the window directly or by reflection from exterior surfaces. Light from the window reaches the workplane directly or via reflection from the interior surfaces of the room.

For fixed sun position, sky condition (clear or overcast) and room geometry, the sky-related interior daylight will be proportional to the exterior horizontal illuminance, $E_{h,sky}$, due to light from the sky. Similarly, the sun-related interior daylight will be proportional to the exterior horizontal solar illuminance, $E_{h,sun}$.

7.2.3 Daylight Factors

The following daylight factors are calculated:

¹The sun positions for which the daylight factors are calculated are the same as those for which the solar shadowing calculations are done.

$$d_{sky} = \frac{\text{Illuminance at reference point due to sky – related light}}{E_{h,sky}} \quad (7.1)$$

$$d_{sun} = \frac{\text{Illuminance at reference point due to sun – related light}}{E_{h,sun}} \quad (7.2)$$

$$w_{sky} = \frac{\text{Average window luminance due to sky – related light}}{E_{h,sky}} \quad (7.3)$$

$$w_{sun} = \frac{\text{Average window luminance due to sun – related light}}{E_{h,sun}} \quad (7.4)$$

$$b_{sky} = \frac{\text{Window background luminance due to sky – related light}}{E_{h,sky}} \quad (7.5)$$

$$b_{sun} = \frac{\text{Window background luminance due to sun – related light}}{E_{h,sun}} \quad (7.6)$$

For a daylight zone with N windows these six daylight factors are calculated for each of the following combinations of reference point, window, sky-condition/sun-position and shading device:

$$\begin{bmatrix} \text{Ref pt 1} \\ \text{Ref pt 2} \end{bmatrix} \begin{bmatrix} \text{Window 1} \\ \text{Window 2} \\ \dots \\ \text{Window N} \end{bmatrix} \begin{bmatrix} \text{Clear sky, first sun – up hour} \\ \text{Clear/turbid sky, first sun – up hour} \\ \text{Intermediate sky, first sun – up hour} \\ \text{Overcast sky, first sun – up hour} \\ \dots \\ \text{Clear sky, last sun – up hour} \\ \text{Clear/turbid sky, last sun – up hour} \\ \text{Intermediate sky, last sun – up hour} \\ \text{Overcase sky, last sun – up hour} \end{bmatrix} \begin{bmatrix} \text{Unshaded window} \\ \text{Shaded window} \\ \text{(if shade assigned)} \end{bmatrix} \quad (7.7)$$

7.2.4 Sky Luminance Distributions

The luminance distribution of the sky is represented as a superposition of four standard CIE skies using the approach described in (Perez et al. 1990). The standard skies are as follows.

7.2.4.1 Clear Sky

The clear sky luminance distribution has the form (Kittler, 1965; CIE, 1973)

$$\psi_{cs}(\theta_{sky}, \phi_{sky}) = L_z \frac{(0.91 + 10e^{-3\gamma} + 0.45\cos^2\gamma)(1 - e^{-0.32\text{cosec}\phi_{sky}})}{0.27385(0.91 + 10e^{-3(\frac{\pi}{2}-\phi_{sun})} + 0.45\sin^2\phi_{sun})} \quad (7.8)$$

Here, L_z is the zenith luminance (i.e., the luminance of the sky at a point directly overhead). In the calculation of daylight factors, which are ratios of interior and exterior illumination quantities

that are both proportional to L_z , the zenith luminance cancels out. For this reason we will use $L_z = 1.0$ for all sky luminance distributions.

The various angles, which are defined in the building coordinate system, are shown in Figure 7.1. The angle, γ , between sun and sky element is given by:

$$\gamma = \cos^{-1} [\sin \phi_{sky} \sin \phi_{sun} + \cos \phi_{sky} \cos \phi_{sun} \cos(\theta_{sky} - \theta_{sun})] \quad (7.9)$$

The general characteristics of the clear-sky luminance distribution are a large peak near the sun; a minimum at a point on the other side of the zenith from the sun, in the vertical plane containing the sun; and an increase in luminance as the horizon is approached.

7.2.4.2 Clear Turbid Sky

The clear turbid sky luminance distribution has the form [Matsuura, 1987]:

$$\psi_{ts}(\theta_{sky}, \phi_{sky}) = L_z \frac{(0.856 + 16e^{-3\gamma} + 0.3\cos^2\gamma)(1 - e^{-0.32\cos\phi_{sky}})}{0.27385(0.856 + 10e^{-3(\frac{\pi}{2} - \phi_{sun})} + 0.3\sin^2\phi_{sun})} \quad (7.10)$$

7.2.4.3 Intermediate Sky

The intermediate sky luminance distribution has the form [Matsuura, 1987]:

$$\psi_{is}(\theta_{sky}, \phi_{sky}) = L_z Z_1 Z_2 / (Z_3 Z_4) \quad (7.11)$$

where

$$Z_1 = [1.35(\sin(3.59\phi_{sky} - 0.009) + 2.31) \sin(2.6\phi_{sun} + 0.316) + \phi_{sky} + 4.799] / 2.326 \quad (7.12)$$

$$Z_2 = \exp[-0.563\gamma\{(\phi_{sun} - 0.008)(\phi_{sky} + 1.059) + 0.812\}] \quad (7.13)$$

$$Z_3 = 0.99224 \sin(2.6\phi_{sun} + 0.316) + 2.73852 \quad (7.14)$$

$$Z_4 = \exp\left[-0.563\left(\frac{\pi}{2} - \phi_{sun}\right)\{2.6298(\phi_{sun} - 0.008) + 0.812\}\right] \quad (7.15)$$

7.2.4.4 Overcast Sky

The overcast sky luminance distribution has the form [Moon & Spencer, 1942]:

$$\psi_{os}(\phi_{sky}) = L_z \frac{1 + 2 \sin \phi_{sky}}{3} \quad (7.16)$$

Unlike the clear sky case, the overcast sky distribution does not depend on the solar azimuth or the sky azimuth. Note that at fixed solar altitude the zenith ($\phi_{sky} = \pi/2$) is three times brighter than the horizon ($\phi_{sky} = 0$).

Figure 7.1: Angles appearing in the expression for the clear-sky luminance distribution.

7.2.5 Direct Normal Solar Illuminance

For purposes of calculating daylight factors associated with beam solar illuminance, the direct normal solar illuminance is taken to be 1.0 W/m^2 . The actual direct normal solar illuminance, determined from direct normal solar irradiance from the weather file and empirically-determined luminous efficacy, is used in the time-step calculation.

7.2.6 Exterior Horizontal Illuminance

The illuminance on an unobstructed horizontal plane due to diffuse radiation from the sky is calculated for each of the four sky types by integrating over the appropriate sky luminance distribution:

$$E_{h,k} = \int_0^{2\pi} \int_0^{\pi/2} \psi_k(\theta_{sky}, \phi_{sky}) \sin \phi_{sky} \cos \phi_{sky} d\theta_{sky} d\phi_{sky} \quad (7.17)$$

where $k = cs, ts, is$ or os . The integral is evaluated as a double summation:

$$E_{h,k} = \sum_{i=1}^{N_\theta} \sum_{j=1}^{N_\phi} \psi_k(\theta_{sky}(i), \phi_{sky}(j)) \sin \phi_{sky}(j) \cos \phi_{sky}(j) \Delta\theta_{sky} \Delta\phi_{sky} \quad (7.18)$$

where

$$\begin{aligned} \theta_{sky}(i) &= (i - 1/2)\Delta\theta_{sky} \\ \phi_{sky}(j) &= (j - 1/2)\Delta\phi_{sky} \\ \Delta\theta_{sky} &= 2\pi/N_\theta \\ \Delta\phi_{sky} &= \pi/2N_\phi \end{aligned} \quad (7.19)$$

$N_\theta = 18$ and $N_\phi = 8$ were found to give a $\pm 1\%$ accuracy in the calculation of $E_{h,k}$.

7.2.7 Direct Component of Interior Daylight Illuminance

The direct daylight illuminance at a reference point from a particular window is determined by dividing the window into an x-y grid and finding the flux reaching the reference point from each grid element. The geometry involved is shown in Figure 7.2. The horizontal illuminance at the reference point, \vec{R}_{ref} , due to a window element is:

$$dE_h = L_w d\Omega \cos \gamma \quad (7.20)$$

where L_w is the luminance of the window element as seen from the reference point. The subtended solid angle is approximated by:

$$d\Omega = \frac{dx dy}{D^2} \cos B \quad (7.21)$$

where

$$D = |\vec{R}_{win} - \vec{R}_{ref}| \quad (7.22)$$

$\cos B$ is found from:

$$\cos B = \hat{R}_{ray} \cdot \hat{W}_n \quad (7.23)$$

where

$$\vec{R}_{ray} = (\vec{R}_{win} - \vec{R}_{ref})/D \quad (7.24)$$

$$\hat{W}_n = \text{window outward normal} = \hat{W}_{21} \times \hat{W}_{23} = \frac{\vec{W}_1 - \vec{W}_2}{|\vec{W}_1 - \vec{W}_2|} \times \frac{\vec{W}_3 - \vec{W}_2}{|\vec{W}_3 - \vec{W}_2|} \quad (7.25)$$

Equation 7.21 becomes exact as dx/D and $dy/D \rightarrow 0$ and is accurate to better than about 1% for $dx \leq D/4$ and $dy \leq D/4$.

The net illuminance from the window is obtained by summing the contributions from all the window elements:

$$E_h = \sum_{\substack{\text{window} \\ \text{elements}}} L_w d\Omega \cos \gamma \quad (7.26)$$

In performing the summation, window elements that lie below the workplane ($\cos \gamma < 0$) are omitted since light from these elements cannot reach the workplane directly.

Figure 7.2: Geometry for calculation of direct component of daylight illuminance at a reference point. Vectors R_{ref} , W_1 , W_2 , W_3 and R_{win} are in the building coordinate system.

7.2.7.1 Unshaded Window

For the unshaded window case, the luminance of the window element is found by projecting the ray from reference point to window element and determining whether it intersects the sky or an exterior obstruction such as an overhang. If L is the corresponding luminance of the sky or obstruction, the window luminance is:

$$L_w = L\tau_{vis}\cos B \quad (7.27)$$

where τ_{vis} is the visible transmittance of the glass for incidence angle B .

Exterior obstructions are generally opaque (like fins, overhangs, neighboring buildings, and the building's own wall and roof surfaces) but can be transmitting (like a tree or translucent awning). Exterior obstructions are assumed to be non-reflecting. If L_{sky} is the sky luminance and τ_{obs} is the transmittance of the obstruction (assumed independent of incidence angle), then $L = L_{sky}\tau_{obs}$. Interior obstructions are assumed to be opaque ($\tau_{obs} = 0$).

7.2.7.2 Shaded Window

For the window-plus-shade case the shade is assumed to be a perfect diffuser, i.e., the luminance of the shade is independent of angle of emission of light, position on shade, and angle of incidence of solar radiation falling on the shade. Closely-woven drapery fabric and translucent roller shades are closer to being perfect diffusers than Venetian blinds or other slatted devices, which usually have non-uniform luminance characteristics.

The calculation of the window luminance with the shade in place, $L_{w,sh}$, is described in [Winkelmann, 1983]. The illuminance contribution at the reference point from a shaded window element is then given by Equation 7.26 with $L_w = L_{w,sh}$.

7.2.8 Internally-Reflected Component of Interior Daylight Illuminance

Daylight reaching a reference point after reflection from interior surfaces is calculated using the *split-flux* method [Hopkinson et al., 1954], [Lynes, 1968]. In this method the daylight transmitted by the window is split into two parts—a downward-going flux, Φ_{FW} (lumens), which falls on the floor and portions of the walls below the imaginary horizontal plane passing through the center of the window (*window midplane*), and an upward-going flux, Φ_{CW} , that strikes the ceiling and portions of the walls above the window midplane. A fraction of these fluxes is absorbed by the room surfaces. The remainder, the first-reflected flux, F_1 , is approximated by

$$F_1 = \Phi_{FW}\rho_{FW} + \Phi_{CW}\rho_{CW} \quad (7.28)$$

where ρ_{FW} is the area-weighted average reflectance of the floor and those parts of the walls below the window midplane, and ρ_{CW} is the area-weighted average reflectance of the ceiling and those parts of the walls above the window midplane.

To find the final average internally-reflected illuminance, E_r , on the room surfaces (which in this method is uniform throughout the room) a flux balance is used. The total reflected flux absorbed by the room surfaces (or lost through the windows) is $AE_r(1-\rho)$, where A is the total inside surface area of the floor, walls, ceiling and windows in the room, and ρ is the area-weighted average reflectance of the room surfaces, including windows. From conservation of energy:

$$AE_r(1 - \rho) = F_1 \quad (7.29)$$

or

$$E_r = \frac{\Phi_{FW}\rho_{FW} + \Phi_{CW}\rho_{CW}}{A(1 - \rho)} \quad (7.30)$$

This procedure assumes that the room behaves like an integrating sphere with perfectly diffusing interior surfaces and with no internal obstructions. It therefore works best for rooms that are close to cubical in shape, have matte surfaces (which is usually the case), and have no internal partitions. Deviations from these conditions, such as would be the case for rooms whose depth measured from the window-wall is more than three times greater than ceiling height, can lead to substantial inaccuracies in the split-flux calculation.

7.2.9 Transmitted Flux from Sky and Ground

The luminous flux incident on the center of the window from a luminous element of sky or ground at angular position (θ, ϕ) , of luminance $L(\theta, \phi)$, and subtending a solid angle $\cos \phi d\theta d\phi$ is:

$$d\Phi_{inc} = A_w L(\theta, \phi) \cos \beta \cos \phi d\theta d\phi \quad (7.31)$$

The transmitted flux is:

$$d\Phi = d\Phi_{inc} T(\beta) \quad (7.32)$$

where $T(\beta)$ is the window transmittance for light at incidence angle β . This transmittance depends on whether or not the window has a shade.

For an unshaded window the total downgoing transmitted flux is obtained by integrating over the part of the exterior hemisphere seen by the window that lies above the window midplane. This gives:

$$\Phi_{FW,unshaded} = A_w \int_{\theta_{min}}^{\theta_{max}} \int_0^{\pi/2} L(\theta, \phi) T(\beta) \cos \beta \cos \phi d\theta d\phi \quad (7.33)$$

The upgoing flux is obtained similarly by integrating over the part of the exterior hemisphere that lies below the window midplane:

$$\Phi_{CW,unshaded} = A_w \int_{\theta_{min}}^{\theta_{max}} \int_{\pi/2-\phi_w}^0 L(\theta, \phi) T(\beta) \cos \beta \cos \phi d\theta d\phi \quad (7.34)$$

where ϕ_w is the angle the window outward normal makes with the horizontal plane.

For a window with a diffusing shade the total transmitted flux is:

$$\Phi_{sh} = A_w \int_{\theta_{min}}^{\theta_{max}} \int_{\pi/2-\phi_w}^{\pi/2} L(\theta, \phi) T(\beta) \cos \beta \cos \phi d\theta d\phi \quad (7.35)$$

The downgoing and upgoing portions of this flux are:

$$\begin{aligned}\Phi_{FW,sh} &= \Phi(1 - f) \\ \Phi_{CW,sh} &= \Phi f\end{aligned}\tag{7.36}$$

where f , the fraction of the hemisphere seen by the inside of the window that lies above the window midplane, is given by

$$f = 0.5 - \phi_w/\pi\tag{7.37}$$

For a vertical window ($\phi_w = 0$) the up- and down-going transmitted fluxes are equal:

$$\Phi_{FW,sh} = \Phi_{CW,sh} = \Phi/2\tag{7.38}$$

For a horizontal skylight ($\phi_w = \pi/2$):

$$\Phi_{FW,sh} = \Phi, \Phi_{CW,sh} = 0\tag{7.39}$$

The limits of integration of θ in Equations 7.33, 7.34 and 7.35 depend on ϕ . From Figure 12 of Winkelmann (1983), we have:

$$\sin \alpha = \sin(A - \pi/2) = \frac{\sin \phi \tan \phi_w}{\cos \phi}\tag{7.40}$$

which gives:

$$A = \cos^{-1}(\tan \phi \tan \phi_w)\tag{7.41}$$

Thus:

$$\begin{aligned}\theta_{min} &= -|\cos^{-1}(-\tan \phi \tan \phi_w)| \\ \theta_{max} &= |\cos^{-1}(-\tan \phi \tan \phi_w)|\end{aligned}\tag{7.42}$$

7.2.10 Transmitted Flux from Direct Sun

The flux incident on the window from direct sun is:

$$\Phi_{inc} = A_w E_{DN} \cos \beta f_{sunlit}\tag{7.43}$$

The transmitted flux is:

$$\Phi = T(\beta) \Phi_{inc}\tag{7.44}$$

where T is the net transmittance of the window glazing (plus shade, if present).

For an unshaded window all of the transmitted flux is downward since the sun always lies above the window midplane. Therefore:

$$\begin{aligned}\Phi_{FW,unsh} &= \Phi \\ \Phi_{CW,unsh} &= 0\end{aligned}\tag{7.45}$$

For a window with a diffusing shade:

$$\begin{aligned}\Phi_{FW,sh} &= \Phi(1 - f) \\ \Phi_{CW,sh} &= \Phi f\end{aligned}\tag{7.46}$$

7.2.11 Luminance of Shaded Window

The luminance of a shaded window is determined at the same time that the transmitted flux is calculated. It is given by:

$$L_{sh} = \frac{1}{\pi} \int_{\theta_{\min}}^{\theta_{\max}} \int_{\pi/2-\phi_w}^{\pi/2} L(\theta, \phi) T(\beta) \cos \beta \cos \phi d\theta d\phi \quad (7.47)$$

7.2.12 Daylight Discomfort Glare

The discomfort glare at a reference point due to luminance contrast between a window and the interior surfaces surrounding the window is given by [Hopkinson, 1970] and [Hopkinson, 1972]:

$$G = \frac{L_w^{1.6} \Omega^{0.8}}{L_b + 0.07 \omega^{0.5} L_w} \quad (7.48)$$

where

G = discomfort glare constant

L_w = average luminance of the window as seen from the reference point

Ω = solid angle subtended by window, modified to take direction of occupant view into account

L_b = luminance of the background area surrounding the window

By dividing the window into N_x by N_y rectangular elements, as is done for calculating the direct component of interior illuminance, we have:

$$L_w = \frac{\sum_{j=1}^{N_y} \sum_{i=1}^{N_x} L_w(i, j)}{N_x N_y} \quad (7.49)$$

where $L_w(i, j)$ is the luminance of element (i, j) as seen from the reference point.

Similarly,

$$\omega = \sum_{j=1}^{N_y} \sum_{i=1}^{N_x} d\omega(i, j) \quad (7.50)$$

where $d\omega(i, j)$ is the solid angle subtended by element (i, j) with respect to the reference point.

The modified solid angle is:

$$\Omega = \sum_{j=1}^{N_y} \sum_{i=1}^{N_x} d\omega(i, j) p(x_R, y_R) \quad (7.51)$$

where p is a “position factor” [Petherbridge & Longmore, 1954] that accounts for the decrease in visual excitation as the luminous element moves away from the line of sight. This factor depends on the horizontal and vertical displacement ratios, x_R and y_R (Figure 7.3), given by:

$$\begin{aligned} x_R(i, j) &= \frac{\sqrt{A^2 - (YD)^2}}{RR} \\ y_R(i, j) &= |YD/RR| \end{aligned} \quad (7.52)$$

where

$$\begin{aligned}
 RR &= D(\hat{R}_{ray} \cdot \hat{v}_{view}) \\
 A^2 &= D^2 - (RR)^2 \\
 YD &= R_{win}(3) - R_{ref}(3)
 \end{aligned}
 \tag{7.53}$$

Figure 7.3: Geometry for calculation of displacement ratios used in the glare formula.

The factor p can be obtained from graphs given in [Petherbridge & Longmore, 1954] or it can be calculated from tabulated values of p_H , the Hopkinson position factor [Hopkinson, 1966], since $p = p_H^{1.25}$. The values resulting from the latter approach are given in Table 7.2. Interpolation of this table is used in EnergyPlus to evaluate p at intermediate values of x_R and y_R .

Table 7.2: Position factor for glare calculation

		x_R : Horizontal Displacement Factor							
		0	0.5	1.0	1.5	2.0	2.5	3.0	>3.0
y_R :	0	1.00	0.492	0.226	0.128	0.081	0.061	0.057	0
Vertical	0.5	0.123	0.119	0.065	0.043	0.029	0.026	0.023	0
Displacement	1.0	0.019	0.026	0.019	0.016	0.014	0.011	0.011	0

Factor	1.5	0.008	0.008	0.008	0.008	0.008	0.006	0.006	0
	2.0	0	0	0.003	0.003	0.003	0.003	0.003	0
	>2.0	0	0	0	0	0	0	0	0

The background luminance is:

$$L_b = E_b \rho_b \quad (7.54)$$

where ρ_b is approximated by the average interior surface reflectance of the entire room and

$$E_b = \max(E_r, E_s) \quad (7.55)$$

where E_r is the total internally-reflected component of daylight illuminance produced by all the windows in the room and E_s is the illuminance setpoint at the reference point at which glare is being calculated. A precise calculation of E_b is not required since the glare index (see next section) is logarithmic. A factor of two variation in E_b generally produces a change of only 0.5 to 1.0 in the glare index.

7.2.12.1 Glare Index

The net daylight glare at a reference point due to all of the windows in a room is expressed in terms of a *glare index* given by

$$G_I = 10 \log_{10} \sum_{i=1}^{\text{number of windows}} G_i \quad (7.56)$$

where G_i is the glare constant at the reference point due to the i^{th} window.

7.3 Time-Step Daylighting Calculation

7.3.1 Overview

A daylighting calculation is performed each time step that the sun is up for each zone that has one or more daylighting reference points specified. The exterior horizontal illuminance from the sun and sky is determined from solar irradiance data from the weather file. The interior illuminance at each reference point is found for each window by interpolating the daylight illuminance factors for the current sun position, then, for sky-related interior illuminance, multiplying by the exterior horizontal illuminance from the appropriate sky types that time step, and, for sun-related interior illuminance, multiplying by the exterior horizontal solar illuminance that time step. By summation, the net illuminance and glare due to all of the windows in a zone are found. If glare control has been specified window shading (by movable shading devices or switchable glazing) is deployed to reduce glare. Finally the illuminance at each reference point for the final window and shade configuration is used by the lighting control system simulation to determine the electric lighting power required to meet the illuminance setpoint at each reference point.

Table 7.3: Variables in Time-Step Calculations

Mathematical variable	Description	Units	C++ variable
$S_{norm,dir}$	Direct normal solar irradiance	W/m ²	BeamSolarRad
$S_{h,dif}$	Exterior diffuse horizontal solar irradiance	W/m ²	SDIFH, DifSolarRad
$S_{h,dir}$	Exterior direct horizontal solar irradiance	W/m ²	SDIRH
Z	Solar zenith angle	radians	Zeta
m	Relative optical air mass	-	AirMass
Δ	Sky brightness	-	SkyBrightness
ε	Sky clearness	-	SkyClearness
k, k'	Sky type index	-	ISky
$s_{k,k'}$	Interpolation factor for skies k and k'	-	SkyWeight
$\psi_{k,k'}$	Sky luminance distribution formed from linear interpolation of skies k and k'	cd/m ²	-
f_k	Fraction of sky that is type k	-	-
$E_{h,k}$	Horizontal illuminance from sky type k	cd/m ²	HorIllSky
$E_{h,sky}$	Exterior horizontal illuminance from sky	lux	HISKF
$E_{h,sun}$	Exterior horizontal illuminance from sun	lux	HISUNF
η_{dif}, η_{dir}	Luminous efficacy of diffuse and direct solar radiation	lm/W	DiffLumEff, DirLumEff
I_{win}	Interior illuminance from a window	lux	DaylIllum

f_p	Fractional electric lighting input power	-	FP
N_L	Number of steps in a stepped control system	-	LightControlSteps
M_P	Lighting power multiplier	-	ZonePowerReductionFactor

7.3.2 Time-Step Sky Luminance

The sky luminance distribution, ψ , for a particular time step is expressed as a linear interpolation of two of the four standard skies — ψ_{cs} , ψ_{ts} , ψ_{is} and ψ_{os} — described above under “Sky Luminance Distributions.” The two sky types that are interpolated depend on the value of the sky clearness. The interpolation factors are a function of sky clearness and sky brightness (Perez et al., 1990). Sky clearness is given by:

$$\varepsilon = \frac{\frac{S_{h,dif} + S_{norm,dif}}{S_{h,dif}} + \kappa Z^3}{1 + \kappa Z^3} \quad (7.57)$$

where $S_{h,dif}$ is the diffuse horizontal solar irradiance, $S_{norm,dif}$ is the direct normal solar irradiance, Z is the solar zenith angle and κ is a constant equal to 1.041 for Z in radians.

Sky brightness is given by:

$$\Delta = S_{h,dif} m / S_{norm,dif}^{ext} \quad (7.58)$$

where m is the relative optical air mass and $S_{norm,dif}^{ext}$ is the extraterrestrial direct normal solar irradiance.

The relative optional air mass is calculated as follows:

$$m = \frac{1 - 1e-4 \cdot h}{\frac{\sin(b)+0.15}{(b+3.885)^{1.253}}} \quad (7.59)$$

where b is the Solar Altitude Angle, that is the angle of the sun above the horizontal (in degrees), and h is the building altitude (elevation, in meters).

$$b = \frac{\frac{\pi}{2} - Z}{\text{DegToRadians}} \quad (7.60)$$

If $\varepsilon \leq 1.2$,

$$\psi_{is,os} = s_{is,os}\psi_{is} + (1 - s_{is,os})\psi_{os} \quad (7.61)$$

where ψ_{is} is the intermediate sky luminance distribution, ψ_{os} is the overcast sky luminance distribution, and

$$s_{is,os} = \min\{1, \max[0, (\varepsilon - 1)/0.2, (\Delta - 0.05)/0.4]\} \quad (7.62)$$

If $1.2 < \varepsilon \leq 3$

$$\psi_{ts,is} = s_{ts,is}\psi_{ts} + (1 - s_{ts,is})\psi_{is} \quad (7.63)$$

where ψ_{ts} is the clear turbid sky luminance distribution and

$$s_{ts,is} = (\varepsilon - 1.2)/1.8 \quad (7.64)$$

If $\varepsilon > 3$,

$$\psi_{cs,ts} = s_{cs,ts}\psi_{cs} + (1 - s_{cs,ts})\psi_{ts} \quad (7.65)$$

where ψ_{cs} is the clear sky luminance distribution and

$$s_{cs,ts} = \min[1, (\varepsilon - 3)/3] \quad (7.66)$$

7.3.3 Interior Illuminance

For each time step the interior illuminance, I_{win} , from a window is calculated as follows by multiplying daylight factors and exterior illuminance.

First, the sun- and sky-related daylight illuminance factors for the time step are determined by interpolation of the hourly factors:

$$\bar{d}_{sun}(i_L, i_S) = w_j d_{sun}(i_L, i_S, i_h) + (1 - w_j) d_{sun}(i_L, i_S, i_h + 1) \quad (7.67)$$

$$\bar{d}_{sky,k}(i_L, i_S) = w_j d_{sky,k}(i_L, i_S, i_h) + (1 - w_j) d_{sky,k}(i_L, i_S, i_h + 1) \quad (7.68)$$

where i_L is the reference point index (1 or 2), i_S is the window shade index (1 for unshaded window, 2 for shaded window), i_h is the hour number, and k is the sky type index. For the j^{th} time step in an hour, the time-step interpolation weight is given by:

$$w_j = 1 - \min[1, j/N_t] \quad (7.69)$$

where N_t is the number of time steps per hour.

The interior illuminance from a window is calculated as:

$$I_{win}(i_L, i_S) = \bar{d}_{sun} E_{h,sun} + [\bar{d}_{sky,k}(i_L, i_S) f_k + \bar{d}_{sky,k'}(i_L, i_S) f_{k'}] E_{h,sky} \quad (7.70)$$

where $E_{h,sun}$ and $E_{h,sky}$ are the exterior horizontal illuminance from the sun and sky, respectively, and f_k and $f_{k'}$ are the fraction of the exterior horizontal illuminance from the sky that is due to sky type k and k' , respectively.

The horizontal illuminance from sun and sky are given by:

$$\begin{aligned} E_{h,sun} &= \eta_{dir} S_{norm,dir} \cos Z \\ E_{h,sky} &= \eta_{dif} S_{h,dif} \end{aligned} \quad (7.71)$$

where Z is the solar zenith angle, η_{dif} is the luminous efficacy (in lumens/Watt) of diffuse solar radiation from the sky and η_{dir} is the luminous efficacy of direct radiation from the sun. The efficacies are calculated from direct and global solar irradiance using a method described in (Perez et al, 1990), inside the DayltgLuminousEfficacy routine of the WeatherManager module.

The fractions f_k and $f_{k'}$ are given by:

$$\begin{aligned} f_k &= \frac{s_{k,k'} E_{h,k}}{s_{k,k'} E_{h,k} + (1-s_{k,k'}) E_{h,k'}} \\ f_{k'} &= \frac{(1-s_{k,k'}) E_{h,k'}}{s_{k,k'} E_{h,k} + (1-s_{k,k'}) E_{h,k'}} \end{aligned} \quad (7.72)$$

where $E_{h,k}$ and $E_{h,k'}$ are the horizontal illuminances from skies k and k' , respectively (see “Exterior Horizontal Luminance,” above), and $s_{k,k'}$ is the interpolation factor for skies k and k' (see “Time-Step Sky Luminance,” above). For example, if $\varepsilon > 3$, $k = cs$ (clear sky), $k' = ts$ (clear turbid sky) and

$$s_{k,k'} = s_{cs,ts} = \min[1, (\varepsilon - 3)/3] \quad (7.73)$$

Similarly, the window source luminance, S_{win} , and window background luminance, B_{win} , for a window are calculated from

$$S_{win}(i_L, i_S) = \bar{w}_{sun} E_{h,sun} + [\bar{w}_{sky,k}(i_L, i_S) f_k + \bar{w}_{sky,k'}(i_L, i_S) f_{k'}] E_{h,sky} \quad (7.74)$$

$$B_{win}(i_L, i_S) = \bar{b}_{sun} E_{h,sun} + [\bar{b}_{sky,k}(i_L, i_S) f_k + \bar{b}_{sky,k'}(i_L, i_S) f_{k'}] E_{h,sky} \quad (7.75)$$

The total illuminance at a reference point from all of the exterior windows in a zone is

$$I_{tot}(i_L) = \sum_{\substack{\text{windows} \\ \text{in zone}}} I_{win}(i_s, i_L) \quad (7.76)$$

where $i_s = 1$ if the window is unshaded and $i_s = 2$ if the window is shaded that time step. (Before the illuminance calculation is done the window shading control will have been simulated to determine whether or not the window is shaded.)

Similarly, the total background luminance is calculated:

$$B_{tot}(i_L) = \sum_{\substack{\text{windows} \\ \text{in zone}}} B_{win}(i_s, i_L) \quad (7.77)$$

7.3.4 Glare Index

The net glare index at each reference point is calculated as:

$$G_I(i_L) = 10 \log_{10} \sum_{\substack{\text{windows} \\ \text{in zone}}} \frac{S_{win}(i_L, i_S)^{1.6} \Omega(i_L)^{0.8}}{B(i_L) + 0.07 \omega(i_L)^{0.5} S_{win}(i_L, i_S)} \quad (7.78)$$

where

$$B(i_L) = \max(B_{win}(i_L), \rho_b I_{set}(i_L)) \quad (7.79)$$

In the last relationship, the background luminance is approximated as the larger of the background luminance from daylight and the average background luminance that would be produced by the electric lighting at full power if the illuminance on the room surfaces were equal to the setpoint illuminance. In a more detailed calculation, where the luminance of each room surface is separately determined, $B(i_L)$ would be better approximated as an area-weighted luminance of the surfaces surrounding a window, taking into account the luminance contribution from the electric lights.

7.3.4.1 Glare Control Logic

If glare control has been specified and the glare index at either reference point exceeds a user-specified maximum value, $G_{I,max}$, then the windows in the zone are shaded one by one in attempt to bring the glare at both points below $G_{I,max}$. (Each time a window is shaded the glare and illuminance at each reference point is recalculated.) The following logic is used:

- If there is only one reference point, shade a window if it is unshaded and shading it decreases the glare, even if it does not decrease the glare below $G_{I,max}$. Note that if a window has already been shaded, say to control solar gain, it will be left in the shaded state.
- If there are two reference points, then:
 - If glare is too high at both points, shade the window if it decreases glare at both points.
 - If glare is too high only at the first point, shade the window if the glare at the first point decreases, and the glare at the second point stays below $G_{I,max}$.
 - If glare is too high only at the second point, shade the window if the glare at the second point decreases, and the glare at the first point stays below $G_{I,max}$.
- Shades are closed in the order specified by the fenestration objects listed in the Window-ShadingControl object until glare at both points is below $G_{I,max}$, or until there are no more windows left to shade.

7.3.5 Lighting Control System Simulation

Once the final daylight illuminance value at each reference point has been determined, the electric lighting control is simulated. The fractional electric lighting output, f_L , required to meet the setpoint at reference point i_L is given by

$$f_L(i_L) = \max \left[0, \frac{I_{set}(i_L) - I_{tot}(i_L)}{I_{set}(i_L)} \right] \quad (7.80)$$

Here, I_{set} is the illuminance setpoint and I_{tot} is the daylight illuminance at the reference point. This relationship assumes that the electric lights at full power produce an illuminance equal to I_{set} at the reference point.

The fractional electric lighting input power, f_P , corresponding to f_L is then calculated. The relationship between f_P and f_L depends on the lighting control type.

7.3.5.1 Continuous Dimming Control

For a continuously-dimmable control system, it is assumed that f_P is constant and equal to $f_{P,min}$ for $f_L < f_{L,min}$ and that f_P increases linearly from $f_{P,min}$ to 1.0 as f_L increases from $f_{L,min}$ to 1.0 (Figure 7.4). This gives:

$$f_P = \begin{cases} f_{P,min} & \text{for } f_L < f_{L,min} \\ \frac{f_L + (1 - f_L)f_{P,min} - f_{L,min}}{1 - f_{L,min}} & \text{for } f_{L,min} \leq f_L \leq 1 \end{cases} \quad (7.81)$$

Figure 7.4: Control action for a continuous dimming system.

7.3.5.2 Continuous/Off Dimming Control

A “continuous/off” dimming system has the same behavior as a continuous dimming system except that the lights switch off for $f_L < f_{L,min}$ rather than staying at $f_{P,min}$.

7.3.5.3 Stepped Control

For a stepped control system, f_P takes on discrete values depending on the range of f_L and the number of steps, N_L (Figure 7.5). This gives:

$$f_P = \begin{cases} 0 & \text{for } f_L = 0 \\ \frac{\text{int}(N_L f_L) + 1}{N_L} & \text{for } 0 < f_L < 1 \\ 1 & \text{for } f_L = 1 \end{cases} \quad (7.82)$$

If a lighting control probability, P_L , is specified, $f(P)$ is set one level higher a fraction of the time equal to $1 - p(L)$. Specifically, if $f_P < 1$, $f_P = f_P + 1/N_L$ if a random number between 0 and 1 exceeds p_L . This can be used to simulate the uncertainty associated with manual switching of lights.

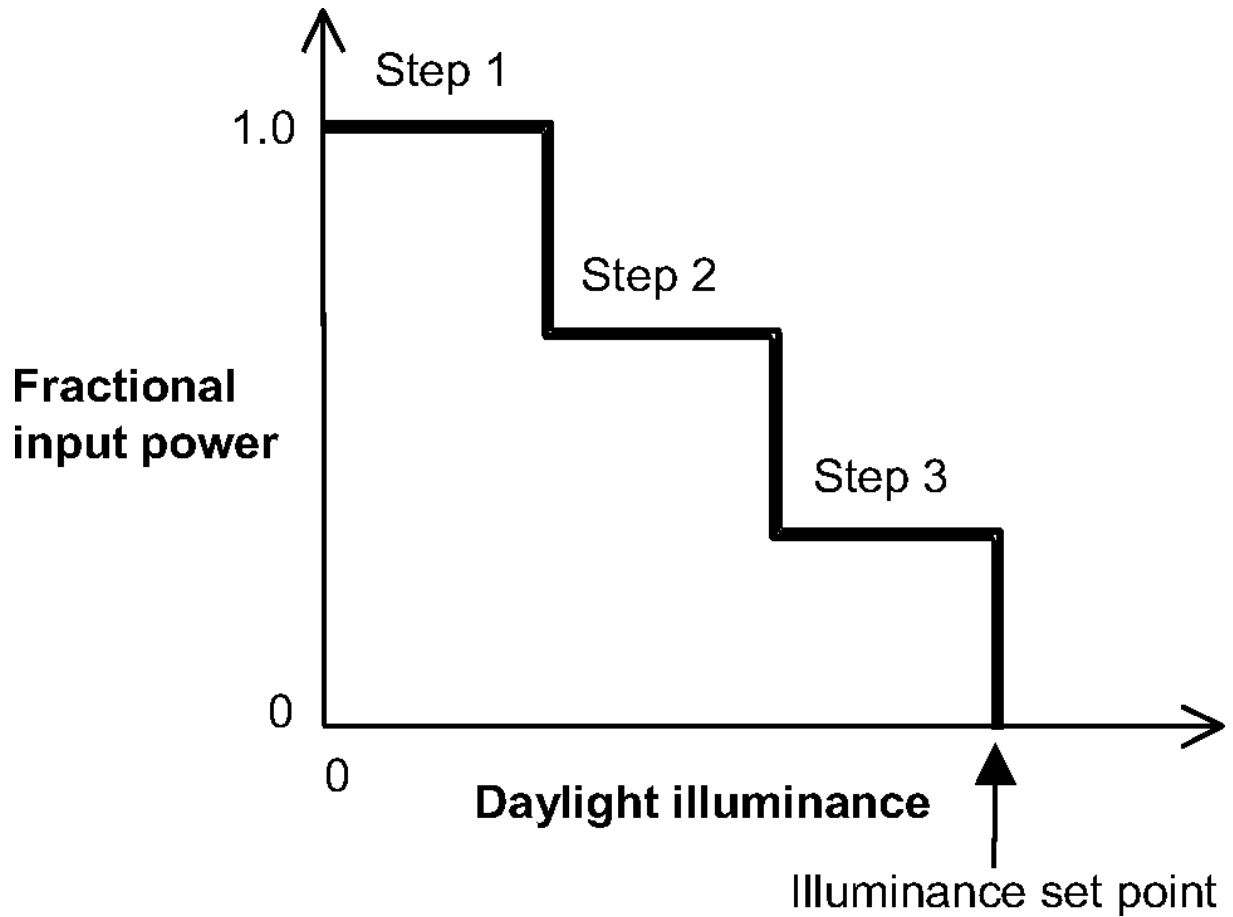

Figure 7.5: Stepped lighting control with three steps.

7.3.5.4 Lighting Power Reduction

Using the value of f_P at each reference point and the fraction f_Z of the zone controlled by the reference point, the net lighting power multiplier, M_P , for the entire zone is calculated; this value multiplies the lighting power output without daylighting.

$$M_P = \sum_{i_L=1}^2 f_P(i_L) f_Z(i_L) + \left(1 - \sum_{i_L=1}^2 f_Z(i_L) \right) \quad (7.83)$$

In this expression, the term to the right in the parentheses corresponds to the fraction of the zone not controlled by either reference point. For this fraction the electric lighting is unaffected and the power multiplier is 1.0.

7.4 DELight Daylighting Calculations

The Daylighting:Controls input objects using the DELight Daylight Method provides an alternative daylighting model to the SplitFlux method. The DELight method of analyzing daylighting applies to both simple apertures (i.e., windows and skylights) and complex fenestration systems that include geometrically complicated shading (e.g., roof monitors) and/or optically complicated glazings (e.g., prismatic or holographic glass). The DELight daylighting calculation methods are derived from the daylighting calculations in DOE-2.1E (as are the models accessed with Daylighting:Controls input object using the SplitFlux Daylighting Method), and Superlite, with several key modifications. The engineering documentation included here focuses on the details of these differences from methods documented elsewhere. For the details of the heritage calculations, refer to the section in this

documentation entitled “Daylighting Calculations” and to [Winkelmann, 1983], [Winkelmann and Selkowitz, 1985], and [Modest, 1982].

For each point in time, DELight calculates the interior daylighting illuminance at user specified reference points and then determines how much the electric lighting can be reduced while still achieving a combined daylighting and electric lighting illuminance target. The daylight illuminance level in a zone depends on many factors, including exterior light sources; location, size, and visible light transmittance of simple and complex fenestration systems; reflectance of interior surfaces; and location of reference points. The subsequent reduction of electric lighting depends on daylight illuminance level, design illuminance setpoint, fraction of zone controlled by reference point, and type of lighting control.

The DELight daylighting calculation has three main steps:

1. *Daylight Factor Calculation:* Daylight factors, which are ratios of interior illuminance to exterior horizontal illuminance, are pre-calculated and stored for later use. The user specifies the coordinates of one or more reference points in each daylight zone. DELight first calculates the contribution of light transmitted through all simple and complex fenestration systems in the zone to the illuminance at each reference point, and to the luminance at subdivided nodal patches of interior surfaces, for a given exterior luminous environment (including sky, sun, and exterior reflecting surfaces). The effect of inter-reflection of this initial light between interior reflecting surfaces is then calculated, resulting in a final total illuminance at each reference point. This total illuminance is then divided by the exterior horizontal illuminance for the given exterior environment to give a daylight factor. Daylight factors are calculated for each reference point, for a set of sun positions and sky conditions that are representative of the building location.
2. *Time-Step Interior Daylighting Calculation:* A daylighting calculation is performed for each heat-balance time step when the sun is up. In this calculation the illuminance at the reference points in each zone is found by interpolating the stored daylight factors using the current time step sun position and sky condition, then multiplying by the exterior horizontal illuminance.
3. *Electric Lighting Control Calculation:* The electric lighting control system is simulated to determine the proportion of lighting energy needed to make up the difference between the daylighting illuminance level at the given time step, and the design illuminance level. Finally, the zone lighting electric reduction factor is passed to the thermal calculation, which uses this factor to reduce the heat gain from lights.

7.4.1 DELight Daylight Factor Calculation Differences from SplitFlux Methods

- *Initial Interior Illuminance/Luminance Calculation:* DELight calculates the total initial contribution of light transmitted through all simple fenestration systems (i.e., windows and skylights) in the zone to the illuminance at each reference point, and to the luminance at each gridded nodal patch of interior surfaces. This differs from the models behind the “Daylighting:Controls” object using the SplitFlux Daylighting Method (henceforth referred to as “SplitFlux”) in two ways. The first is that SplitFlux calculates initial illuminance values at reference points for each pair of reference point and aperture (window/skylight) in the zone, whereas DELight calculates the total contribution from all apertures to each reference point. The second difference from SplitFlux is that the initial luminance of interior surface nodal patches is calculated to support the inter-reflection calculation described below. This calculation uses the same formula as SplitFlux modified for arbitrarily oriented surfaces (i.e., non-horizontal),

and to calculate luminance rather than illuminance. Note however, DELight does not account for interior surface obstructions (e.g., partitions) in this initial interior illuminance/luminance distribution. The SplitFlux method does account for interior surface obstruction of initial illuminance distribution on reference points.

- *Reference Points:* DELight allows up to 100 reference points to be arbitrarily positioned with a daylighting zone. At this time all reference points are assumed to be oriented on a horizontal virtual surface “facing” toward the zenith and “seeing” the hemisphere above the horizontal plane.
- *Complex Fenestration System Calculation:* DELight calculates the contribution to the initial interior illuminance at each reference point, and to the luminance at each gridded nodal patch of interior surfaces, of the light transmitted by complex fenestration systems (CFS). The analysis of a CFS within DELight is based on the characterization of the system using bi-directional transmittance distribution functions (BTDF), which must be either pre-calculated (e.g., using ray-tracing techniques) or pre-measured, prior to analysis by DELight. A BTDF is a set of data for a given CFS, which gives the ratios of incident to transmitted light for a range of incoming and outgoing directions. As illustrated in Figure 7.6, a BTDF can be thought of as collapsing a CFS to a “black box” that is represented geometrically as a flat two-dimensional light-transmitting surface that will be treated as an aperture surface in the daylit zone description. For each incoming direction across the exterior hemisphere of the CFS, varying portions of that light are transmitted at multiple outgoing directions across the interior hemisphere of the CFS. The two-dimensional CFS “surface” and directional hemispheres are “abstract” in that they may not literally correspond to actual CFS component geometric details.

The pre-calculated or pre-measured BTDF for a CFS is independent of its final position and orientation within a building. Once a specific instance of a CFS aperture has been positioned within a building, the incident light from all exterior sources across the CFS exterior hemisphere can be integrated over all incident directions for each relevant transmitted direction to determine the light transmitted by the CFS surface in that direction. The light transmitted by the CFS aperture is then distributed to surfaces in the zone according to its non-uniform directionality. The algorithms for this BTDF treatment of CFS in DELight are still under development, and are subject to change in the future.

- *Inter-reflected Interior Illuminance/Luminance Calculation:* The effect of inter-reflection of the initial interior illuminance/luminance between interior reflecting surfaces is calculated using a radiosity method derived from Superlite [Modest, 1982]. This method subdivides each reflecting surface in the zone into nodal patches and uses view factors between all nodal patch pairs in an iterative calculation of the total contribution of reflected light within the zone. This method replaces the SplitFlux method, resulting in a more accurate calculation of the varied distribution of inter-reflected light throughout the zone. The ability to input up to 100 reference points supports a more complete assessment of this distribution. Also, the radiosity method explicitly accounts for interior obstructions between pairs of nodal patches. The split-flux method used in the SplitFlux approach only implicitly accounts for interior surfaces by including their reflectance and surface area in the zone average surface reflectance calculations.

Figure 7.6: Bi-Directional Transmittance Data.

7.4.2 DElight Time-Step Interior Daylighting Calculation Differences from SplitFlux Methods

- *Interior Illuminance Calculation:* As discussed above, DElight only calculates daylight factors for the total contribution from all windows/skylights and CFS to each defined reference point. Thus DElight does not support dynamic control of fenestration shading during the subsequent time-step calculations, as does SplitFlux method.
- *Visual Quality:* DElight does not currently calculate a measure of visual quality such as glare due to daylighting. DElight does calculate luminance on nodal patches of all interior, reflecting surfaces. A variety of visual quality metrics could be calculated from these data in future implementations.
- *Electric Lighting Control Calculation:* Up to 100 reference points can be defined within a DElight daylighting zone. One or more of these reference points must be included in the control of the electric lighting system in the zone. Each reference point input includes the fraction of the zone controlled by that point. Values of 0.0 are valid, which allows the definition of reference points for which interior illuminance levels are calculated, but which do not control the electric lighting. Any non-zero fraction is thus the equivalent of a relative weighting given to that reference point's influence on the overall electric lighting control. The sum of all fractions for defined reference points must less than or equal to 1.0 for this relative weighting to make physical sense. If the sum is less than 1.0, the remaining fraction is assumed to have no lighting control.

7.5 Complex Fenestration Daylighting Calculations

The complex fenestration systems (CFS) daylighting calculation method results in the same Daylighting Factor style output as the it is described in Daylighting Calculations chapter.

Transmitted solar radiation reaches the daylighting sensor in two different ways. The first is an indirect path when solar radiation is reflected from surfaces and uniformly distributed into the space. The second is a direct path when the sensor is directly illuminated by the fenestration system.

For the indirect path, the method performs a one-bounce calculation to determine the diffuse illumination for the zone. For a certain sky condition, including the sun position, the method will calculate which surfaces are illuminated from each of the BSDF directions, taking into account the reflectance of the surfaces. This indirect illumination is calculated from both direct sunlight hitting a window with or without a shading device and diffuse illumination calculated from diffuse light

coming into the zone from the sky or the ground. This transmitted light strikes the zone interior surfaces and creates a diffuse component. The CFS daylighting method determines the contribution of each sky patch to the illumination of the zone surfaces based on the BSDF transmittances and then luminance is calculated based on the surface reflection.

For the direct path, the window is subdivided using existing subdivision procedures. From the center of each subdivided element, the angle is calculated to the reference point. The illuminance is calculated based on the BSDF data for the outgoing direction that corresponds to that angle and the incident illumination from sky, ground and sun.

7.5.1 Internal Average Reflected Illuminance From Window

To calculate internal average reflected illuminance from the window it is necessary to calculate transmitted flux at the window. Observing an infinitesimal window element, illuminance can originate from the sky or sun, and in both cases the ray can reach the window directly or after reflecting from the ground. Based on this, the calculation of luminance at the window is divided into three parts:

- Sky-related illuminance and luminous flux
- Sun-related illuminance and luminous flux, excluding entering beam
- Sun-related illuminance and luminous flux, due to entering beam

where total illuminance will be calculated as a superposition of these three parts.

For any case, illuminance at a window element can be calculated by using the following general approach:

$$dEW_{at_window} = Lum_{el}(\theta_{el}, \phi_{el}) \cdot \cos(\beta_{el}) \cdot \cos(\phi_{el}) \cdot d\theta_{el} \cdot d\phi_{el} \quad (7.84)$$

where dEW_{at_window} is the illuminance at a window element, $Lum_{el}(\theta_{el}, \phi_{el})$ represents the function of horizontal luminance from the exterior element in the direction (θ_{el}, ϕ_{el}) , β_{el} represents the angle at which the ray hits the surface of the window and (θ_{el}, ϕ_{el}) represents the exterior element azimuth and altitude relative to the window (see Figure 7.7).

This will produce luminous flux at the interior side of the window:

$$d\phi W_{inside} = dEW_{at_window} \cdot \tau(\beta_{el}) \cdot dA \quad (7.85)$$

where dEW_{at_window} is given by Equation 7.84, $\tau(\beta_{el})$ is the window transmittance at the incoming angle β_{el} and dA is infinitesimal window element surface area.

Integrating luminous flux given by Equation 7.84 over entire window area will give luminous flux on the interior side of the window.

To calculate the internal average reflected illuminance from the window, a similar approach will be used as described in the chapter “Internally-Reflected Component of Interior Daylight Illuminance”, which gives the flux balance equation:

$$A \cdot E_r \cdot (1 - \rho) = F_1 \quad (7.86)$$

where F_1 represents first reflected flux which in the case of non-CFS is calculated by using the split-flux method. In the case of CFS, first the reflected flux can be calculated more precisely by

Figure 7.7: Exterior Luminance Element

using light patches area. Since each CFS is described by a BSDF, it is possible to calculate the light patches for each outgoing direction (see Figure 7.8).

Figure 7.8: Complex Fenestration System Light Patches

Considering the total flux passing through the window at the outgoing direction “k”, the first reflect flux ($F_{1,k}$) can be calculated as:

$$F_{1,k} = \phi_k \cdot \frac{\sum_{a=1}^N (A_{overlap,k,a} \cdot \rho_{vis,k,a})}{\sum_{a=1}^N A_{overlap,k,a}} \quad (7.87)$$

where ϕ_k is the total flux entering the zone at the BSDF outgoing direction “k” and is calculated by integrating Equation 7.84 over the entire window area for a given outgoing direction “k”, N is the number of interior surfaces hit by the BSDF outgoing direction “k” (see Figure 7.8), $A_{overlap,k,a}$ is the surface (patch) area which the window from the BSDF outgoing direction “k” makes at surface “a” and $\rho_{vis,k,a}$ is the visible reflectance from surface “a”.

Summing all the outgoing directions will result in total first reflected flux:

$$F_1 = \sum_{k=1}^{N_{out}} F_{1,k} \quad (7.88)$$

7.5.2 Luminance from Exterior Elements

The case of CFS luminance from exterior elements can be calculated by using BSDF incoming directions defined for a given CFS. Applying Equation 7.84 for a certain incoming BSDF direction will give:

$$\Delta EW_{el,i} = Lum(\theta_i, \psi_i) \cdot \cos(\beta_i) \cdot \cos(\phi_i) \cdot \Delta\theta_i \cdot \Delta\psi_i \quad (7.89)$$

This equation can be translated in the BSDF coordinate system where, instead of standard azimuth and altitude angles, the equation will be transformed into the BSDF coordinate system. In that case, Equation 7.84 becomes:

$$\Delta EW_{el,i} = Lum(\theta_i, \psi_i) \cdot \Lambda_i \quad (7.90)$$

where Λ_i represents the lambda value for the incoming direction “i”.

7.5.3 Luminous Flux and Direct Illuminance at Interior Side of the Window

In the case of CFS it is of interest to calculate fluxes for each outgoing BSDF direction. For a given amount of illuminance at an incoming direction “i”, flux into direction “o” will be calculated as:

$$\Delta\phi W_{i,o} = \Delta EW_{el} \cdot T_{dir-dir,i,o} \quad (7.91)$$

where $T_{dir-dir,i,o}$ is the direct-direct transmittance for given incoming and outgoing directions (“i” and “o”).

Total flux from the window at the outgoing direction “o” can be calculated by summing over all the incoming directions:

$$\Delta\phi W_o = \sum_{i=1}^{N_{inc}} (\Delta EW_{el,i} \cdot T_{dir-dir,i,o}) \quad (7.92)$$

where N_{inc} is the number of BSDF incident directions.

Flux transmitted in the outgoing direction “o”, calculated by equation , can be used for any given distribution of an exterior luminous element. Knowing the intensity of the luminous flux, the direct illuminance at a certain point is calculated as:

$$ED_o = \Delta\Omega_{el} \cdot \sin(\phi_{el}) \cdot \Delta\phi W_o \quad (7.93)$$

where ED_o is the direct illuminance at the BSDF outgoing direction “o”, $\Delta\Omega_{el}$ is the spatial angle of the element viewed from a certain reference point and ϕ_{el} is the altitude of the window element viewed from the reference point.

7.5.4 Handling Exterior Obstructions

Exterior obstructions are handled for two different cases. The first case is to handle obstructions between the luminous element (sky/ground/sun) and the CFS window element. In that case,

Figure 7.9: Complex Fenestration System Flux Transition - Single Incoming Direction to Single Outgoing Direction

the direct illuminance at the window element is modified for the product of all the obstruction transmittances between the luminous and window elements, and Equation 7.84 is modified as:

$$\Delta EW_{el,i} = Lum(\theta_i, \psi_i) \cdot \Lambda_i \cdot \prod_{p=1}^{N_o} \tau_{obs,p} \quad (7.94)$$

where N_o is the number of exterior obstructions and $\tau_{obs,p}$ is the visible transmittance of obstruction “p”.

The second case is to handle all obstructions between the luminous elements and the ground element. The luminance from the ground element is calculated as:

$$Lum_{gnd} = \frac{E_h}{\pi} \cdot \rho_{gnd} \quad (7.95)$$

where E_h is the horizontal illuminance and ρ_{gnd} is the ground reflectance. Horizontal illuminance is obtained by the integration over sky/sun elements and it is of interest to examine if all elements are visible from a certain ground point. The integration examines if the ray between the sky and the ground element is hitting an obstruction. It does not take into account whether or not the obstruction is transparent, it simply counts the number of hits. The sky obstruction multiplier is calculated as:

$$SOM = \frac{NumberOfUnobstructedRays}{NumberOfRays} \quad (7.96)$$

and in case the incoming element is from the ground, the illuminance at the window element (Equation 7.84) will be additionally modified from the sky obstruction multiplier:

$$\Delta EW_{el,i} = Lum(\theta_i, \psi_i) \cdot \Lambda_i \cdot SOM \cdot \prod_{p=1}^{N_o} \tau_{obs,p} \quad (7.97)$$

7.6 Daylighting Devices

Daylighting devices are used to improve daylighting in a zone. Besides their contribution to illuminance, daylighting devices also have a thermal impact on the zone heat balance. As a result the simulation of daylighting devices is tightly integrated into both the daylighting model and the zone heat balance.

There are two types of daylighting device in EnergyPlus: tubular daylighting devices and daylighting shelves.

7.6.1 Tubular Daylighting Devices

The input object DaylightingDevice:Tubular provides a special model for fenestration components known as Tubular Daylighting Devices (TDDs), also known as tubular skylights or light pipes. TDDs are constructed of three components: a dome, a pipe, and a diffuser.

The dome is typically a hemisphere made of clear plastic. It allows daylight into the pipe while keeping exterior weather out. The pipe is assumed to be a smooth cylinder with a highly reflective inside surface. The surface is usually either bare polished metal or a special reflective sheet adhered to the inside. The pipe channels the daylight from the dome to the diffuser via multiple internal

Figure 7.10: Tubular Daylighting Devices

reflections. The diffuser is typically a flat frosted plastic cover. The diffuser evenly distributes the daylight to the zone. The dome/diffuser area and pipe area must be approximately equal (within 2%) for running the simulation successfully.

In EnergyPlus the TDD model includes three different, but related, phenomena:

- Daylighting
- Solar gains
- Conductive/convective gains

Solar gains and conductive/convective gains are simulated by the zone heat balance. Daylighting is simulated independently.

For both daylighting and heat balance simulations, the dome and diffuser are treated as special window surfaces to take advantage of many of the standard daylighting and heat transfer routines. Together the dome and diffuser become “receiver” and “transmitter”, i.e. radiation entering the dome ends up exiting the diffuser.

Figure 7.11: Dome and Diffuser Surfaces

The pipe is simulated by a separate code module. While several different measures for characterizing TDD performance are in use (Zhang 2002; Harrison 1998), the total transmittance of the TDD is most compatible with the EnergyPlus daylighting and heat balance code. Calculation of the transmittance of the pipe and the TDD for different types of radiation is fundamental to all phenomena covered by the model.

7.6.1.1 Pipe Beam Transmittance

The transmittance of beam radiation is derived from the integration of the transmittance of many discrete rays. The transmittance of a discrete ray through a pipe is dependent on the reflectivity of the inside pipe surface, the aspect ratio of the pipe, the incident angle of the ray, and the point of entry into the pipe.

Figure 7.12: Discrete Ray in a Pipe

For an opaque surface, the reflectivity is:

$$\rho = 1 - \alpha \quad (7.98)$$

where α = surface absorptivity. Visible (i.e. daylighting) and solar absorptivities give visible and solar reflectivities, respectively. Measured reflectivities for commercial TDDs range from 0.90 to 0.99. Although the actual surface reflectivity is slightly dependent on the incident angle, the model assumes a constant reflectivity for all angles.

The full analytical expression for the transmittance of a beam of light in a highly reflective pipe has been developed by Swift and Smith and verified by experiment (1994). By integrating over all rays incident on the pipe entrance, they find the transmittance of a beam of collimated radiation to be:

$$\tau = \frac{4}{\pi} \int_{s=0}^1 \frac{s^2}{\sqrt{1-s^2}} \rho^{INT[a \tan \theta / s]} (1 - (1 - \rho) (a \tan \theta / s - INT[a \tan \theta / s])) ds \quad (7.99)$$

where

$a = L/D$, the aspect ratio of the TDD

ρ = surface reflectivity

θ = incident angle

s = entry point

This integral does not have an analytical solution and must be calculated numerically. It was found that a large number of points (100,000) were necessary to achieve an acceptable accuracy. Since the integration is time consuming and the transmittance of the pipe must be utilized many times at every time step, values are calculated over a range of incident angles and stored in a table. The tabulated values are interpolated to rapidly give the transmittance at any incident angle. A polynomial fit was also considered but it was found that interpolation gave superior results.

In the graph below, interpolated values from EnergyPlus are compared to the results of ray tracing simulations performed at the Florida Solar Energy Center for an incident angle of 30 degrees (McCluney 2003).

Figure 7.13: Pipe Transmittance Comparison.

During initialization of each unique TDD, the program integrates and tabulates values for the visible and solar transmittance of the pipe. The results are subsequently used in the daylighting simulation and heat balance simulation respectively.

The effect of bends in the pipe on beam transmittance is not included in this model. Recent research (Zhang 2002) has suggested that a 30 degree bend has a 20% loss in transmitted light. If the effect of bends must be simulated, it can be approximated by the user by appropriately decreasing the transmittance of the diffuser material.

7.6.1.2 TDD Beam Transmittance

The beam transmittance of the TDD takes into account the dome and diffuser transmittances in addition to the pipe transmittance.

$$\tau_{TDD}(\theta) = \tau_{dome}(\theta)\tau_{pipe}(\theta)\tau_{diffuser} \quad (7.100)$$

where

$\tau_{dome}(\theta)$ = beam transmittance of the dome glazing at the incident angle

$\tau_{pipe}(\theta)$ = beam transmittance of the pipe at the incident angle, as described above

$\tau_{diffuser}$ = diffuse transmittance of the diffuser glazing

The dome transmittance is calculated for a flat window. The model does not take into account refraction due to the curvature of the dome surface.

Diffuse transmittance is always assumed for the diffuser because multiple internal reflections in the pipe scatter the beam with a diffusing effect. Although the light exiting the pipe is not isotropic, it can be approximated as diffuse. The use of a frosted diffuser on the TDD, however, ensures that the light delivered to the zone is very close to isotropic diffuse.

The calculation of TDD diffuse transmittance is considerably more complex and is handled differently in the daylighting simulation and the heat balance simulation. The details are discussed in the following sections.

7.6.1.3 Daylighting

The daylighting simulation of the TDD treats the diffuser surface as a regular window illuminated from the outside by sun, sky, and ground. However, the TDD model replaces the window glazing transmittance with the appropriate TDD transmittance and converts all transmitted light to diffuse.

The illuminance due to the direct beam of the sun is found using the TDD beam transmittance $\tau_{TDD}(\theta)$ as described above. The incident angle θ is relative to the dome surface.

The illuminance due to sky radiation and ground reflected radiation is calculated with the normal daylighting model integration over the sky and ground within the viewable hemisphere of the dome. The transmittance of each sky or ground element is also found using the TDD beam transmittance at the incident angle of the sky or ground element relative to the dome.

Light from the diffuser is converted to diffuse inside the zone in the same way as an interior shade.

7.6.1.4 Solar Gains

Solar radiation incident on a window is calculated separately as sun, sky, and ground radiation. A different transmittance must be applied for each type of radiation.

For beam radiation the TDD beam transmittance $\tau_{TDD}(\theta)$ for the solar spectrum is used as described above. For sky and ground radiation a diffuse transmittance for the TDD must be developed.

The transmittance of diffuse radiation can be defined as the total transmitted flux divided by the total incident flux.

$$\tau_{diff} = \frac{\sum I_{trans}}{\sum I_{inc}} \quad (7.101)$$

Swift and Smith (1994) suggest a weighted integral of the beam transmittance over the hemisphere for an arbitrary angular distribution:

$$\tau_{diff} = \frac{\int_{\theta=0}^{\pi/2} \tau(\theta) P(\theta) \sin \theta d\theta}{\int_{\theta=0}^{\pi/2} P(\theta) \sin \theta d\theta} \quad (7.102)$$

where

$P(\theta)$ = angular distribution function

For isotropic diffuse radiation $P(\theta)$ is the cosine of the incident angle θ .

$$\tau_{diff,iso} = \frac{\int_{\theta=0}^{\pi/2} \tau(\theta) \cos \theta \sin \theta d\theta}{\int_{\theta=0}^{\pi/2} \cos \theta \sin \theta d\theta} \quad (7.103)$$

For a given pipe or TDD, $\tau_{diff,iso}$ is a constant. The program calculates $\tau_{diff,iso}$ once during initialization using a numerical integration.

The diffuse isotropic transmittance is useful, but not sufficient, for determining the transmittance of sky radiation. As described in the *Sky Radiance Model* section, sky radiation has an anisotropic distribution modeled as the superposition of three simple distributions: a diffuse isotropic background, a circumsolar brightening near the sun, and a horizon brightening. While the daylighting model is capable of calculating the luminance of any position in the sky, the solar code only calculates the ultimate irradiance on a surface. For this reason it is not possible to integrate over an angular distribution function for sky radiance. Instead the three sky distributions must be handled piecewise.

$$\tau_{diff,aniso} = \frac{\sum I_{trans,aniso}}{\sum I_{inc,aniso}} = \frac{I_{trans,iso} + I_{trans,circumsolar} + I_{trans,horiz}}{I_{inc,iso} + I_{inc,circumsolar} + I_{inc,horiz}} \quad (7.104)$$

Substituting in the appropriate transmittances:

$$\tau_{diff,aniso} = \frac{\tau_{diff,iso} I_{inc,iso} + \tau(\theta) I_{inc,circumsolar} + \tau_{diff,horiz} I_{inc,horiz}}{I_{inc,iso} + I_{inc,circumsolar} + I_{inc,horiz}} \quad (7.105)$$

where

$\tau_{diff,iso}$ = diffuse isotropic transmittance

$\tau(\theta)$ = beam transmittance at incident angle θ of sun

$\tau_{diff,horiz}$ = diffuse transmittance of the horizon, derived below

It is important to note that transmittances above are for the total TDD. The transmittance of the dome and diffuser must be included to account for their angular dependences as well.

The beam transmittance is used as an approximation for all circumsolar radiation.

The diffuse horizon transmittance is found by integrating the beam transmittance over the arc of the horizon.

$$\tau_{diff,horiz} = \frac{\sum I_{trans,horiz}}{\sum I_{inc,horiz}} = \frac{\int_{\theta=-\pi/2}^{\pi/2} \tau(\theta) \cos \theta d\theta}{\int_{\theta=-\pi/2}^{\pi/2} \cos \theta d\theta} \quad (7.106)$$

Since the radiance of the horizon is isotropic, and therefore constant across the entire horizon, the actual value of the radiance cancels out. The result is a constant that is calculated once during initialization.

Ground radiation is assumed to be isotropic diffuse. The transmittance of ground radiation is the diffuse isotropic transmittance.

$$\tau_{diff,gnd} = \tau_{diff,iso} \quad (7.107)$$

The solar flux transmitted by a TDD due to beam, sky, and ground radiation is calculated as normal for a window but uses the respective transmittances for the TDD.

$$q''_{TDD-trans,beam} = (I_{sun} \cos \theta) f_{sunlit} \tau_{TDD}(\theta) \quad (7.108)$$

$$q''_{TDD-trans,sky} = I_{h,sky} f_{skymult} \tau_{TDD,diff,aniso} \quad (7.109)$$

$$q''_{TDD-trans,gnd} = (I_{sun} \cos \theta + I_{h,sky}) F_{sg} \tau_{TDD,diff,iso} \quad (7.110)$$

where

I_{sun} = solar beam intensity of the sun

$I_{h,sky}$ = total horizontal diffuse solar radiation due to the sky

θ = incident angle of the beam on the dome

f_{sunlit} = sunlit beam fraction of the dome area

$f_{skymult}$ = anisotropic sky view multiplier (see AnisoSkyMult)

F_{sg} = view from ground to dome

$\tau_{TDD}(\theta)$ = TDD beam transmittance

$\tau_{TDD,diff,aniso}$ = TDD anisotropic sky transmittance

$\tau_{TDD,diff,iso}$ = TDD isotropic diffuse transmittance

7.6.1.5 Daylighting vs. Solar

The beam transmittance of a TDD is calculated in the same way for both daylighting and solar gains. If the visible and solar properties (i.e. absorptances in the input file) are the same, the reported TDD beam transmittances are equal.

However, because the daylighting and solar models treat diffuse radiation differently, the TDD diffuse transmittances reported for visible and solar radiation will not necessarily be equal, even though the properties may be the same.

Since the daylighting model calculates the diffuse illuminance using a sky and ground integration of many discrete elements, a visible diffuse transmittance is not required for the TDD daylighting simulation. For reporting purposes only, the visible diffuse transmittance is estimated concurrent with the sky and ground integration using:

$$\tau_{diff} = \frac{\int \tau_{TDD}(\theta) d\Phi_{inc}}{\int d\Phi_{inc}} \quad (7.111)$$

7.6.1.6 Conductive/Convective Gains

For conductive and convective heat gain, TDDs are treated as one entity with an effective thermal resistance (i.e. R-value) between the outside and inside surfaces. The outside face temperature of the dome and the inside face temperature of the diffuser are calculated as usual by the outside and inside heat balances respectively. The temperatures are then copied to the inside face of the dome and the outside face of the diffuser. Normal exterior and interior convection and IR radiation exchange occurs for both surfaces.

Although little research has been done on the thermal characteristics of TDDs, one experiment (Harrison 1998) reports an average effective thermal resistance of 0.279 m² K/W for a commercial TDD measuring 0.33 m in diameter by 1.83 m in length. This value, however, reflects a measurement from outdoor air temperature to indoor air temperature. The model assumes an effective thermal resistance from outside surface temperature to inside surface temperature.

Solar radiation is inevitably absorbed by the TDD before it reaches the zone. Every reflection in the pipe leaves behind some solar radiation according to the surface absorptance. Rays incident at a greater angle make more reflections and leave behind more absorbed solar in the pipe wall.

The total absorbed solar radiation in the TDD is the sum of the following gains:

- Inward bound solar absorbed by multiple pipe reflections
- Outward bound solar absorbed by multiple pipe reflections due to: reflection off of diffuser surface (inside of TDD) and zone diffuse interior shortwave incident on the diffuser from lights, etc.
- Inward flowing absorbed solar in dome and diffuser glazing

$$Q_{abs,pipe} = Q_{abs,in} + Q_{abs,out} + Q_{abs,glazing} \quad (7.112)$$

The inward bound solar absorbed by the pipe is the difference between the solar transmitted by the dome and the solar incident on the diffuser.

$$Q_{abs,in} = q''_{trans,dome} A_{dome} - q''_{inc,diffuser} A_{diffuser} \quad (7.113)$$

The solar transmitted by the dome $q''_{trans,dome}$ is calculated as usual for a window. The solar incident on the diffuser $q''_{inc,diffuser}$ is more complicated because each component must be treated separately.

$$q''_{inc,diffuser} = q''_{beam} \frac{\tau_{TDD,beam}(\theta)}{\tau_{diffuser}} + q''_{sky} \frac{\tau_{TDD,aniso}(Hour)}{\tau_{diffuser}} + q''_{gnd} \frac{\tau_{TDD,iso}}{\tau_{diffuser}} \quad (7.114)$$

The outward bound solar absorbed by the pipe is given by:

$$Q_{abs,out} = \left(q''_{refl,diffuser} \frac{(1 - \tau_{TDD})}{\tau_{diffuser}} + q''_{zoneSW} (1 - \tau_{TDD}) \right) A_{diffuser} \quad (7.115)$$

where q''_{zoneSW} is the zone interior diffuse shortwave flux from window, lights, and ambient surface reflections, and

$$q''_{refl,diffuser} = q''_{inc,diffuser} - q''_{abs,diffuser} - q''_{trans,diffuser} \quad (7.116)$$

The inward flowing portion of solar absorbed in the dome and diffuser glazing is:

$$Q_{abs,glazing} = \frac{q''_{abs,dome} A_{dome}}{2} + \frac{q''_{abs,diffuser} A_{diffuser}}{2} \quad (7.117)$$

All absorbed solar radiation in the TDD is distributed among the transition zones that the pipe passes through between dome and diffuser. The transition zone heat gain is proportional to the length of the zone. Any exterior length of pipe also receives a proportional amount of heat, but this is lost to the outside.

7.6.2 Daylighting Shelves

The input object `DaylightingDevice:Shelf` provides a special model for light shelves used to augment daylighting. Light shelves are constructed from up to three components: a window, an inside shelf, and an outside shelf. The inside shelf acts to reflect all transmitted light from the upper window onto the ceiling of the zone as diffuse light. The outside shelf changes the amount of light incident on the window. All light reflected from the outside shelf also goes onto the zone ceiling. The inside shelf and outside shelf are both optional. However, if neither shelf is specified, the daylighting shelf object has no effect on the simulation.

The window is divided into two window surfaces: an upper window and a lower window. The upper window interacts with the daylighting shelf but the lower window does not, except to receive shading from the outside shelf.

Figure 7.14: Daylighting Shelf Diagram

Daylighting shelves are simulated separately for daylighting and the zone heat balance. The general model is similar in both cases, but the details vary.

7.6.2.1 Inside Shelf Daylighting

The inside shelf is modeled in the daylighting simulation by converting all light transmitted by the upper window into diffuse upgoing flux. It is assumed that no beam or downgoing flux can pass the end of the shelf regardless of the shelf's position or orientation.

In the daylighting simulation this is accomplished by forcing all the transmitted flux to be upgoing:

$$\Phi_{CW} = \Phi \quad (7.118)$$

$$\Phi_{FW} = 0 \quad (7.119)$$

where

Φ_{CW} = upgoing flux

Φ_{FW} = downgoing flux

Φ = total flux

Since it is assumed that all light falls on the inside shelf, it is implied that the upper window cannot contribute any direct illuminance (i.e. the upper window cannot be seen from anywhere in the zone). The remaining light is entirely interreflected sky-related and interreflected sun-related upgoing flux.

7.6.2.2 Inside Shelf Heat Balance

In the heat balance simulation the inside shelf is defined as an interzone heat transfer surface, e.g. partition. Since the inside shelf external boundary condition is required to refer to itself, the shelf is essentially equivalent to internal mass. Because the shelf surface has two sides that participate in the zone heat balance, the surface area is doubled by the program during initialization. Like internal mass, the shelf surface is allowed to interact convectively and radiatively with the zone air and other zone surfaces.

The zone interior solar distribution is modified by the inside shelf. Regardless of the solar distribution selected in the input file, all beam solar radiation transmitted by the upper window is incident on one side (half the doubled surface area) of the shelf surface. The beam radiation not absorbed is reflected throughout the zone as diffuse shortwave radiation. The treatment of sky and ground radiation is unchanged; both are added directly to the zone diffuse shortwave.

The total beam, sky, and ground radiation transmitted by the upper window does not change.

7.6.2.3 Outside Shelf Daylighting

In the daylighting model the luminous flux transmitted by the upper window is determined by integrating over the sky and ground and summing the luminance contribution of each sky or ground element. The luminance of any intervening exterior or interior surfaces is assumed to be zero. As a shading surface, the effect of the outside shelf during the integration is to block part of the view of the ground, thereby reducing the window transmitted flux due to diffuse ground luminance. After the integration is complete, the program calculates the amount of diffuse light that is reflected through

the window from the outside shelf and adds it as a lump sum to the upgoing flux transmitted by the window.

The additional shelf upgoing flux is the sum of sun-related and sky-related flux:

$$\Phi_{shelf,CW} = \Phi_{shelf,sun} + \Phi_{shelf,sky} \quad (7.120)$$

where

$$\Phi_{shelf,sun} = (E_{sun} \cos \theta) f_{sunlit} \rho_{vis} F_{ws} \tau_{diff,vis} \quad (7.121)$$

$$\Phi_{shelf,sky} = E_{h,sky} f_{skymult} \rho_{vis} F_{ws} \tau_{diff,vis} \quad (7.122)$$

and

E_{sun} = exterior illuminance due to light from the sun

$E_{h,sky}$ = exterior horizontal illuminance due to light from the sky

θ = incident angle of the beam on the shelf

f_{sunlit} = sunlit beam fraction of the shelf surface area

$f_{skymult}$ = anisotropic sky view multiplier (see AnisoSkyMult)

ρ_{vis} = shelf surface reflectivity in the visible spectrum

F_{ws} = view factor from window to shelf

$\tau_{diff,vis}$ = diffuse window transmittance in the visible spectrum

The sunlit beam fraction f_{sunlit} and the anisotropic sky view multiplier $f_{skymult}$ are borrowed from the heat balance solar calculations.

The sunlit beam fraction f_{sunlit} takes into account the effect of shading due to other surfaces. Although shadows on the shelf surface change the luminance distribution of the shelf, there is no angular dependence because diffuse properties are assumed. Therefore, the flux is simply proportional to the sunlit fraction.

The anisotropic sky view multiplier $f_{skymult}$ takes into account the anisotropic distribution of sky radiation, the shelf view factor to the sky, and shading. This value is utilized in the heat balance simulation for solar calculations but is not currently available in the daylighting simulation. A value of 1.0 is assumed until a better model is developed. For this reason the sky-related flux may be over-predicted for some building and shelf geometries. However, for clear sky conditions the sun-related flux is dominant and the resulting error is small.

The view factor to the outside shelf, F_{ws} , if not specified by the user in the input object, is an exact view factor calculated for adjacent perpendicular rectangles.

For this geometry the view factor is given by (Mills 1995):

$$F_{ws} = \frac{1}{\pi M} \left\{ M \tan^{-1} \left(\frac{1}{M} \right) + N \tan^{-1} \left(\frac{1}{N} \right) - (M^2 + N^2)^{1/2} \tan^{-1} \left((M^2 + N^2)^{-1/2} \right) \right. \\ \left. + \frac{1}{4} \ln \left[\left(\frac{(1+M^2)(1+N^2)}{1+M^2+N^2} \right) \left(\frac{M^2(1+M^2+N^2)}{(1+M^2)(M^2+N^2)} \right)^{M^2} \left(\frac{N^2(1+M^2+N^2)}{(1+N^2)(M^2+N^2)} \right)^{N^2} \right] \right\} \quad (7.123)$$

where

$$M = H/W \quad (7.124)$$

$$N = L/W \quad (7.125)$$

Figure 7.15: Window and Outside Shelf as Adjacent Perpendicular Rectangles.

7.6.2.4 Outside Shelf Heat Balance

The heat balance simulation does not do a sky and ground integration. View factors to sky and ground are used instead. Consequently, the heat balance calculation for the outside shelf is very similar to the daylighting calculation. The main difference is that the incident flux on the upper window is calculated first and reported. The transmitted and absorbed fractions are subsequently determined.

The solar flux incident on the upper window due to the shelf is given by:

$$q''_{shelf-inc} = q''_{shelf-inc,sun} + q''_{shelf-inc,sky} \quad (7.126)$$

where

$$q''_{shelf-inc,sun} = (I_{sun} \cos \theta) f_{sunlit} \rho_{sol} F_{ws} \quad (7.127)$$

$$q''_{shelf-inc,sky} = I_{h,sky} f_{skymult} \rho_{sol} F_{ws} \quad (7.128)$$

and

I_{sun} = solar beam intensity of the sun

$I_{h,sky}$ = total horizontal diffuse solar radiation due to the sky

θ = incident angle of the beam on the shelf

f_{sunlit} = sunlit beam fraction of the surface area

$f_{skymult}$ = anisotropic sky view multiplier (see AnisoSkyMult)

ρ_{sol} = shelf surface reflectivity in the solar spectrum

F_{ws} = view factor from window to shelf

The view factor F_{ws} is the same as described above for daylighting.

The total diffuse incident radiation due to the shelf is internally added to the ground diffuse incident radiation on the window. For reporting purposes the shelf radiation is included in the *Surface Outside Face Incident Ground Diffuse Solar Radiation Rate per Area* output variable.

With the incident radiation determined, the remaining window heat balance is calculated normally. The resulting transmitted diffuse radiation from the sky, ground, and shelf is:

$$q''_{trans} = (q''_{sky-inc} + q''_{gnd-inc} + q''_{shelf-inc}) \tau_{diff,sol} \quad (7.129)$$

where

$\tau_{diff,sol}$ = diffuse window transmittance in the solar spectrum

7.6.3 Window Light Well

The input object DaylightingDevice:LightWell provides a model for attenuation of light transmitted by windows and skylights that can result from surrounding interior finish surfaces that form a “light well.” The light well model simply attenuates the light transmitted by the exterior window. The model does not redirect light distributions or alter the relative mixture of diffuse and beam transmitted by the window.

The attenuation is characterized by the **well efficiency**, which is the ratio of the amount of light leaving the well to the amount of light entering the well. The well efficiency varies from close to 1.0 to close to zero if there is high attenuation. The well efficiency is used only in the EnergyPlus detailed daylighting calculation, where it multiplies the beam and diffuse light transmitted by the skylight. (The well efficiency is not used in calculating the solar gain through the skylight.)

Figure 7.16: Skylight with light well: (a) perspective view, (b) vertical section. If the bottom of the light well is a rectangle of side lengths c and d , as shown in (a), then the perimeter of the bottom of the well = $2(c+d)$ and the area = cd (see description of field names for the Light Well object).

The well efficiency depends on the visible reflectance of well's side walls and on the well cavity ratio, **WCR**, which is given by:

$$WCR = \frac{2.5 \times \text{Well Height} \times \text{Well Perimeter}}{\text{Well Area}} \quad (7.130)$$

Well Height, Well Perimeter and Well Area are inputs to the model and are discussed in the figure caption above.

The model in EnergyPlus was implemented by fitting a curve to the data presented as Figure 8-21, “Efficiency factors for various depths of light wells based on well-interreflectance values,” found in the Lighting Handbook (IES 1993). The figure below reproduces that reference data and shows well efficiency vs. WCR for different side wall reflectances. For use in the EnergyPlus calculation, a fit has been made to this graph that gives the following mathematical expression, where “Reflectance” is the user input value of the well-wall reflectance expressed as a fraction:

$$\text{Well efficiency} = e^{-WCR \cdot (0.16368 - 0.144678 \cdot \text{Reflectance})} \quad (7.131)$$

Figure 7.17: Graph showing light well efficiency vs. well cavity ratio (WCR) for well-wall visible reflectances of 80% (upper curve), 60% (middle curve) and 40% (lower curve). Based on Fig. 8-21 of the Lighting Handbook: Reference and Application, 8th Edition, 1993, Illuminating Engineering Society of North America.

The well efficiency calculated using this curve fit and user inputs is then applied to daylight transmission rates to attenuate daylight as a result of the presence of the light well,

7.7 Window Calculation Module

This section describes two potential modeling approaches for Windows. The first (layer by layer) is implemented. The second, simple approach, reuses the layer-by-layer approach but converts an arbitrary window performance into an equivalent single layer.

The primary Window calculation is a layer-by-layer approach where windows are considered to be composed of the following components, only the first of which, glazing, is required to be present:

- **Glazing**, which consists of one or more plane/parallel glass layers. If there are two or more glass layers, the layers are separated by gaps filled with air or another gas. The glazing optical and thermal calculations are based on algorithms from the WINDOW 4 and WINDOW 5 programs [Arasteh et al., 1989], [Finlayson et al., 1993]. Glazing layers are described using the input object WindowMaterial:Glazing.
- **Gap**, layers filled with air or another gas that separate glazing layers. Gaps are described using the input object WindowMaterial:Gas.
- **Frame**, which surrounds the glazing on four sides. Frames are described using the input object WindowProperty:FrameAndDivider.
- **Divider**, which consists of horizontal and/or vertical elements that divide the glazing into individual lites.
- **Shading device**, which is a separate layer, such as drapery, roller shade or blind, on the inside or outside of the glazing, whose purpose is to reduce solar gain, reduce heat loss (movable insulation) or control daylight glare. Shading layers are described using “WindowShading-Control” input objects.

In the following, the description of the layer-by-layer glazing algorithms is based on material from Finlayson et al., 1993. The frame and divider thermal model, and the shading device optical and thermal models, are new to EnergyPlus.

A second approach has been developed where windows are modeled in a simplified approach that requires minimal user input that is processed to develop an equivalent layer that then reuses much of the layer-by-model. This “Simple Window Construction: model is described below.

7.7.1 Optical Properties of Glazing

The solar radiation transmitted by a system of glass layers and the solar radiation absorbed in each layer depends on the solar transmittance, reflectance and absorptance properties of the individual layers. The absorbed solar radiation enters the glazing heat balance calculation that determines the inside surface temperature and, therefore, the heat gain to the zone from the glazing (see “Window Heat Balance Calculation”). The transmitted solar radiation is absorbed by interior zone surfaces

and, therefore, contributes to the zone heat balance. In addition, the visible transmittance of the glazing is an important factor in the calculation of interior daylight illuminance from the glazing.

Table 7.4: Variables in Window Calculations

Mathematical variable	Description	Units	C++ variable
T	Transmittance	-	-
R	Reflectance	-	-
R^f, R^b	Front reflectance, back reflectance	-	-
$T_{i,j}$	Transmittance through glass layers i to j	-	-
T_{gl}^{dir}	Direct transmittance of glazing	-	-
$R_{i,j}^f, R_{i,j}^b$	Front reflectance, back reflectance from glass layers i to j	-	-
$R_{gl,f}^{dir}, R_{gl,b}^{dir}$	Direct front and back reflectance of glazing	-	-
A_i^f, A_i^b	Front absorptance, back absorptance of layer i	-	-
N	Number of glass layers	-	Nlayer
λ	Wavelength	microns	Wle
$E_s(\lambda)$	Solar spectral irradiance function	W/m ² -micron	E
$V(\lambda)$	Photopic response function of the eye	-	y30
φ	Angle of incidence (angle between surface normal and direction of incident beam radiation)	Rad	Phi
τ	Transmittivity or transmittance	-	tf0
ρ	Reflectivity or reflectance	-	rf0, rb0
α	Spectral absorption coefficient	m ⁻¹	-
d	Glass thickness	M	Material.Thickness
n	Index of refraction	-	ngf, ngb
κ	Extinction coefficient	-	-
β	Intermediate variable	-	betaf, betab
P, p	A general property, such as transmittance	-	-
τ_{sh}	Shade transmittance	-	Material.Trans
ρ_{sh}	Shade reflectance	-	Material.ReflectShade
α_{sh}	Shade absorptance	-	Material.AbsorpSolar
$\tau_{bl}, \rho_{bl}, \alpha_{bl}$	Blind transmittance, reflectance, absorptance	-	-
Q, G, J	Source, irradiance and radiosity for blind optical properties calculation	W/m ²	-

Table 7.4: Variables in Window Calculations

Mathematical variable	Description	Units	C++ variable
F_{ij}	View factor between segments i and j	-	-
f_{switch}	Switching factor	-	SwitchFac
T	Transmittance	-	-
R	Reflectance	-	-
R^f, R^b	Front reflectance, back reflectance	-	-
$T_{i,j}$	Transmittance through glass layers i to j	-	-
$R_{i,j}^f, R_{i,j}^b$	Front reflectance, back reflectance from glass layers i to j	-	-
A_i^f, A_i^b	Front absorptance, back absorptance of layer i	-	-
N	Number of glass layers	-	Nlayer
λ	Wavelength	microns	Wle
$E_s(\lambda)$	Solar spectral irradiance function	W/m ² -micron	E
$R(\lambda)$	Photopic response function of the eye	-	y30
φ'	Relative azimuth angle (angle between screen surface normal and vertical plane through sun, Ref. Figure 87)	Rad	SunAzimuthToScreenNormal
α'	Relative altitude angle (angle between screen surface horizontal normal plane and direction of incident beam radiation, Ref. Figure 87)	Rad	SunAltitudeToScreenNormal
ρ_{sc}	Beam-to-diffuse solar reflectance of screen material	-	Screens.ReflectCylinder
γ	Screen material aspect ratio	-	Screens.ScreenDiameterToSpacingRatio
A	Spectral absorption coefficient	m ⁻¹	-
D	Glass thickness	M	Material.Thickness

K	Extinction coefficient	-	-
B	Intermediate variable	-	betaf, betab
P, p	A general property, such as transmittance	-	-

7.7.2 Glass Layer Properties

In EnergyPlus, the optical properties of individual glass layers are given by the following quantities at normal incidence as a function of wavelength:

Transmittance, T

Front reflectance, R^f

Back reflectance, R^b

Here “front” refers to radiation incident on the side of the glass closest to the outside environment, and “back” refers to radiant incident on the side of the glass closest to the inside environment. For glazing in exterior walls, “front” is therefore the side closest to the outside air and “back” is the side closest to the zone air. For glazing in interior (i.e., interzone) walls, “back” is the side closest to the zone in which the wall is defined in and “front” is the side closest to the adjacent zone.

7.7.3 Glass Optical Properties Conversion

7.7.3.1 Conversion from Glass Optical Properties Specified as Index of Refraction and Transmittance at Normal Incidence

The optical properties of uncoated glass are sometimes specified by index of refraction, n ,^{*}^{*} and transmittance at normal incidence, T .

The following equations show how to convert from this set of values to the transmittance and reflectance values required by Material:WindowGlass. These equations apply only to uncoated glass, and can be used to convert either spectral-average solar properties or spectral-average visible properties (in general, n and T are different for the solar and visible). Note that since the glass is uncoated, the front and back reflectances are the same and equal to the R that is solved for in the following equations.

Given n and T , find R :

$$\begin{aligned} r &= \left(\frac{n-1}{n+1} \right)^2 \\ \tau &= \frac{[(1-r)^4 + 4r^2 T^2]^{1/2} - (1-r)^2}{2r^2 T} \\ R &= r + \frac{(1-r)^2 r \tau^2}{1 - r^2 \tau^2} \end{aligned} \tag{7.132}$$

Example:

$$\begin{aligned} T &= 0.86156 \\ n &= 1.526 \\ r &= \left(\frac{1.526-1}{1.526+1} \right)^2 \\ \tau &= 0.93974 \\ R &= 0.07846 \end{aligned} \tag{7.133}$$

7.7.4 Simple Window Model

EnergyPlus includes an alternate model that allows users to enter in simplified window performance indices. This model is accessed through the WindowMaterial:SimpleGlazingSystem input object and converts the simple indices into an equivalent single layer window. (In addition a special model is used to determine the angular properties of the system – described below). Once the

model generates the properties for the layer, the program reuses the bulk of the layer-by-layer model for subsequent calculations. The properties of the equivalent layer are determined using the step by step method outlined by Arasteh, Kohler, and Griffith (2009) with modifications to formulate the angular performance in a manner consistent with the angular properties for coated glass in other window models. The core equations are documented here. The reference contains additional information.

The simplified window model accepts U and SHGC indices and is useful for several reasons:

- 1) Sometimes, the only thing that is known about the window are its U and SHGC;
- 2) Codes, standards, and voluntary programs are developed in these terms;
- 3) A single-layer calculation is faster than multi-layer calculations.

Note: This use of U and SHGC to describe the thermal properties of windows is only appropriate for specular glazings.

While it is important to include the ability to model windows with only U-value and SHGC, we note that any method to use U and SHGC alone in building simulation software will inherently be approximate. This is due primarily to the following factors:

- SHGC combines directly transmitted solar radiation and radiation absorbed by the glass which flows inward. These have different implications for space heating/cooling. Different windows with the same SHGC often have different ratios of transmitted to absorbed solar radiation.
- SHGC is determined at normal incidence; angular properties of glazings vary with number of layers, tints, coatings. So products which have the same SHGC, can have different angular properties.
- Window U-factors vary with temperatures.

Thus, for modeling specific windows, we recommend using more detailed data than just the U and SHGC, if at all possible.

The simplified window model determines the properties of an equivalent layer in the following steps.

7.7.4.1 Step 1. Determine glass-to-glass Resistance.

Window U-values include interior and exterior surface heat transfer coefficients. The resistance of the bare window product, or glass-to-glass resistance is augmented by these film coefficients so that,

$$\frac{1}{U} = R_{i,w} + R_{o,w} + R_{l,w} \quad (7.134)$$

Where,

$R_{i,w}$ is the resistance of the interior film coefficient under standard winter conditions in units of $\text{m}^2 \cdot \text{K}/\text{W}$,

$R_{o,w}$ is the resistance of the exterior film coefficient under standard winter conditions in units of $\text{m}^2 \cdot \text{K}/\text{W}$, and

$R_{l,w}$ is the resistance of the bare window under winter conditions (without the film coefficients) in units of $\text{m}^2 \cdot \text{K}/\text{W}$.

The values for $R_{i,w}$ and $R_{o,w}$ depend on U and are calculated using the following correlations.

$$R_{i,w} = \frac{1}{(0.359073 \ln(U) + 6.949915)}; \quad \text{for } U < 5.85 \quad (7.135)$$

$$R_{i,w} = \frac{1}{(1.788041 U - 2.886625)}; \quad \text{for } U \geq 5.85 \quad (7.136)$$

$$R_{o,w} = \frac{1}{(0.025342 U + 29.163853)} \quad (7.137)$$

So that the glass-to-glass resistance is calculated using:

$$R_{l,w} = \frac{1}{U} - R_{i,w} - R_{o,w} \quad (7.138)$$

Because the window model in EnergyPlus is for flat geometries, the models are not necessarily applicable to low-performance projecting products, such as skylights with uninsulated curbs. The model cannot support glazing systems with a U higher than 7.0 because the thermal resistance of the film coefficients alone can provide this level of performance and none of the various resistances can be negative.

7.7.4.2 Step 2. Determine Layer Thickness.

The thickness of the equivalent layer in units of meters is calculated using,

$$Thickness = \begin{cases} 0.002 & \text{for } \frac{1}{R_{l,w}} > 7.0 \\ 0.05914 - \frac{0.00714}{R_{l,w}} & \text{for } \frac{1}{R_{l,w}} \leq 7.0 \end{cases} \quad (7.139)$$

7.7.4.3 Step 3. Determine Layer Thermal Conductivity

The effective thermal conductivity, λ_{eff} , of the equivalent layer is calculated using,

$$\lambda_{eff} = \frac{Thickness}{R_{l,w}} \quad (7.140)$$

7.7.4.4 Step 4. Determine Layer Solar Transmittance

The layer's solar transmittance at normal incidence, T_{sol} , is calculated using correlations that are a function of SHGC and U-Factor.

$$T_{sol} = 0.939998 SHGC^2 + 0.20332 SHGC; \quad U > 4.5; SHGC < 0.7206 \quad (7.141)$$

$$T_{sol} = 1.30415 SHGC - 0.30515; \quad U > 4.5; SHGC \geq 0.7206 \quad (7.142)$$

$$T_{sol} = 0.41040 SHGC; \quad U < 3.4; SHGC \leq 0.15 \quad (7.143)$$

$$T_{sol} = 0.085775 SHGC^2 + 0.963954 SHGC - 0.084958; \quad U < 3.4; SHGC > 0.15 \quad (7.144)$$

And for U-values between 3.4 and 4.5, the value for T_{sol} is interpolated using results of the equations for both ranges.

7.7.4.5 Step 5. Determine Layer Solar Reflectance

The layer's solar reflectance is calculated by first determining the inward flowing fraction which requires values for the resistance of the inside and outside film coefficients under summer conditions, $R_{i,s}$ and $R_{o,s}$, respectively. The correlations are:

$$\begin{aligned}
 R_{i,s} &= \frac{1}{\left(29.436546 (SHGC - T_{Sol})^3 - 21.943415 (SHGC - T_{Sol})^2 + 9.945872 (SHGC - T_{Sol}) + 7.426151\right)}; U > 4.5 \\
 R_{i,s} &= \frac{1}{\left(199.8208128 (SHGC - T_{Sol})^3 - 90.639733 (SHGC - T_{Sol})^2 + 19.737055 (SHGC - T_{Sol}) + 6.766575\right)}; U < 3.4 \\
 R_{o,s} &= \frac{1}{(2.225824 (SHGC - T_{Sol}) + 20.57708)}; U > 4.5 \\
 R_{o,s} &= \frac{1}{(5.763355 (SHGC - T_{Sol}) + 20.541528)}; U < 3.4
 \end{aligned} \tag{7.145}$$

And for U-values between 3.4 and 4.5, the values are interpolated using results from both sets of equations.

The inward flowing fraction, $Frac_{inward}$, is then calculated using:

$$Frac_{inward} = \frac{(R_{o,s} + 0.5 R_{l,w})}{(R_{o,s} + R_{l,w} + R_{i,s})} \tag{7.146}$$

Then, the solar reflectances of the front face, $R_{s,f}$, and back face, $R_{s,b}$, are calculated using:

$$R_{s,f} = R_{s,b} = 1 - T_{Sol} - \frac{(SHGC - T_{Sol})}{Frac_{inward}} \tag{7.147}$$

The thermal absorptance, or emittance, is taken as 0.84 for both the front and back and the longwave transmittance is 0.0.

7.7.4.6 Step 6. Determine Layer Visible Properties

The user has the option of entering a value for visible transmittance as one of the simple performance indices. If the user does not enter a value, then the visible properties are the same as the solar properties. If the user does enter a value then layer's visible transmittance at normal incidence, T_{Vis} , is set to that value. The visible light reflectance for the back surface is calculated using:

$$R_{Vis,b} = -0.7409 T_{Vis}^3 + 1.6531 T_{Vis}^2 - 1.2299 T_{Vis} + 0.4547 \tag{7.148}$$

The visible light reflectance for the front surface is calculated using:

$$R_{Vis,f} = -0.0622 T_{Vis}^3 + 0.4277 T_{Vis}^2 - 0.4169 T_{Vis} + 0.2399 \tag{7.149}$$

7.7.4.7 Step 7. Determine Angular Performance

The angular properties of windows are important because during energy modeling, the solar incidence angles are usually fairly high. Angles of incidence are defined as angles from the normal direction extending out from the window. The simple glazing system model includes a range of correlations that are selected based on the values for U and SHGC. These were chosen to match the types of windows likely to have such performance levels. The matrix of possible combinations of U and SHGC values have been mapped to a set of 28 bins shown in the Figure 7.18.

Figure 7.18: Diagram of Transmittance and Reflectance Correlations Used based on U and SHGC

There are ten different correlations, A thru J, for both transmission and reflectance. The correlations are used in various weighting and interpolation schemes according the figure above. The correlations are normalized against the performance at normal incidence. EnergyPlus uses these correlations to store the glazing system's angular performance at 10 degree increments and interpolates between them during simulations. The model equations use the cosine of the incidence angle, $\cos(\phi)$, as the independent variable. The correlations for transmittance have the form:

$$T(\phi) = T(0)\tau(\phi) \quad (7.150)$$

where

$$\tau(\phi) = a + b \cos(\phi) + c \cos(\phi)^2 + d \cos(\phi)^3 + e \cos(\phi)^4 \quad (7.151)$$

While the original method described by Arasteh, Kohler, and Griffith (2009) uses a similar equation form for reflectance, the form of the equation and its coefficients used in EnergyPlus have

Table 7.5: Normalized Transmittance Correlations for Angular Performance

Curve	a	b	c	d	e
A - Single: 3mm clear	0.00	3.36	-3.85	1.49	0.01
B - Single: 3mm bronze	0.00	2.83	-2.42	0.04	0.55
C - Single: 6mm bronze	0.00	2.45	-1.58	-0.64	0.77
D - Single: 3mm coated	0.00	2.85	-2.58	0.40	0.35
E - Double: 3mm clear, clear	0.00	1.51	2.49	-5.87	2.88
F - Double: 3mm coated, clear	0.00	1.21	3.14	-6.37	3.03
G - Double: 3mm tinted, clear	0.00	1.09	3.54	-6.84	3.23
H - Double: 6mm coated, clear	0.00	0.98	3.83	-7.13	3.33
I - Double: 6mm tinted, clear	0.00	0.79	3.93	-6.86	3.15
J - Triple: 3mm coated, clear, coated	0.00	0.08	6.02	-8.84	3.74

been modified algebraically to use a form consistent with what is used for coated glass elsewhere in the program. To convert from the original equation form,

$$R(\phi) = R(0)\rho_{old}(\phi) \quad (7.152)$$

to the form used for coated glazing,

$$R(\phi) = R(0)(1 - \rho_{new}(\phi)) + \rho_{new}(\phi) \quad (7.153)$$

set them equal to each other and solve algebraically for $\rho_{new}(\phi)$:

$$\rho_{new}(\phi) = \frac{R(0)(\rho_{old}(\phi) - 1)}{1 - R(0)} \quad (7.154)$$

where,

$$\rho_{new}(\phi) = a_{new} + b_{new} \cos(\phi) + c_{new} \cos^2(\phi) + d_{new} \cos^3(\phi) + e_{new} \cos^4(\phi) - \tau(\phi) \quad (7.155)$$

and,

$$\rho_{old}(\phi) = a_{old} + b_{old} \cos(\phi) + c_{old} \cos^2(\phi) + d_{old} \cos^3(\phi) + e_{old} \cos^4(\phi) \quad (7.156)$$

The updated coefficient values for a, b, c, d, and e are listed for transmittance and reflectance in Tables 7.5 and 7.6, respectively.

7.7.4.8 Application Issues

EnergyPlus's normal process of running the detailed layer-by-layer model, with the equivalent layer produced by this model, creates reports (sent to the EIO file) of the overall performance indices and the properties of the equivalent layer. Both of these raise issues that may be confusing.

The simplified window model does not reuse all aspects of the detailed layer-by-layer model, in that the angular solar transmission properties use a different model when the simple window model

Table 7.6: Normalized Reflectance Correlations for Angular Performance

Curve	a	b	c	d	e
A - Single: 3mm clear	1.00	-0.70	2.57	-3.20	1.33

J - Triple: 3mm coated, clear, coated	1.00	-4.35	14.27	-16.32	6.39

is in effect. If the user takes the material properties of an equivalent glazing layer from the simple window model and then re-enters them into just the detailed model, then the performance will not be the same because of the angular transmission model will have changed. It is not proper use of the model to re-enter the equivalent layer's properties and expect the exact level of performance.

There may not be an exact agreement between the performance indices echoed out and those input in the model. This is expected with the model and the result of a number of factors. For example, when there is a conflict between the SHGC and the U that are not physical and compromises need to be made. In the versions up till 9.6.0, the reported U value is limited to no higher than about $5.8\text{W}/\text{m}^2\cdot\text{K}$ when input is allowed to go up to $U=7\text{W}/\text{m}^2\cdot\text{K}$. In later versions, this mismatch of the input and the reported U-factors among exterior windows are resolved with the application of an adjustment ratio. The adjustment ratio is computed iteratively. In each iteration, the nominal (or effective) U is re-evaluated, and the adjustment ratio at the current iteration is computed as a ratio between the input U and nominal U at the current iteration. The iterative process stops when the input U and the nominal U is close enough (with a less than $0.01\text{W}/\text{m}^2\cdot\text{K}$ difference). In general, the simple window model is intended to generate a physically reasonable glazing that approximates the input entered as well as possible. But the model is not always able to do exactly what is specified when the specifications are not physical.

7.7.5 Glazing System Properties

The optical properties of a glazing system consisting of N glass layers separated by nonabsorbing gas layers (see Figure 7.19) are determined by solving the following recursion relations for $T_{i,j}$, the transmittance through layers i to j ; $R_{i,j}^f$ and $R_{i,j}^b$, the front and back reflectance, respectively, from layers i to j ; and A_j , the absorption in layer j . Here layer 1 is the outermost layer and layer N is the innermost layer. These relations account for multiple internal reflections within the glazing system.

Each of the variables is a function of wavelength.

$$T_{i,j} = \frac{T_{i,j-1}T_{j,j}}{1 - R_{j,j}^f R_{j-1,i}^b} \quad (7.157)$$

$$R_{i,j}^f = R_{i,j-1}^f + \frac{T_{i,j-1}^2 R_{j,j}^f}{1 - R_{j,j}^f R_{j-1,i}^b} \quad (7.158)$$

$$R_{j,i}^b = R_{j,j}^b + \frac{T_{j,j}^2 R_{j-1,i}^b}{1 - R_{j-1,i}^b R_{j,j}^f} \quad (7.159)$$

$$A_j^f = \frac{T_{1,j-1}(1 - T_{j,j} - R_{j,j}^f)}{1 - R_{j,N}^f R_{j-1,1}^b} + \frac{T_{1,j} R_{j+1,N}^f (1 - T_{j,j} - R_{j,j}^b)}{1 - R_{j,N}^f R_{j-1,1}^b} \quad (7.160)$$

In Equation 7.160, $T_{i,j} = 1$ and $R_{i,j} = 0$ if $i < 0$ or $j > N$.

Figure 7.19: Schematic of transmission, reflection and absorption of solar radiation within a multi-layer glazing system.

As an example, for double glazing ($N=2$), these equations reduce to:

$$T_{1,2} = \frac{T_{1,1}T_{2,2}}{1 - R_{2,2}^f R_{1,1}^b} \quad (7.161)$$

$$R_{1,2}^f = R_{1,1}^f + \frac{T_{1,1}^2 R_{2,2}^f}{1 - R_{2,2}^f R_{1,1}^b} \quad (7.162)$$

$$R_{2,1}^b = R_{2,2}^b + \frac{T_{2,2}^2 R_{1,1}^b}{1 - R_{1,1}^b R_{2,2}^f} \quad (7.163)$$

$$A_1^f = (1 - T_{1,1} - R_{1,1}^f) + \frac{T_{1,1} R_{2,2}^f (1 - T_{1,1} - R_{1,1}^b)}{1 - R_{2,2}^f R_{1,1}^b} \quad (7.164)$$

$$A_2^f = \frac{T_{1,1}(1 - T_{2,2} - R_{2,2}^f)}{1 - R_{2,2}^f R_{1,1}^b} \quad (7.165)$$

If the above transmittance and reflectance properties are input as a function of wavelength, EnergyPlus calculates “spectral average” values of the above glazing system properties by integrating over wavelength.

The spectral-average solar property is:

$$P_s = \frac{\int P(\lambda) E_s(\lambda) d\lambda}{\int E_s(\lambda) d\lambda} \quad (7.166)$$

The spectral-average visible property is:

$$P_v = \frac{\int P(\lambda) E_s(\lambda) V(\lambda) d\lambda}{\int E_s(\lambda) V(\lambda) d\lambda} \quad (7.167)$$

where $E_s(\lambda)$ is the solar spectral irradiance function and $V(\lambda)$ is the photopic response function of the eye. The default functions are shown in Table 7.7 and Table 7.8. They can be overwritten by user defined solar and/or visible spectrum using the objects Site:SolarAndVisibleSpectrum and Site:SpectrumData. They are expressed as a set of values followed by the corresponding wavelengths for values.

When a choice of Spectral is entered as the optical data type, the correlations to store the glazing system’s angular performance are generated based on angular performance at 10 degree increments. When a choice of SpectralAndAngle is entered as the optical data type, the correlations for the glazing system will be generated using 10 degree increments or more if the SpectralAndAngle properties include data for more angles. For each incident angle, the properties of the SpectralAndAngle layer(s) is calculated by linear interpolation, and then the performance of the entire glazing system is calculated for that angle. The glazing system properties at each angle are used to generate polynomial curve fits with 6 coefficients as a function of cosine of incident angle. The polynomial curves are then used in the simulation to calculate optical properties at each timestep.

If a glazing layer has optical properties that are roughly constant with wavelength, the wavelength-dependent values of $T_{i,i}$, $R_{i,i}^f$ and $R_{i,i}^b$ in Equations 7.157 to 7.160 can be replaced with constant values for that layer.

7.7.6 Calculation of Angular Properties

Calculation of optical properties is divided into two categories: uncoated glass and coated glass.

7.7.6.1 Angular Properties for Uncoated Glass

The following discussion assumes that optical quantities such as transmissivity, reflectivity, absorptivity, and index of refraction are a function of wavelength, λ . If there are no spectral data the angular dependence is calculated based on the single values for transmittance and reflectance in the visible and solar range. In the visible range an average wavelength of 0.575 microns is used in the calculations. In the solar range an average wavelength of 0.898 microns is used.

The spectral data include the transmittance, T , and the reflectance, R . For uncoated glass the reflectance is the same for the front and back surfaces. For angle of incidence, ϕ , the transmittance and reflectance are related to the transmissivity, τ , and reflectivity, ρ , by the following relationships:

2.1480,	2.1980,	2.2700,	2.3600,	2.4500,	2.4940,	2.5370			

$$T(\phi) = \frac{\tau(\phi)^2 e^{-\alpha d / \cos \phi'}}{1 - \rho(\phi)^2 e^{-2\alpha d / \cos \phi'}} \quad (7.168)$$

$$R(\phi) = \rho(\phi) \left(1 + T(\phi) e^{-\alpha d / \cos \phi'} \right) \quad (7.169)$$

The spectral reflectivity is calculated from Fresnel's equation assuming unpolarized incident radiation:

$$\rho(\phi) = \frac{1}{2} \left(\left(\frac{n \cos \phi - \cos \phi'}{n \cos \phi + \cos \phi'} \right)^2 + \left(\frac{n \cos \phi' - \cos \phi}{n \cos \phi' + \cos \phi} \right)^2 \right) \quad (7.170)$$

The spectral transmittivity is given by:

$$\tau(\phi) = 1 - \rho(\phi) \quad (7.171)$$

The spectral absorption coefficient is defined as:

$$\alpha = \frac{4\pi\kappa}{\lambda} \quad (7.172)$$

where κ is the dimensionless spectrally-dependent extinction coefficient and λ is the wavelength expressed in the same units as the sample thickness.

Solving Equation 7.170 at normal incidence gives:

$$n = \frac{1 + \sqrt{\rho(0)}}{1 - \sqrt{\rho(0)}} \quad (7.173)$$

Evaluating Equation 7.169 at normal incidence gives the following expression for κ :

$$\kappa = -\frac{\lambda}{4\pi d} \ln \frac{R(0) - \rho(0)}{\rho(0)T(0)} \quad (7.174)$$

Eliminating the exponential in Equations 7.168 and 7.169 gives the reflectivity at normal incidence:

$$\rho(0) = \frac{\beta - \sqrt{\beta^2 - 4(2 - R(0))R(0)}}{2(2 - R(0))} \quad (7.175)$$

where

$$\beta = T(0)^2 - R(0)^2 + 2R(0) + 1 \quad (7.176)$$

The value for the reflectivity, $\rho(0)$, from Equation 7.175 is substituted into Equations 7.173 and 7.174. The result from Equation 7.174 is used to calculate the absorption coefficient in Equation 7.172. The index of refraction is used to calculate the reflectivity in Equation 7.170 which is then used to calculate the transmittivity in Equation 7.171. The reflectivity, transmissivity and absorption coefficient are then substituted into Equations 7.168 and 7.169 to obtain the angular values of the reflectance and transmittance.

7.7.6.2 Angular Properties for Coated Glass

A regression fit is used to calculate the angular properties of coated glass from properties at normal incidence. If the transmittance of the coated glass is > 0.645 , the angular dependence of uncoated clear glass is used. If the transmittance of the coated glass is ≤ 0.645 , the angular dependence of uncoated bronze glass is used. The values for the angular functions for the transmittance and reflectance of both clear glass $(\bar{\tau}_{clr}, \bar{\rho}_{clr})$ and bronze glass $(\bar{\tau}_{bnz}, \bar{\rho}_{bnz})$ are determined from a fourth-order polynomial regression:

$$\bar{\tau}(\phi) = \bar{\tau}_0 + \bar{\tau}_1 \cos(\phi) + \bar{\tau}_2 \cos^2(\phi) + \bar{\tau}_3 \cos^3(\phi) + \bar{\tau}_4 \cos^4(\phi) \quad (7.177)$$

and

$$\bar{\rho}(\phi) = \bar{\rho}_0 + \bar{\rho}_1 \cos(\phi) + \bar{\rho}_2 \cos^2(\phi) + \bar{\rho}_3 \cos^3(\phi) + \bar{\rho}_4 \cos^4(\phi) - \bar{\tau}(\phi) \quad (7.178)$$

The polynomial coefficients are given in Table 7.9.

Table 7.9: Polynomial coefficients used to determine angular properties of coated glass.

	0	1	2	3	4
$\bar{\tau}_{clr}$	-0.0015	3.355	-3.840	1.460	0.0288
$\bar{\rho}_{clr}$	0.999	-0.563	2.043	-2.532	1.054
$\bar{\tau}_{bnz}$	-0.002	2.813	-2.341	-0.05725	0.599
$\bar{\rho}_{bnz}$	0.997	-1.868	6.513	-7.862	3.225

These factors are used as follows to calculate the angular transmittance and reflectance:

For $T(0) > 0.645$:

$$T(\phi) = T(0)\bar{\tau}_{clr}(\phi) \quad (7.179)$$

$$R(\phi) = R(0)(1 - \bar{\rho}_{clr}(\phi)) + \bar{\rho}_{clr}(\phi) \quad (7.180)$$

For $T(0) \leq 0.645$:

$$T(\phi) = T(0)\bar{\tau}_{bnz}(\phi) \quad (7.181)$$

$$R(\phi) = R(0)(1 - \bar{\rho}_{bnz}(\phi)) + \bar{\rho}_{bnz}(\phi) \quad (7.182)$$

7.7.7 Calculation of Hemispherical Values

The hemispherical value of a property is determined from the following integral:

$$P_{hemispherical} = 2 \int_0^{\frac{\pi}{2}} P(\phi) \cos(\phi) \sin(\phi) d\phi \quad (7.183)$$

The integral is evaluated by Simpson's rule for property values at angles of incidence from 0 to 90 degrees in 10-degree increments.

7.7.8 Optical Properties of Window Shading Devices

Shading devices affect the system transmittance and glass layer absorptance for short-wave radiation and for long-wave (thermal) radiation. The effect depends on the shade position (interior, exterior or between-glass), its transmittance, and the amount of inter-reflection between the shading device and the glazing. Also of interest is the amount of radiation absorbed by the shading device.

In EnergyPlus, shading devices are divided into four categories, "shades," "blinds," "screens," and "switchable glazing." "Shades" are assumed to be perfect diffusers. This means that direct radiation incident on the shade is reflected and transmitted as hemispherically uniform diffuse radiation: there is no direct component of transmitted radiation. It is also assumed that the transmittance, τ_{sh} , reflectance, ρ_{sh} , and absorptance, α_{sh} , are the same for the front and back of the shade and are independent of angle of incidence. Many types of drapery and pull-down roller devices are close to being perfect diffusers and can be categorized as "shades."

"Blinds" in EnergyPlus are slat-type devices such as venetian blinds. Unlike shades, the optical properties of blinds are strongly dependent on angle of incidence. Also, depending on slat angle and the profile angle of incident direct radiation, some of the direct radiation may pass between the slats, giving a direct component of transmitted radiation.

"Screens" are debris or insect protection devices made up of metallic or non-metallic materials. Screens may also be used as shading devices for large glazing areas where excessive solar gain is an issue. The EnergyPlus window screen model assumes the screen is composed of intersecting orthogonally-crossed cylinders, with the surface of the cylinders assumed to be diffusely reflecting. Screens may only be used on the exterior surface of a window construction. As with blinds, the optical properties affecting the direct component of transmitted radiation are dependent on the angle of incident direct radiation.

With "Switchable glazing," shading is achieved making the glazing more absorbing or more reflecting, usually by an electrical or chemical mechanism. An example is electrochromic glazing where the application of an electrical voltage or current causes the glazing to switch from light to dark.

Shades and blinds can be either fixed or moveable. If moveable, they can be deployed according to a schedule or according to a trigger variable, such as solar radiation incident on the window. Screens can be either fixed or moveable according to a schedule.

7.7.8.1 Shades

7.7.8.2 Shade/Glazing System Properties for Short-Wave Radiation

Short-wave radiation includes:

- Beam solar radiation from the sun and diffuse solar radiation from the sky and ground incident on the outside of the window,
- Beam and/or diffuse radiation reflected from exterior obstructions or the building itself,
- Solar radiation reflected from the inside zone surfaces and incident as diffuse radiation on the inside of the window,

- Beam solar radiation from one exterior window incident on the inside of another window in the same zone, and
- Short-wave radiation from electric lights incident as diffuse radiation on the inside of the window.

Exterior Shade

For an exterior shade we have the following expressions for the system transmittance, the effective system glass layer absorptance, and the system shade absorptance, taking inter-reflection between shade and glazing into account. Here, “system” refers to the combination of glazing and shade. The system properties are given in terms of the isolated shade properties (i.e., shade properties in the absence of the glazing) and the isolated glazing properties (i.e., glazing properties in the absence of the shade).

$$T_{sys}(\phi) = T_{1,N}^{dif} \frac{\tau_{sh}}{1 - R_f^{dif} \rho_{sh}} \quad (7.184)$$

$$T_{sys}^{dif} = T_{1,N}^{dif} \frac{\tau_{sh}}{1 - R_f^{dif} \rho_{sh}} \quad (7.185)$$

$$A_{j,f}^{sys}(\phi) = A_{j,f}^{dif} \frac{\tau_{sh}}{1 - R_f \rho_{sh}}, \quad j = 1 \text{ to } N \quad (7.186)$$

$$A_{j,f}^{dif,sys} = A_{j,f}^{dif} \frac{\tau_{sh}}{1 - R_f \rho_{sh}}, \quad j = 1 \text{ to } N \quad (7.187)$$

$$A_{j,b}^{dif,sys} = A_{j,b}^{dif} \frac{T_{1,N}^{dif} \rho_{sh}}{1 - R_f \rho_{sh}}, \quad j = 1 \text{ to } N \quad (7.188)$$

$$\alpha_{sh}^{sys} = \alpha_{sh} \left(1 + \frac{\tau_{sh} R_f}{1 - R_f \rho_{sh}} \right) \quad (7.189)$$

Interior Shade

The system properties when an interior shade is in place are the following:

$$T_{sys}(\phi) = T_{1,N}(\phi) \frac{\tau_{sh}}{1 - R_b^{dif} \rho_{sh}} \quad (7.190)$$

$$T_{sys}^{dif} = T_{1,N}^{dif} \frac{\tau_{sh}}{1 - R_b^{dif} \rho_{sh}} \quad (7.191)$$

$$A_{j,f}^{sys}(\phi) = A_{j,f}(\phi) + T_{1,N}(\phi) \frac{\rho_{sh}}{1 - R_b^{dif} \rho_{sh}} A_{j,b}^{dif}, \quad j = 1 \text{ to } N \quad (7.192)$$

$$A_{j,f}^{dif,sys} = A_{j,f}^{dif} + T_{1,N}^{dif} \frac{\rho_{sh}}{1 - R_b^{dif} \rho_{sh}} A_{j,b}^{dif}, \quad j = 1 \text{ to } N \quad (7.193)$$

$$A_{j,b}^{dif,sys} = \frac{\tau_{sh}}{1 - R_b^{dif} \rho_{sh}} A_{j,b}^{dif}, \quad j = 1 \text{ to } N \quad (7.194)$$

$$\alpha_{sh}^{sys}(\phi) = T_{1,N}(\phi) \frac{\alpha_{sh}}{1 - R_b^{dif} \rho_{sh}} \quad (7.195)$$

$$\alpha_{sh}^{dif,sys} = T_{1,N}^{dif} \frac{\alpha_{sh}}{1 - R_b^{dif} \rho_{sh}} \quad (7.196)$$

7.7.8.3 Long-Wave Radiation Properties of Window Shades

Long-wave radiation includes:

- Thermal radiation from the sky, ground and exterior obstructions incident on the outside of the window,
- Thermal radiation from other room surfaces incident on the inside of the window, and
- Thermal radiation from internal sources, such as equipment and electric lights, incident on the inside of the window.

The program calculates how much long-wave radiation is absorbed by the shade and by the adjacent glass surface. The system emissivity (thermal absorptance) for an interior or exterior shade, taking into account reflection of long-wave radiation between the glass and shade, is given by:

$$\varepsilon_{sh}^{lw,sys} = \varepsilon_{sh}^{lw} \left(1 + \frac{\tau_{sh}^{lw} \rho_{gl}^{lw}}{1 - \rho_{sh}^{lw} \rho_{gl}^{lw}} \right) \quad (7.197)$$

where ρ_{gl}^{lw} is the long-wave reflectance of the outermost glass surface for an exterior shade or the innermost glass surface for an interior shade, and it is assumed that the long-wave transmittance of the glass is zero.

The innermost (for interior shade) or outermost (for exterior shade) glass surface emissivity when the shade is present is:

$$\varepsilon_{gl}^{lw,sys} = \varepsilon_{gl}^{lw} \frac{\tau_{sh}^{lw}}{1 - \rho_{sh}^{lw} \rho_{gl}^{lw}} \quad (7.198)$$

7.7.8.4 Switchable Glazing

For switchable glazing, such as electrochromics, the solar and visible optical properties of the glazing can switch from a light state to a dark state. The switching factor, f_{switch} , determines what state the glazing is in. An optical property, p , such as transmittance or glass layer absorptance, for this state is given by:

$$p = (1 - f_{switch})p_{light} + f_{switch}p_{dark} \quad (7.199)$$

where

p_{light} is the property value for the unswitched, or light state, and p_{dark} is the property value for the fully switched, or dark state.

The value of the switching factor in a particular time step depends on what type of switching control has been specified: “schedule,” “trigger,” or “daylighting.” If “schedule,” f_{switch} = schedule value, which can be 0 or 1.

7.7.9 Thermochromic Windows

Thermochromic (TC) materials have active, reversible optical properties that vary with temperature. Thermochromic windows are adaptive window systems for incorporation into building envelopes. Thermochromic windows respond by absorbing sunlight and turning the sunlight energy into heat. As the thermochromic film warms it changes its light transmission level from less absorbing to more absorbing. The more sunlight it absorbs the lower the light level going through it. Figure 7.20 shows the variations of window properties with the temperature of the thermochromic glazing layer. By using the sun's own energy the window adapts based solely on the directness and amount of sunlight. Thermochromic materials will normally reduce optical transparency by absorption and/or reflection, and are specular (maintaining vision).

Figure 7.20: Variations of Window Properties with the Temperature of the Thermochromic Glazing Layer

On cloudy days the window is at full transmission and letting in diffuse daylighting. On sunny days the window maximizes diffuse daylighting and tints based on the angle of the sun relative to the window. For a south facing window (northern hemisphere) the daylight early and late in the day is maximized and the direct sun at mid day is minimized.

The active thermochromic material can be embodied within a laminate layer or a surface film. The overall optical state of the window at a given time is a function primarily of:

- thermochromic material properties
- solar energy incident on the window
- construction of the window system that incorporates the thermochromic layer
- environmental conditions (interior, exterior, air temperature, wind, etc).

The tinted film, in combination with a heat reflecting, low-e layer allows the window to reject most of the absorbed radiation thus reducing undesirable heat load in a building. In the absence of direct sunlight the window cools and clears and again allows lower intensity diffuse radiation into a building. TC windows can be designed in several ways (Figure 7.21), with the most common being a triple pane windows with the TC glass layer in the middle a double pane windows with the TC layer on the inner surface of the outer pane or for sloped glazing a double pane with the laminate layer on the inner pane with a low-e layer toward the interior. The TC glass layer has variable optical properties depending on its temperature, with a lower temperature at which the optical change is initiated, and an upper temperature at which a minimum transmittance is reached. TC windows act as passive solar shading devices without the need for sensors, controls and power supplies but their optical performance is dependent on varying solar and other environmental conditions at the location of the window.

Figure 7.21: Configurations of Thermochromic Windows

EnergyPlus describes a thermochromic window with a Construction object which references a special layer defined with a WindowMaterial:GlazingGroup:Thermochromic object. The WindowMaterial:GlazingGroup:Thermochromic object further references a series of WindowMaterial:Glazing objects corresponding to each specification temperature of the TC layer. During EnergyPlus run time, a series of TC windows corresponding to each specification temperature is created once. At the beginning of a particular time step calculations, the temperature of the TC glass layer from the previous time step is used to look up the most closed specification temperature whose corresponding TC window construction will be used for the current time step calculations. The current time step calculated temperature of the TC glass layer can be different from the previous time step, but no iterations are done in the current time step for the new TC glass layer temperature. This is an approximation that considers the reaction time of the TC glass layer can be close to EnergyPlus simulation time step say 10 to 15 minutes.

7.7.9.1 Blinds

Window blinds in EnergyPlus are defined as a series of equidistant slats that are oriented horizontally or vertically. All of the slats are assumed to have the same optical properties. The overall optical properties of the blind are determined by the slat geometry (width, separation and angle) and the slat optical properties (front-side and back-side transmittance and reflectance). Blind properties for direct radiation are also sensitive to the “profile angle,” which is the angle of incidence in a plane that is perpendicular to the window plane and to the direction of the slats. The blind optical model in EnergyPlus is based on Simmler, Fischer and Winkelmann, 1996; however, that document has numerous typographical errors and should be used with caution.

The following assumptions are made in calculating the blind optical properties:

- The slats are flat.
- The spectral dependence of inter-reflections between slats and glazing is ignored; spectral-average slat optical properties are used.
- The slats are perfect diffusers. They have a perfectly matte finish so that reflection from a slat is isotropic (hemispherically uniform) and independent of angle of incidence, i.e., the reflection has no specular component. This also means that absorption by the slats is hemispherically uniform with no incidence angle dependence. If the transmittance of a slat is non-zero, the transmitted radiation is isotropic and the transmittance is independent of angle of incidence.
- Inter-reflection between the blind and wall elements near the periphery of the blind is ignored.
- If the slats have holes through which support strings pass, the holes and strings are ignored. Any other structures that support or move the slats are ignored.

7.7.9.2 Slat Optical Properties

The slat optical properties used by EnergyPlus are shown in the following table.

Table 7.10: Slat Optical Properties

$\tau_{dir,dif}$	Direct-to-diffuse transmittance (same for front and back of slat)
$\tau_{dif,dif}$	Diffuse-to-diffuse transmittance (same for front and back of slat)
$\rho_{dir,dif}^f, \rho_{dir,dif}^b$	Front and back direct-to-diffuse reflectance
$\rho_{dif,dif}^f, \rho_{dif,dif}^b$	Front and back diffuse-to-diffuse reflectance

It is assumed that there is no direct-to-direct transmission or reflection, so that $\tau_{dir,dir} = 0$, $\rho_{dir,dir}^f = 0$, and $\rho_{dir,dir}^b = 0$. It is further assumed that the slats are perfect diffusers, so that $\tau_{dir,dif}$, $\rho_{dir,dif}^f$ and $\rho_{dir,dif}^b$ are independent of angle of incidence. Until the EnergyPlus model is improved to take into account the angle-of-incidence dependence of slat transmission and reflection, it is assumed that $\tau_{dir,dif} = \tau_{dif,dif}$, $\rho_{dir,dif}^f = \rho_{dif,dif}^f$, and $\rho_{dir,dif}^b = \rho_{dif,dif}^b$.

7.7.9.3 Direct Transmittance of Blind

The direct-to-direct and direct-to-diffuse transmittance of a blind is calculated using the slat geometry shown in Figure 7.22(a), which shows the side view of one of the cells of the blind. For the case shown, each slat is divided into two segments, so that the cell is bounded by a total of six segments, denoted by s_1 through s_6 (note in the following that s_i refers to both segment i and the length of segment i). The lengths of s_1 and s_2 are equal to the slat separation, h , which is the distance between adjacent slat faces. s_3 and s_4 are the segments illuminated by direct radiation. In the case shown in Figure 7.22(a) the cell receives radiation by reflection of the direct radiation incident on s_4 and, if the slats have non-zero transmittance, by transmission through s_3 , which is illuminated from above.

The goal of the blind direct transmission calculation is to determine the direct and diffuse radiation leaving the cell through s_2 for unit direct radiation entering the cell through s_1 .

7.7.9.4 Direct-to-Direct Blind Transmittance

Figure 7.22(b) shows the case where some of the direct radiation passes through the cell without hitting the slats. From the geometry in this figure we see that

$$\tau_{bl,f}^{dir,dir} = 1 - \frac{|w|}{h}, |w| \leq h \quad (7.200)$$

where

$$w = s \frac{\cos(\varphi_b - \varphi_s)}{\cos \varphi_s} \quad (7.201)$$

Note that we are assuming that the slat thickness is zero. A correction for non-zero slat thickness is described later.

Figure 7.22: (a) Side view of a cell formed by adjacent slats showing how the cell is divided into segments, s_i , for the calculation of direct solar transmittance; (b) side view of a cell showing case where some of the direct solar passes between adjacent slats without touching either of them. In this figure ϕ_s is the profile angle and ϕ_b is the slat angle.

7.7.9.5 Direct-to-Diffuse Blind Transmittance, Reflectance and Absorptance

The direct-to-diffuse and transmittance and reflectance of the blind are calculated using a radiosity method that involves the following three vector quantities:

J_i = the radiosity of segment s_i , i.e., the total radiant flux into the cell from s_i

G_i = the irradiance on the cell side of s_i

Q_i = the source flux from the cell side of s_i

Based on these definitions we have the following equations that relate J , G and Q for the different segments:

$$\begin{aligned}
 J_1 &= Q_1 \\
 J_2 &= Q_2 \\
 J_3 &= Q_3 + \rho_{dif,dif}^b G_3 + \tau_{dif,dif} G_4 \\
 J_4 &= Q_4 + \tau_{dif,dif} G_3 + \rho_{dif,dif}^f G_4 \\
 J_5 &= Q_5 + \rho_{dif,dif}^b G_5 + \tau_{dif,dif} G_6 \\
 J_6 &= Q_6 + \tau_{dif,dif} G_5 + \rho_{dif,dif}^f G_6
 \end{aligned} \tag{7.202}$$

In addition we have the following equation relating G and J :

$$G_i = \sum_{j=1}^6 J_j F_{ji}, \quad i = 1, 6 \tag{7.203}$$

where F_{ji} is the view factor between s_j and s_i , i.e., F_{ji} is the fraction of radiation leaving s_j that is intercepted by s_i .

Using $J_1 = Q_1 = 0$ and $J_2 = Q_2 = 0$ and combining the above equations gives the following equation set relating J and Q :

$$J_3 - \rho_{dif,dif}^b \sum_{j=3}^6 J_j F_{j3} - \tau_{dif,dif} \sum_{j=3}^6 J_j F_{j4} = Q_3 \quad (7.204)$$

$$J_4 - \tau_{dif,dif} \sum_{j=3}^6 J_j F_{j3} - \rho_{dif,dif}^f \sum_{j=3}^6 J_j F_{j4} = Q_4 \quad (7.205)$$

$$J_5 - \rho_{dif,dif}^b \sum_{j=3}^6 J_j F_{j5} - \tau_{dif,dif} \sum_{j=3}^6 J_j F_{j6} = Q_5 \quad (7.206)$$

$$J_6 - \tau_{dif,dif} \sum_{j=3}^6 J_j F_{j3} - \rho_{dif,dif}^f \sum_{j=3}^6 J_j F_{j6} = Q_6 \quad (7.207)$$

This can be written in the form:

$$Q' = X J' \quad (7.208)$$

where X is a 4x4 matrix and

$$J' = \begin{bmatrix} J_3 \\ J_4 \\ J_5 \\ J_6 \end{bmatrix} \quad (7.209)$$

$$Q' = \begin{bmatrix} Q_3 \\ Q_4 \\ Q_5 \\ Q_6 \end{bmatrix} \quad (7.210)$$

We then obtain J' from:

$$J' = X^{-1} Q' \quad (7.211)$$

The view factors, F_{ij} , are obtained as follows. The cell we are dealing with is a convex polygon with n sides. In such a polygon the view factors must satisfy the following constraints:

$$\sum_{j=1}^n F_{ij} = 1, \quad i = 1, n \quad (7.212)$$

$$s_i F_{ij} = s_j F_{ji}, \quad i = 1, n; \quad j = 1, n \quad (7.213)$$

$$F_{ii} = 0, \quad i = 1, n \quad (7.214)$$

These constraints lead to simple equations for the view factors for $n = 3$ and 4. For $n = 3$, we have the following geometry and view factor expression:

For $n = 4$ we have:

$$F_{12} = \frac{s_1 + s_2 - s_3}{2s_1}$$

Figure 7.23: View Factor for Three Surfaces

$$F_{12} = \frac{d_1 + d_2 - (s_3 + s_4)}{2s_1}$$

Figure 7.24: View Factor for Four Surfaces

Applying these to the slat cell shown in Figure 7.25 we have the following:

$$F_{12} = \frac{d_1 + d_2 - 2s}{2h} \quad (7.215)$$

$$F_{13} = \frac{h + s_3 - d_3}{2h}, \text{ etc.} \quad (7.216)$$

The sources for the direct-to-diffuse transmittance calculation are:

$$Q_1 = Q_2 = Q_5 = Q_6 = 0 \text{ (and therefore } J_1 = J_2 = 0) \quad (7.217)$$

$$\left. \begin{array}{l} Q_3 = \tau_{dir,dif} \\ Q_4 = \rho_{dir,dif}^f \end{array} \right\} \varphi_b \leq \varphi_s + \frac{\pi}{2} \text{ (beam hits front of slats)} \quad (7.218)$$

$$\left. \begin{array}{l} Q_3 = \rho_{dir,dif}^b \\ Q_4 = \tau_{dir,dif} \end{array} \right\} \varphi_b > \varphi_s + \frac{\pi}{2} \text{ (beam hits back of slats)} \quad (7.219)$$

For unit incident direct flux, the front direct-to-diffuse transmittance and reflectance of the blind are:

$$\begin{aligned} \tau_{bl,f}^{dir,dif} &= G_2 \\ \rho_{bl,f}^{dir,dif} &= G_1 \end{aligned} \quad (7.220)$$

where

$$\begin{aligned} G_2 &= \sum_{j=3}^6 J_j F_{j2} \\ G_1 &= \sum_{j=3}^6 J_j F_{j1} \end{aligned} \quad (7.221)$$

and J_3 to J_6 are given by Equation 7.208.

Figure 7.25: Slat cell showing geometry for calculation of view factors between the segments of the cell.

The front direct absorptance of the blind is then:

$$\alpha_{bl,f}^{dir} = 1 - \tau_{bl,f}^{dir,dif} - \tau_{bl,f}^{dir,dir} - \rho_{bl,f}^{dir,dif} \quad (7.222)$$

The direct-to-diffuse calculations are performed separately for solar and visible slat properties to get the corresponding solar and visible blind properties.

7.7.9.6 Dependence on Profile Angle

The direct-to-direct and direct-to-diffuse blind properties are calculated for direct radiation profile angles (see Figure 7.22) ranging from -90° to $+90^\circ$ in 5° increments. (The “profile angle” is the angle of incidence in a plane that is perpendicular to the window *and* perpendicular to the slat direction.) In the time step loop the blind properties for a particular profile angle are obtained by interpolation.

7.7.9.7 Dependence on Slat Angle

All blind properties are calculated for slat angles ranging from -90° to $+90^\circ$ in 10° increments. In the time-step loop the slat angle is determined by the slat-angle control mechanism and then the blind properties at that slat angle are determined by interpolation. Three slat-angle controls are available: (1) slat angle is adjusted to just block beam solar incident on the window; (2) slat angle is determined by a schedule; and (3) slat angle is fixed.

7.7.9.8 Diffuse-to-Diffuse Transmittance and Reflectance of Blind

To calculate the diffuse-to-diffuse properties, assuming uniformly distributed incident diffuse radiation, each slat bounding the cell is divided into two segments of equal length (Figure 7.26), i.e., $s_3 = s_4$ and $s_5 = s_6$. For front-side properties we have a unit source, $Q_1 = 1$. All the other Q_i are zero. Using this source value, we apply the methodology described above to obtain G_2 and G_1 . We then have:

$$\begin{aligned} \tau_{bl,f}^{dif,dif} &= G_2 \\ \rho_{bl,f}^{dif,dif} &= G_1 \\ \alpha_{bl,f}^{dif} &= 1 - \tau_{bl,f}^{dif,dif} - \rho_{bl,f}^{dif,dif} \end{aligned} \quad (7.223)$$

The back-side properties are calculated in a similar way by setting $Q_2 = 1$ with the other Q_i equal to zero.

The diffuse-to-diffuse calculations are performed separately for solar, visible and IR slat properties to get the corresponding solar, visible and IR blind properties.

7.7.9.9 Blind properties for sky and ground diffuse radiation

For horizontal slats on a vertical window (the most common configuration) the blind diffuse-to-diffuse properties will be sensitive to whether the radiation is incident upward from the ground or downward from the sky (Figure 7.27). For this reason we also calculate the following solar properties for a blind consisting of horizontal slats in a vertical plane:

$$\begin{aligned} \tau_{bl,f}^{gnd-dif,dif} &= \text{front transmittance for ground diffuse solar} \\ \tau_{bl,f}^{sky-dif,dif} &= \text{front transmittance for sky diffuse solar} \end{aligned}$$

Figure 7.26: Slat cell showing arrangement of segments and location of source for calculation of diffuse-to-diffuse optical properties.

$\rho_{bl,f}^{gnd-dif,dif}$ = front reflectance for ground diffuse solar
 $\rho_{bl,f}^{sky-dif,dif}$ = front reflectance for sky diffuse solar
 $\alpha_{bl,f}^{gnd-dif,dif}$ = front absorptance for ground diffuse solar
 $\alpha_{bl,f}^{sky-dif,dif}$ = front absorptance for sky diffuse solar

These are obtained by integrating over sky and ground elements, as shown in Figure 7.27, treating each element as a source of direct radiation of irradiance $I(\phi_s)$ incident on the blind at profile angle ϕ_s . This gives:

$$\tau_{bl,f}^{sky-dif,dif} = \frac{\int_0^{\pi/2} \left[\tau_{bl,f}^{dir,dir}(\phi_s) + \tau_{bl,f}^{dir,dif}(\phi_s) \right] I_{sky}(\phi_s) \cos \phi_s d\phi_s}{\int_0^{\pi/2} I_{sky}(\phi_s) \cos \phi_s d\phi_s} \quad (7.224)$$

$$\rho_{bl,f}^{sky-dif,dif} = \frac{\int_0^{\pi/2} \rho_{bl,f}^{dir,dif} I_{sky}(\phi_s) \cos \phi_s d\phi_s}{\int_0^{\pi/2} I_{sky}(\phi_s) \cos \phi_s d\phi_s} \quad (7.225)$$

$$\alpha_{bl,f}^{sky-dif} = \frac{\int_0^{\pi/2} \alpha_{bl,f}^{dir} I_{sky}(\phi_s) \cos \phi_s d\phi_s}{\int_0^{\pi/2} I_{sky}(\phi_s) \cos \phi_s d\phi_s} \quad (7.226)$$

We assume that the sky radiance is uniform. This means that I_{sky} is independent of ϕ_s , giving:

$$\tau_{bl,f}^{sky-dif,dif} = \int_0^{\pi/2} \left[\tau_{bl,f}^{dir,dir} + \tau_{bl,f}^{dir,dif} \right] \cos \phi_s d\phi_s \quad (7.227)$$

$$\rho_{bl,f}^{sky-dif,dif} = \int_0^{\pi/2} \rho_{bl,f}^{dir,dif} \cos \phi_s d\phi_s \quad (7.228)$$

$$\alpha_{bl,f}^{sky-dif} = \int_0^{\pi/2} \alpha_{bl,f}^{dir} \cos \phi_s d\phi_s \quad (7.229)$$

The corresponding ground diffuse quantities are obtained by integrating ϕ_s from $-\pi/2$ to 0.

An improvement to this calculation would be to allow the sky radiance distribution to be non-uniform, i.e., to depend on sun position and sky conditions, as is done in the detailed daylighting calculation (see “Sky Luminance Distributions” under “Daylight Factor Calculation”).

7.7.9.10 Correction Factor for Slat Thickness

A correction has to be made to the blind transmittance, reflectance and absorptance properties to account for the amount of radiation incident on a blind that is reflected and absorbed by the slat edges (the slats are assumed to be opaque to radiation striking the slat edges). This is illustrated in

Figure 7.27: Side view of horizontal slats in a vertical blind showing geometry for calculating blind transmission, reflection and absorption properties for sky and ground diffuse radiation.

Figure 7.28 for the case of direct radiation incident on the blind. The slat cross-section is assumed to be rectangular. The quantity of interest is the fraction, f_{edge} , of direct radiation incident on the blind that strikes the slat edges. Based on the geometry shown in Figure 7.28 we see that

$$f_{edge} = \frac{t \cos \gamma}{\left(h + \frac{t}{\cos \xi}\right) \cos \varphi_s} = \frac{t \cos(\varphi_s - \xi)}{\left(h + \frac{t}{\cos \xi}\right) \cos \varphi_s} = \frac{t \sin(\varphi_b - \varphi_s)}{\left(h + \frac{t}{\sin \varphi_b}\right) \cos \varphi_s} \quad (7.230)$$

The edge correction factor for diffuse incident radiation is calculated by averaging this value of f_{edge} over profile angles, φ_s , from -90° to $+90^\circ$.

As an example of how the edge correction factor is applied, the following two equations show how blind front diffuse transmittance and reflectance calculated assuming zero slat thickness are modified by the edge correction factor. It is assumed that the edge transmittance is zero and that the edge reflectance is the same as the slat front reflectance, ρ_f .

$$\begin{aligned} \tau_{bl,f}^{dif,dif} &\rightarrow \tau_{bl,f}^{dif,dif} (1 - f_{edge}) \\ \rho_{bl,f}^{dif} &\rightarrow \rho_{bl,f}^{dif} (1 - f_{edge}) + f_{edge} \rho_f \end{aligned} \quad (7.231)$$

7.7.9.11 Comparison with ISO 15099 Calculation of Blind Optical Properties

Table 7.11 compares EnergyPlus and ISO 15099 [2001] calculations of blind optical properties for a variety of profile angles, slat angles and slat optical properties. The ISO 15099 calculation method is similar to that used in EnergyPlus, except that the slats are divided into five equal segments. The ISO 15099 and EnergyPlus results agree to within 12%, except for the solar transmittances for the 10-degree slat angle case. Here the transmittances are small (from 1% to about 5%) but differ by about a factor of up to two between ISO 15099 and EnergyPlus. This indicates that the slats should be divided into more than two segments at small slat angles.

Table 7.11: Comparison of blind optical properties calculated with the EnergyPlus and ISO 15099 methods. EnergyPlus values that differ by more than 12% from ISO 15099 values are shown in bold italics.

7.7.9.12 Blind/Glazing System Properties for Short-Wave Radiation

When a blind is in place we have the following expressions for the system transmittance, the system glass layer absorptance, and the system blind absorptance, taking inter-reflection between blind and glazing into account. The system properties, indicated by “sys,” are given in terms of the isolated blind properties (i.e., blind properties in the absence of the glazing)—indicated by “bl”—and the isolated glazing properties (i.e., glazing properties in the absence of the blind)—indicated by “gl.”

7.7.9.13 Interior Blind

The system properties when an interior blind is in place are the following:

$$T_{f,sys}^{dir,all}(\phi, \phi_s) = T_{gl}^{dir}(\phi) \left(\tau_{bl,f}^{dir,dir}(\phi_s) + \tau_{bl,f}^{dir,dif}(\phi_s) + \frac{\tau_{bl,f}^{dif} \rho_{bl,f}^{dir,dif}(\phi_s) R_{gl,b}^{dif}}{1 - \rho_{bl,f}^{dif} R_{gl,b}^{dif}} \right) \quad (7.232)$$

$$A_{gl,j,f}^{dir,sys}(\phi, \phi_s) = A_{gl,j,f}^{dir}(\phi) + \frac{T_{gl}^{dir}(\phi) \alpha_{gl,j,b}^{dif} \rho_{bl,f}^{dir}(\phi_s)}{1 - \rho_{bl,f}^{dir}(\phi_s) R_{gl,b}^{dif}}, \quad j = 1, N \quad (7.233)$$

$$\alpha_{bl,f}^{dir,sys}(\phi, \phi_s) = T_{gl}^{dir}(\phi) \left(\alpha_{bl,f}^{dir}(\phi_s) + \frac{\rho_{bl,f}^{dir}(\phi_s) R_{gl,b}^{dif} \alpha_{bl,f}^{dif}}{1 - \rho_{bl,f}^{dif} R_{gl,b}^{dif}} \right) \quad (7.234)$$

$$T_{f,sys}^{dif,dif} = \frac{T_{gl}^{dif} \tau_{bl,f}^{dif,dif}}{1 - \rho_{bl,f}^{dif} R_{gl,b}^{dif}} \quad (7.235)$$

$$T_{f,sys}^{sky-dif,dif} = \frac{T_{gl}^{dif} \tau_{bl,f}^{sky-dif,dif}}{1 - \rho_{bl,f}^{sky-dif} R_{gl,b}^{dif}} \quad (7.236)$$

Figure 7.28: Side view of slats showing geometry for calculation of slat edge correction factor for incident direct radiation.

$$T_{f,sys}^{gnd-dif,dif} = \frac{T_{gl}^{dif} \tau_{bl,f}^{gnd-dif,dif}}{1 - \rho_{bl,f}^{gnd-dif} R_{gl,b}^{dif}} \quad (7.237)$$

$$A_{gl,j,f}^{dif,sys} = A_{gl,j,f}^{dif} + \frac{T_{gl}^{dif} \rho_{bl,f}^{dif} A_{gl,j,b}^{dif}}{1 - \rho_{bl,f}^{dif} R_{gl,b}^{dif}}, j = 1, N \quad (7.238)$$

$$A_{gl,j,f}^{sky-dif,sys} = A_{gl,j,f}^{dif} + \frac{T_{gl}^{dif} \rho_{bl,f}^{sky-dif} A_{gl,j,b}^{dif}}{1 - \rho_{bl,f}^{sky-dif} R_{gl,b}^{dif}}, j = 1, N \quad (7.239)$$

$$A_{gl,j,f}^{gnd-dif,sys} = A_{gl,j,f}^{dif} + \frac{T_{gl}^{dif} \rho_{bl,f}^{gnd-dif} A_{gl,j,b}^{dif}}{1 - \rho_{bl,f}^{gnd-dif} R_{gl,b}^{dif}}, j = 1, N \quad (7.240)$$

$$\alpha_{bl,f}^{dif,sys} = \frac{T_{gl}^{dif} \alpha_{bl,f}^{dif}}{1 - \rho_{bl,f}^{dif} R_{gl,b}^{dif}} \quad (7.241)$$

$$\alpha_{bl,f}^{sky-dif,sys} = \frac{T_{gl}^{dif} \alpha_{bl,f}^{sky-dif}}{1 - \rho_{bl,f}^{sky-dif} R_{gl,b}^{dif}} \quad (7.242)$$

$$\alpha_{bl,f}^{gnd-dif,sys} = \frac{T_{gl}^{dif} \alpha_{bl,f}^{gnd-dif}}{1 - \rho_{bl,f}^{gnd-dif} R_{gl,b}^{dif}} \quad (7.243)$$

7.7.9.14 Exterior Blind

The system properties when an exterior blind is in place are the following:

$$T_{f,sys}^{dir,all}(\phi, \phi_s) = \tau_{bl,f}^{dir,dir}(\phi_s) \left(T_{gl}^{dir}(\phi) + \frac{T_{gl}^{dif} R_{gl,f}^{dir} \rho_{bl,b}^{dir,dif}}{1 - R_{gl,f}^{dif} \rho_{bl,b}^{dif}} \right) + \frac{\tau_{bl}^{dir,dif}(\phi_s) T_{gl}^{dif}}{1 - R_{gl,f}^{dif} \rho_{bl,b}^{dif}} \quad (7.244)$$

$$A_{gl,j,f}^{dir,sys}(\phi, \phi_s) = \tau_{bl,f}^{dir,dir}(\phi_s) A_{gl,j,f}^{dir}(\phi) + \frac{\left(\tau_{bl,f}^{dir,dir}(\phi_s) R_{gl}^{dir}(\phi) \rho_{bl,b}^{dir}(\phi_s) + \tau_{bl,f}^{dir,dif}(\phi_s) \right) A_{gl,j,f}^{dif}}{1 - R_{gl,f}^{dif} \rho_{bl,b}^{dif}}, j = 1, N \quad (7.245)$$

$$\begin{aligned} \alpha_{bl,f}^{dir,sys}(\phi, \phi_s) = & \alpha_{bl,f}^{dir}(\phi_s) + \alpha_{bl,b}^{dir}(\phi_s) R_{gl,f}^{dir}(\phi) \tau_{bl,f}^{dir,dir}(\phi_s) \\ & + \frac{\alpha_{bl,b}^{dif} R_{gl,f}^{dif}}{1 - \rho_{bl,b}^{dif} R_{gl,f}^{dif}} \left(R_{gl,f}^{dir}(\phi) \tau_{bl,f}^{dir,dir}(\phi_s) \rho_{bl,b}^{dir}(\phi_s) + \tau_{bl,f}^{dir,dif}(\phi_s) \right) \end{aligned} \quad (7.246)$$

$$T_{f,sys}^{dif,dif} = \frac{\tau_{bl,f}^{dif,dif} T_{gl}^{dif}}{1 - R_{gl,f}^{dif} \rho_{bl,b}^{dif}} \quad (7.247)$$

$$T_{f,sys}^{sky-dif,dif} = \frac{\tau_{bl,f}^{sky-dif,dif} T_{gl}^{dif}}{1 - R_{gl,f}^{dif} \rho_{bl,b}^{dif}} \quad (7.248)$$

$$T_{f,sys}^{gnd-dif,dif} = \frac{\tau_{bl,f}^{gnd-dif,dif} T_{gl}^{dif}}{1 - R_{gl,f}^{dif} \rho_{bl,b}^{dif}} \quad (7.249)$$

$$A_{gl,j,f}^{dif,sys} = \frac{\tau_{bl,f}^{dif,dif} A_{gl,j,f}^{dif}}{1 - R_{gl,f}^{dif} \rho_{bl,b}^{dif}}, \quad j = 1, N \quad (7.250)$$

$$A_{gl,j,f}^{sky-dif,sys} = \frac{\tau_{bl,f}^{sky-dif,dif} A_{gl,j,f}^{dif}}{1 - R_{gl,f}^{dif} \rho_{bl,b}^{dif}}, \quad j = 1, N \quad (7.251)$$

$$A_{gl,j,f}^{gnd-dif,sys} = \frac{\tau_{bl,f}^{gnd-dif,dif} A_{gl,j,f}^{dif}}{1 - R_{gl,f}^{dif} \rho_{bl,b}^{dif}}, \quad j = 1, N \quad (7.252)$$

$$\alpha_{bl,f}^{dif,sys} = \alpha_{bl,f}^{dif} + \frac{\tau_{bl,f}^{dif,dif} R_{gl,f}^{dif}}{1 - R_{gl,f}^{dif} \rho_{bl,b}^{dif}} \alpha_{bl,b}^{dif} \quad (7.253)$$

$$\alpha_{bl,f}^{sky-dif,sys} = \alpha_{bl,f}^{sky-dif} + \frac{\tau_{bl,f}^{sky-dif,dif} R_{gl,f}^{dif}}{1 - R_{gl,f}^{dif} \rho_{bl,b}^{dif}} \alpha_{bl,b}^{dif} \quad (7.254)$$

$$\alpha_{bl,f}^{gnd-dif,sys} = \alpha_{bl,f}^{gnd-dif} + \frac{\tau_{bl,f}^{gnd-dif,dif} R_{gl,f}^{dif}}{1 - R_{gl,f}^{dif} \rho_{bl,b}^{dif}} \alpha_{bl,b}^{dif} \quad (7.255)$$

7.7.9.15 Blind/Glazing System Properties for Long-Wave Radiation

The program calculates how much long-wave radiation is absorbed by the blind and by the adjacent glass surface. The effective emissivity (long-wave absorptance) of an interior or exterior blind, taking into account reflection of long-wave radiation between the glass and blind, is given by:

$$\varepsilon_{bl}^{lw,eff} = \varepsilon_{bl}^{lw} \left(1 + \frac{\tau_{bl}^{lw} \rho_{gl}^{lw}}{1 - \rho_{bl}^{lw} \rho_{gl}^{lw}} \right) \quad (7.256)$$

where ρ_{gl}^{lw} is the long-wave reflectance of the outermost glass surface for an exterior blind or the innermost glass surface for an interior blind, and it is assumed that the long-wave transmittance of the glass is zero.

The effective innermost (for interior blind) or outermost (for exterior blind) glass surface emissivity when the blind is present is:

$$\varepsilon_{gl}^{lw,eff} = \varepsilon_{gl}^{lw} \frac{\tau_{bl}^{lw}}{1 - \rho_{bl}^{lw} \rho_{gl}^{lw}} \quad (7.257)$$

The effective inside surface emissivity is the sum of the effective blind and effective glass emissivities:

$$\varepsilon_{ins}^{lw,eff} = \varepsilon_{bl}^{lw,eff} + \varepsilon_{gl}^{lw,eff} \quad (7.258)$$

The effective temperature of the blind/glazing combination that is used to calculate the window's contribution to the zone's mean radiant temperature (MRT) is given by:

$$T^{eff} = \frac{\varepsilon_{bl}^{lw,eff} T_{bl} + \varepsilon_{gl}^{lw,eff} T_{gl}}{\varepsilon_{bl}^{lw,eff} + \varepsilon_{gl}^{lw,eff}} \quad (7.259)$$

7.7.9.16 Solar Radiation Transmitted and Absorbed by a Window/Blind System

Let the direct solar incident on the window be:

$$I_{dir,inc} = f_{sunlit} I_{dir,norm} \cos \phi (W/m^2) \quad (7.260)$$

where f_{sunlit} is the fraction of the window that is sunlit (determined by the shadowing calculations), $I_{dir,norm}$ is the direct normal solar irradiance, and ϕ is the angle of incidence.

Let $I_{sky,inc}$ be the irradiance on the window due to diffuse solar radiation from the sky (W/m^2) and let $I_{gnd,inc}$ be the irradiance on the window due to diffuse solar radiation from the ground (W/m^2).

Then we have the following expressions for different classes of transmitted and absorbed solar radiation for the window/blind system (where ϕ_s is the direct solar profile angle), all in W/m^2 :

Direct solar entering zone from incident direct solar:

$$I_{dir,inc} T_{f,sys}^{dir,dir}(\phi, \phi_s) \quad (7.261)$$

Diffuse solar entering zone from incident direct solar:

$$I_{dir,inc} T_{f,sys}^{dir,dif}(\phi, \phi_s) \quad (7.262)$$

Direct solar absorbed by blind:

$$I_{dir,inc} \alpha_{bl,f}^{dir,sys}(\phi, \phi_s) \quad (7.263)$$

Direct solar absorbed by glass layers:

$$I_{dir,inc} A_{gl,j,f}^{dir,sys}(\phi, \phi_s), \quad j = 1, N \quad (7.264)$$

7.7.9.17 For windows whose blinds have vertical slats:

Diffuse solar entering zone from incident diffuse solar:

$$(I_{sky,inc} + I_{gnd,inc}) T_{f,sys}^{dif,dif} \quad (7.265)$$

Diffuse solar absorbed by blind:

$$(I_{sky,inc} + I_{gnd,inc}) \alpha_{bl,f}^{dif,sys} \quad (7.266)$$

Diffuse solar absorbed by glass layers:

$$(I_{sky,inc} + I_{gnd,inc}) A_{gl,j,f}^{dif,sys}, \quad j = 1, N \quad (7.267)$$

7.7.9.18 For windows of tilt angle γ whose blinds have horizontal slats:

(vertical windows have tilt = 90° , horizontal windows have tilt = 0°)

Diffuse solar entering zone from incident diffuse solar:

$$T_{f,sys}^{sky-dif,dif} \left[\left(1 - \frac{|\cos \gamma|}{2} \right) I_{sky,inc} + \frac{|\cos \gamma|}{2} I_{gnd,inc} \right] + T_{f,sys}^{gnd-dif,dif} \left[\frac{|\cos \gamma|}{2} I_{sky,inc} + \left(1 - \frac{|\cos \gamma|}{2} \right) I_{gnd,inc} \right] \quad (7.268)$$

Diffuse solar absorbed by blind:

$$\alpha_{bl,f}^{sky-dif,sys} \left[\left(1 - \frac{|\cos \gamma|}{2} \right) I_{sky,inc} + \frac{|\cos \gamma|}{2} I_{gnd,inc} \right] + \alpha_{bl,f}^{gnd-dif,sys} \left[\frac{|\cos \gamma|}{2} I_{sky,inc} + \left(1 - \frac{|\cos \gamma|}{2} \right) I_{gnd,inc} \right] \quad (7.269)$$

Diffuse solar absorbed by glass layers:

$$A_{gl,j,f}^{sky-dif,sys} \left[\left(1 - \frac{|\cos \gamma|}{2} \right) I_{sky,inc} + \frac{|\cos \gamma|}{2} I_{gnd,inc} \right] + A_{gl,j,f}^{gnd-dif,sys} \left[\frac{|\cos \gamma|}{2} I_{sky,inc} + \left(1 - \frac{|\cos \gamma|}{2} \right) I_{gnd,inc} \right], \quad j = 1, N \quad (7.270)$$

7.7.9.19 Screens

The model for window screens currently allows placement on the exterior surface of a window system (i.e., between glass and interior window screens can not be modeled). The exterior screen is modeled as a planar semi-transparent sheet having specular transmittance that is dependent on the angle of incidence of beam solar radiation. The screen transmittance algorithm includes two components. The first one, $T_{beam}(\alpha', \varphi')$, accounts for the blockage of the sun's rays by the screen material. This component accounts for the beam solar radiation passing through the screen openings without hitting the screen material. The second part, $T_{scatt}(\alpha', \varphi')$, accounts for the additional flux of transmitted beam solar radiation by diffuse reflectance (scattering) from the screen material. Since the reflected component is small compared with the incident beam and the direction of scattering is highly dependent on incident angle, the component of transmitted beam radiation due to screen material reflectance can be treated in one of three ways based on a user input to the model.

The user may elect not to model the inward reflected beam transmittance due to the uncertainty of the direction of scattering or its low magnitude for low-reflecting screen materials. The user may alternately choose to model the inwardly-reflected transmitted beam as an additive component to the direct beam transmittance in the same solid angle and direction. Finally, the additional flux due to the inward reflection of direct beam radiation may be modeled as hemispherically-diffuse transmittance.

This reflected beam transmittance component depends upon the diffuse (i.e., beam-to-diffuse) reflectance of the screen material, so this reflectance ρ_{sc} is a required input to the model. Guidance input values for this diffuse reflectance are provided, to account for screens that are dark, medium, or light colored in appearance, in the likely case that more accurate values for the material reflectance

are difficult or time-consuming to obtain. If the diffuse reflectance of the screen material is known, use this value in place of the guidance provided.

The model is based on an orthogonal crossed cylinder geometry in which the screen material's cylindrical diameter and spacing are known. The model assumes that the screen material diameter and spacing are the same in both directions. Figure 7.29 shows a rendering of intersecting orthogonal crossed cylinders used as the basis for the EnergyPlus screen model.

Figure 7.29: Screen model rendering of intersecting orthogonal crossed cylinders

If the required screen material dimensions are not available from the manufacturer, they may be determined using the following procedure:

- Lay the screen next to a finely-divided scale or ruler. A magnifying glass may be helpful in determining the screen material dimensions. Alternately, a photograph can be taken and the image enlarged.
- Determine the diameter D of an individual screen material “cylinder”. Average the diameter values if different in opposing directions.
- Determine the average center-to-center spacing S of the screen material or measure from one side of a “cylinder” to the same side of the next “cylinder” and record the spacing S . Average the spacing values if different in opposing directions.
- Enter these values as inputs to the exterior window screen model.

The screen material diameter and spacing are then used to determine the screen material aspect ratio for use in the screen model.

$$\gamma = D/S \quad (7.271)$$

where

γ = Screen material aspect ratio, dimensionless

D = Screen material diameter, m

S = Screen material spacing, m

Figure 7.30 below shows the input requirements for material diameter and spacing and the associated calculation for openness factor, the equivalent to T_{beam} at direct normal incidence.

Figure 7.30: Physical screen material properties

7.7.10 Screen Properties and Calculations

7.7.10.1 Screen Beam Transmittance

The first component of the window screen transmittance model is a geometric representation of the open area of the screen material and is dependent on the angle of incident beam radiation. Figure 7.31 shows a schematic of a South-facing vertical window screen and the solar angles used in EnergyPlus. The window screen model is based on the relative angles of incidence of the sun's rays with respect to the window screen outward normal. In the figure, the relative solar azimuth and relative solar altitude are represented as φ' and α' , respectively.

Given the diffuse reflectance $\rho_s c$ and the screen aspect ratio γ , the model takes the direction of solar incidence, the relative solar altitude angle α' and the relative solar azimuth angle φ' , illustrated in Figure 7.31, and calculates the direct beam transmittance $T_{beam}(\alpha', \varphi')$ as follows. Since the direct beam transmittance is only a function of the incident angle and the screen material aspect ratio, the following applies to both solar and visible radiation.

$$\alpha'' = \arctan(\tan \alpha' \sec \varphi') \quad (7.272)$$

$$\beta = \frac{\pi}{2} - \alpha' \quad (7.273)$$

$$T_y = 1 - \gamma \left[\cos \alpha'' + \sin \alpha'' \tan \alpha' (1 + \cot^2 \beta)^{\frac{1}{2}} \right] \quad (7.274)$$

$$\mu = \arccos \left(\left[\cos^2 \alpha' \cos^2 \varphi' + \sin^2 \alpha' \right]^{\frac{1}{2}} \right) \quad (7.275)$$

$$\varepsilon = \arccos \left(\frac{\cos \alpha' \cos \varphi'}{\cos \mu} \right) \quad (7.276)$$

Figure 7.31: Schematic of a vertical window screen facing due South

$$\eta = \frac{\pi}{2} - \varepsilon \quad (7.277)$$

$$\mu' = \arctan(\tan \mu \sec \varepsilon) \quad (7.278)$$

$$T_x = 1 - \gamma \left[\cos \mu' + \sin \mu' \tan \mu (1 + \cot^2 \eta)^{\frac{1}{2}} \right] \quad (7.279)$$

$$T_{beam}(\alpha', \varphi') = T_{beam}^{vis}(\alpha', \varphi') = T_x T_y \quad (7.280)$$

where

T_y = vertical component of direct beam transmittance

T_x = horizontal component of direct beam transmittance

T_{beam} = direct screen transmittance that accounts for beam solar radiation passing through the screen openings without hitting the screen material

T_{beam}^{vis} = direct visible screen transmittance that accounts for beam solar radiation passing through the screen openings without hitting the screen material

α' = relative solar altitude angle [radians]

φ' = relative solar azimuth angle [radians]

γ = Screen material aspect ratio, dimensionless

$\alpha'', \beta, \mu, \varepsilon, \eta, \mu'$ = intermediate variables

This first component of screen direct beam transmittance was developed using geometric principals and was verified using an optical ray tracing software program.

The second component of the window screen transmittance model is an empirical algorithm that accounts for the inward reflection of incident beam radiation off the screen material surface. The calculation procedure for the screen's transmittance via beam reflection, $T_{scatt}(\alpha', \varphi')$ is as follows:

$$T_{scattmax} = 0.0229\gamma + 0.2971\rho_{sc} - 0.03624\gamma^2 + 0.04763\rho_{sc}^2 - 0.44416\gamma\rho_{sc} \quad (7.281)$$

$$T_{scattmax}^{vis} = 0.0229\gamma + 0.2971\rho_{sc}^{vis} - 0.03624\gamma^2 + 0.04763(\rho_{sc}^{vis})^2 - 0.44416\gamma\rho_{sc}^{vis} \quad (7.282)$$

$$\delta_{max} = 89.7 - 10\gamma/0.16 \quad (7.283)$$

$$\delta = (\alpha_d'^2 + \varphi_d'^2)^{\frac{1}{2}} \quad (7.284)$$

$$Peak_{ratio} = \frac{1}{0.2\rho_{sc}(1-\gamma)} \quad (7.285)$$

$$Peak_{ratio}^{vis} = \frac{1}{0.2\rho_{sc}^{vis}(1-\gamma)} \quad (7.286)$$

$$T_{scatt}(\alpha', \varphi') = 0.2\rho_{sc}T_{scattmax}(1-\gamma) \left(1 + (Peak_{ratio} - 1)e^{\frac{-|\delta-\delta_{max}|^{2.0}}{600}} \right) \quad (7.287)$$

$$T_{scatt}^{vis}(\alpha', \varphi') = 0.2\rho_{sc}^{vis}T_{scattmax}^{vis}(1-\gamma) \left(1 + (Peak_{ratio}^{vis} - 1)e^{\frac{-|\delta-\delta_{max}|^{2.0}}{600}} \right) \quad (7.288)$$

If $\delta > \delta_{max}$, then:

$$\begin{aligned} T_{scatt}(\alpha', \varphi') &= 0.2\rho_{sc}T_{scattmax}(1-\gamma) \left(1 + (Peak_{ratio} - 1)e^{\frac{-|\delta-\delta_{max}|^{2.5}}{600}} \right) \\ &\quad - 0.2\rho_{sc}T_{scattmax}(1-\gamma) \left(\max \left(0.0, \frac{\delta-\delta_{max}}{90.-\delta_{max}} \right) \right) \\ T_{scatt}^{vis}(\alpha', \varphi') &= 0.2\rho_{sc}^{vis}T_{scattmax}^{vis}(1-\gamma) \left(1 + (Peak_{ratio}^{vis} - 1)e^{\frac{-|\delta-\delta_{max}|^{2.5}}{600}} \right) \\ &\quad - 0.2\rho_{sc}^{vis}T_{scattmax}^{vis}(1-\gamma) \left(\max \left(0.0, \frac{\delta-\delta_{max}}{90.-\delta_{max}} \right) \right) \end{aligned} \quad (7.289)$$

where

$T_{scattmax}$ = maximum reflected (scattered) beam transmittance

$T_{scattmax}^{vis}$ = maximum visible reflected (scattered) beam transmittance

δ_{max}, δ = intermediate variables [degrees]

α_d' = relative solar altitude [degrees]

φ_d' = relative solar azimuth [degrees]

$Peak_{ratio}$ = Ratio of peak scattered beam transmittance to scattered beam transmittance at direct normal incidence.

$Peak_{ratio}^{vis}$ = Ratio of peak scattered visible transmittance to scattered visible transmittance at direct normal incidence.

ρ_{sc} = diffuse solar reflectance of the screen material

ρ_{sc}^{vis} = diffuse visible reflectance of the screen material

T_{scatt} = beam solar transmittance due to reflectance (scattering)

T_{scatt}^{vis} = beam visible transmittance due to reflectance (scattering)

The reflected (scattered) transmittance of incident beam radiation is an empirical model derived by curvefitting results from optical ray trace modeling. Ray traces were performed for a range of screen aspect ratios, diffuse screen reflectances, and relative solar azimuth and altitude angles. The surface of the screen cylinders was assumed to be diffusely reflecting, having the optical properties of a Lambertian surface. The transmitted flux due to reflection was determined by a hemispherical detector on the transmitted side of the screen.

These two components of beam solar transmittance are then used to specify the properties for beam-to-beam and beam-to-diffuse transmittance for the screen based on the user selection for Reflected Beam Transmittance Accounting Method in the WindowMaterial:Screen object. The calculations below apply to both the solar and visible beam solar transmittance.

If the user selects DoNotModel, the direct beam transmittance is set to T_{beam} and the reflected (scattered) portion of the beam solar transmittance is ignored:

$$T_{sc}^{dir,dir} = T_{beam}(\alpha', \varphi') \quad (7.290)$$

$$T_{sc}^{dir,dif} = 0.0 \quad (7.291)$$

$$T_{sc,vis}^{dir,dir} = T_{beam}(\alpha', \varphi') \quad (7.292)$$

$$T_{sc,vis}^{dir,dif} = 0.0 \quad (7.293)$$

where

$T_{sc}^{dir,dir}$ = direct-to-direct beam transmittance of the screen (output report variable Surface Window Screen Beam to Beam Solar Transmittance)

$T_{sc}^{dir,dif}$ = direct-to-diffuse beam transmittance of the screen (output report variable Surface Window Screen Beam to Diffuse Solar Transmittance)

$T_{sc,vis}^{dir,dir}$ = direct-to-direct visible transmittance of the screen

$T_{sc,vis}^{dir,dif}$ = direct-to-diffuse visible transmittance of the screen

If the user selects Model as Direct Beam, the reflected (scattered) portion of the beam solar transmittance is added to the direct beam transmittance T_{beam} in the same solid angle and direction of the unattenuated solar beam:

$$T_{sc}^{dir,dir} = T_{beam}(\alpha', \varphi') + T_{scatt}(\alpha', \varphi') \quad (7.294)$$

$$T_{sc}^{dir,dif} = 0.0 \quad (7.295)$$

$$T_{sc,vis}^{dir,dir} = T_{beam}(\alpha', \varphi') + T_{scatt}^{vis}(\alpha', \varphi') \quad (7.296)$$

$$T_{sc,vis}^{dir,dif} = 0.0 \quad (7.297)$$

If the user selects Model as Diffuse Beam, the direct beam transmittance is set to T_{beam} and the reflected (scattered) portion of the beam solar transmittance is modeled as diffuse hemispherical radiation:

$$T_{sc}^{dir,dir} = T_{beam}(\alpha', \varphi') \quad (7.298)$$

$$T_{sc}^{dir,dif} = T_{scatt}(\alpha', \varphi') \quad (7.299)$$

$$T_{sc,vis}^{dir,dir} = T_{beam}(\alpha', \varphi') \quad (7.300)$$

$$T_{sc,vis}^{dir,dif} = T_{scatt}^{vis}(\alpha', \varphi') \quad (7.301)$$

7.7.10.2 Screen Beam Reflectance

The screen reflectance (overall value for the screen assembly, accounting for the screen material itself and the open spaces between the screen material) is calculated by first subtracting the direct-to-direct screen transmittance from the unit incident beam. This approximates the fraction of incident beam solar radiation striking the screen that is not inwardly transmitted. The result is then multiplied by the screen material diffuse reflectance ρ_{sc} . The inwardly scattered transmittance is then subtracted from this quantity to obtain an approximate value for the screen's reflectance R_{sc} to beam radiation incident as a function of the relative angles of incident radiation. This equation is used for both beam and visible reflectance:

$$R_{SC}^{dir,dif}(\alpha', \varphi') = \rho_{SC} \left(1 - T_{SC}^{dir,dir} \right) - T_{SC}^{dir,dif} \quad (7.302)$$

$$R_{SC,vis}^{dir,dif}(\alpha', \varphi') = \rho_{SC}^{vis} \left(1 - T_{SC,vis}^{dir,dir} \right) - T_{SC,vis}^{dir,dif} \quad (7.303)$$

7.7.10.3 Screen Beam Absorptance

The screen absorptance(overall value for the screen assembly, accounting for the screen material itself and the open spaces between the screen material) is calculated as the quantity of the unit incident flux (1) less the directly-transmitted component $T_{dir,dir}$ multiplied by the quantity 1 minus the screen material diffuse reflectance.

$$A_{SC}^{dir}(\alpha', \varphi') = \left(1 - T_{SC}^{dir,dir} \right) (1 - \rho_{SC}) \quad (7.304)$$

7.7.10.4 Screen Diffuse Properties

The transmittance of the screen to half-hemispherical diffuse (sky) radiation is calculated by performing a finite-element-summation, approximately equivalent to an integration over the solid angle of the beam transmittance, assuming uniform radiance. This single-number screen diffuse transmittance is then multiplied by the irradiance incident on the screen from a uniform half-hemisphere of sky- or ground-reflected radiation to determine the level of additional flux transmitted by the screen to the window from the diffuse sky or ground. The sun angles shown in the figure below represent the solar altitude angle (θ) and solar azimuth angle (ϕ) in polar coordinates. These angles are used to calculate the average diffuse-to-diffuse properties for screens in the following derivations.

The screen transmittance to diffuse radiation $T_{dif,dif}(\gamma, \rho_{sc})$ is computed as the integrated average of the combined beam transmittance $T_{tot}(\gamma, \rho, \theta, \phi)$ over the directions of incidence using

Figure 7.32: Sun Angles in Screen Calculations.

spherical coordinates (θ, ϕ) in which the z-axis is perpendicular to the plane of the screen. Using a finite element computation, this is:

$$T_{tot}(\gamma, \rho_{sc}, \theta_j, \phi_i) = T_{beam}(\alpha', \varphi') + T_{scatt}(\alpha', \varphi') \quad (7.305)$$

$$T_{sc}^{dif,dif}(\gamma, \rho_{sc}) = \frac{\sum_{j=1}^N \sum_{i=1}^M T_{tot}(\gamma, \rho_{sc}, \theta_j, \phi_i) \sin(\theta_j) \cos(\theta_j)}{\sum_{j=1}^N \sum_{i=1}^M \sin(\theta_j) \cos(\theta_j)} \quad (7.306)$$

where

θ = solar altitude angle in polar coordinates [radians]

ϕ = solar azimuth angle in polar coordinates [radians]

$T_{sc}^{dif,dif}(\gamma, \rho_{sc})$ = diffuse-diffuse transmittance (output report variable Surface Window Screen Diffuse to Diffuse Solar Transmittance)

Similarly, the reflectance of the screen to diffuse radiation is given by

$$R_{sc}^{dif,dif}(\gamma, \rho_{sc}) = \frac{\sum_{j=1}^N \sum_{i=1}^M R_{sc}^{dir,dif}(\gamma, \rho_{sc}, \theta_j, \phi_i) \sin(\theta_j) \cos(\theta_j)}{\sum_{j=1}^N \sum_{i=1}^M \sin(\theta_j) \cos(\theta_j)} \quad (7.307)$$

There is an assumption in both of these formulas that the brightness of the sky (or ground) diffuse radiation is the same for all directions. For this reason, the solar azimuth angle ϕ and solar altitude angle θ have a range of 0 to $\pi/2$ (instead of $-\pi/2$ to $+\pi/2$) because the screen is assumed to have identical optical properties for radiation incident at the same angles on either side of a vertical or horizontal plane perpendicular to the screen.

Since the screen direct transmittance model is derived with respect to a different coordinate axis labeling, a coordinate transform is needed in order to calculate the diffuse optical properties. In these calculations, for each spherical solar coordinates (θ, ϕ) we need the corresponding screen relative solar coordinates (α', φ') to evaluate the screen transmittance model for that direction.

For each θ and ϕ in the summation, the corresponding values for the relative solar altitude α' and relative solar azimuth φ' needed to calculate screen transmittance are determined with the following coordinate transform equations:

$$\sin \alpha' = \sin \theta \cos \phi \quad (7.308)$$

$$\tan \varphi' = \tan \theta \sin \phi \quad (7.309)$$

The absorptance of the screen to diffuse incident radiation is calculated by subtracting the diffuse transmittance and diffuse reflectance from unity as follows:

$$A_{sc}^{dif}(\gamma, \rho_{sc}) = 1 - T_{sc}^{dif,dif}(\gamma, \rho_{sc}) - R_{sc}^{dif,dif}(\gamma, \rho_{sc}) \quad (7.310)$$

7.7.10.5 Screen/Glass System Properties for Short-Wave Radiation

The combined system properties of the screen/glass combination are calculated using the properties of the screen in combination with the bare glass material properties. Interreflections of radiation between the screen and glass surfaces are included. The following infinite series serves as an example for calculating the combined screen/glass system properties. The terms of the series are built up as illustrated in the following figure. The terms shown at the right of the figure represent each term in the infinite series for the combined screen/glass property (beam transmittance in this example).

For the example of beam transmittance, the incident solar beam strikes the screen at the incident angle associated with the current relative azimuth and altitude angle. The incident beam splits into reflected and transmitted components at the screen. The transmitted component is attenuated as it passes through the screen material by the screen's beam transmittance ($T_{sc}^{dir,dir}$, shown as T_{sc}^{dir} in the figure and equations below) at this incident angle. The reflected (scattered) transmittance of incident solar beam is also shown at this point and will be discussed later in this section. As the attenuated solar beam continues on towards the front glass surface, a portion of the screen-transmitted beam splits at the window surface into transmitted and reflected components. The reflected component reflects off the front surface of the glass material ($T_{sc}^{dir,dir} R_{gl,f}^{dir}$) and the transmitted component continues to travel through the glass material and is further attenuated by the glass beam transmittance. Thus the first term of the combined screen/glass solar beam transmittance is shown as $T_{sc}^{dir,dir} T_{gl}^{dir}$. Interreflections are accounted for by following the beam as it continues to reflect off the front surface of the glass material and the back surface of the screen material. Continuing on with the glass-reflected beam ($T_{sc}^{dir,dir} R_{gl,f}^{dir}$) described above, this beam strikes the back surface of the screen material at the same incident angle as the incident solar beam. This reflected beam is also assumed to be a collimated beam (solid lines) which strikes the back surface of the screen material and reflects as hemispherically-diffuse radiation (dotted lines). The reflective property of the screen material used here is the beam reflectance calculated at the incident solar angle ($R_{sc}^{dir,dif}$). A single ray of this diffuse light will be followed through the remaining steps and represents the energy associated with **all** diffuse rays interreflecting between the screen and glass layers. To determine the second term of the combined screen/glass beam transmittance, the diffusely-reflected ray ($T_{sc}^{dir,dir} R_{gl,f}^{dir} R_{sc}^{dir,dif}$) passes through and is attenuated by the glass layer. Since this ray originates from diffuse reflection, the attenuation of this ray is accounted for using the diffuse transmittance property of the glass. Thus, the second term is shown as $T_{sc}^{dir,dir} R_{gl,f}^{dir} R_{sc}^{dir,dif} T_{gl}^{dif}$. Defining the remaining terms continues in a similar fashion using diffuse properties of both the screen and glass material. Notice that the 3rd and 4th terms shown below are similar to the 2nd term, but additional terms are raised to increasing powers.

The screen/glass system transmittance equation shown in the figure above is repeated here in an alternate format to emphasize the recurring nature of the infinite series. This equation represents the final solar beam transmittance equation for the screen/glass combination. The recurring terms are shown as a summation of a quantity raised to the n power, with n ranging from 0 to infinity. Since the quantity $R_{gl,f}^{dif} R_{sc}^{dif,dif}$ is less than 1, the summation $\sum_{n=0}^{\infty} (R_{gl,f}^{dif} R_{sc}^{dif,dif})^n$ converges and can be expressed as $(1 - R_{gl,f}^{dif} R_{sc}^{dif,dif})^{-1}$. Since the reflected (scattered) transmittance of incident solar beam ($T_{sc}^{dir,dif}$) and the diffusely reflecting beam $T_{sc}^{dir,dir} R_{gl,f}^{dir} R_{sc}^{dir,dif}$ are both assumed to be hemispherically diffuse radiation, the reflected (scattered) transmittance of incident solar beam is added to the infinite series as shown below.

Figure 7.33: Screen/Glass System Transmittance Equation Schematic.

$$\begin{aligned}
T_{sys}^{dir,all}(\alpha', \varphi', \phi) &= T_{sc}^{dir,dir}(\alpha', \varphi') T_{gl}^{dir}(\phi) \\
&+ (T_{sc}^{dir,dir}(\alpha', \varphi') R_{gl,f}^{dir} R_{sc}^{dir,dif}(\alpha', \varphi') \\
&+ T_{sc}^{dir,dif}(\alpha', \varphi')) T_{gl}^{dif} \sum_{n=0}^{\infty} (R_{gl,f}^{dif} R_{sc}^{dif,dif})^n
\end{aligned} \tag{7.311}$$

or:

$$T_{sys}^{dir,all}(\alpha', \varphi', \phi) = T_{sc}^{dir,dir}(\alpha', \varphi') T_{gl}^{dir}(\phi) + \frac{(T_{sc}^{dir,dir}(\alpha', \varphi') R_{gl,f}^{dir} R_{sc}^{dir,dif}(\alpha', \varphi') + T_{sc}^{dir,dif}(\alpha', \varphi')) T_{gl}^{dif}}{1 - R_{gl,f}^{dif} R_{sc}^{dif,dif}} \tag{7.312}$$

where

$T_{sys}^{dir,all}(\alpha', \varphi', \phi)$ = screen/glass system beam transmittance (output report variable Surface Window Screen and Glazing System Beam Solar Transmittance)

Properties for beam absorptance of the individual glass layers and screen/glass combination are derived in a similar fashion to the transmittance calculation described above. Diffuse transmittance and absorptance of individual glass layers and the screen/glass combination are also shown here.

$$\begin{aligned}
A_{gl,j,f}^{dir,sys}(\alpha', \varphi', \phi) &= T_{sc}^{dir,dir}(\alpha', \varphi') A_{gl,j,f}^{dir}(\phi) + \\
&\frac{(T_{sc}^{dir,dir}(\alpha', \varphi') R_{gl}^{dir}(\phi) R_{sc}^{dir,dif}(\alpha', \varphi') + T_{sc}^{dir,dif}(\alpha', \varphi')) A_{gl,j,f}^{dif}}{1 - R_{gl,f}^{dif} R_{sc}^{dif,dif}}, \quad j = 1, N
\end{aligned} \tag{7.313}$$

$$\begin{aligned}
\alpha_{sc}^{dir,sys}(\alpha', \varphi', \phi) &= A_{sc}^{dir}(\alpha', \varphi') (1 + R_{gl,f}^{dir}(\phi) T_{sc}^{dir,dir}(\alpha', \varphi')) + \\
&\frac{A_{sc}^{dif} R_{gl,f}^{dif}}{1 - R_{sc}^{dif,dif} R_{gl,f}^{dif}} (R_{gl,f}^{dir}(\phi) T_{sc}^{dir,dir}(\alpha', \varphi') R_{sc}^{dir,dif}(\alpha', \varphi'))
\end{aligned} \tag{7.314}$$

$$T_{sys}^{dif,dif} = \frac{T_{sc}^{dif,dif} T_{gl}^{dif}}{1 - R_{gl,f}^{dif} R_{sc}^{dif,dif}} \tag{7.315}$$

$$A_{gl,j,f}^{dif,sys} = \frac{T_{sc}^{dif,dif} A_{gl,j,f}^{dif}}{1 - R_{gl,f}^{dif} R_{sc}^{dif,dif}}, \quad j = 1, N \tag{7.316}$$

$$\alpha_{sc}^{dif,sys} = A_{sc}^{dif} \left(1 + \frac{T_{sc}^{dif,dif} R_{gl,f}^{dif}}{1 - R_{gl,f}^{dif} R_{sc}^{dif,dif}} \right) \tag{7.317}$$

where

$A_{gl,j,f}^{dir,sys}(\alpha', \varphi', \phi)$ = glass layer beam absorptance including interreflections with screen material

$\alpha_{sc}^{dir,sys}(\alpha', \varphi', \phi)$ = beam absorptance of screen material including interreflections with glass

$T_{sys}^{dif,dif}$ = screen/glass system diffuse transmittance (output report variable Surface Window Screen and Glazing System Diffuse Solar Transmittance)

$A_{gl,j,f}^{dif,sys}$ = glass layer diffuse absorptance including interreflections with screen material

$\alpha_{sc}^{dif,sys}$ = diffuse absorptance of screen material including interreflections with glass

7.7.10.6 Screen/Glazing System Properties for Long-Wave Radiation

The program calculates how much long-wave radiation is absorbed by the screen and by the adjacent glass surface. The effective long-wave emissivity (equal to the long-wave absorptance on a wavelength-by-wavelength basis or over the same spectral range) of an exterior screen, taking into account reflection of long-wave radiation between the glass and screen, is given by

$$\varepsilon_{sc}^{lw,eff} = \varepsilon_{sc}^{lw} \left(1 + \frac{T_{sc}^{dif,dif} \rho_{gl}^{lw}}{1 - R_{sc}^{dif,dif} \rho_{gl}^{lw}} \right) \quad (7.318)$$

where ρ_{gl}^{lw} is the long-wave reflectance of the outermost glass surface facing an exterior screen, and it is assumed that the long-wave transmittance of the glass is zero.

The effective outermost (for exterior screen) glass surface emissivity when the screen is present is

$$\varepsilon_{gl}^{lw,eff} = \varepsilon_{gl}^{lw} \frac{T_{sc}^{dif,dif}}{1 - R_{sc}^{dif,dif} \rho_{gl}^{lw}} \quad (7.319)$$

The effective inside surface emissivity is the sum of the effective screen and effective glass emissivities:

$$\varepsilon_{ins}^{lw,eff} = \varepsilon_{sc}^{lw,eff} + \varepsilon_{gl}^{lw,eff} \quad (7.320)$$

The effective temperature of the screen/glazing combination that is used to calculate the window's contribution to the zone's mean radiant temperature (MRT) is given by

$$T^{eff} = \frac{\varepsilon_{sc}^{lw,eff} T_{sc} + \varepsilon_{gl}^{lw,eff} T_{gl}}{\varepsilon_{sc}^{lw,eff} + \varepsilon_{gl}^{lw,eff}} \quad (7.321)$$

7.7.10.7 Solar Radiation Transmitted and Absorbed by a Window/Screen System

Let the direct solar incident on the window be

$$I_{dir,inc} = f_{sunlit} I_{dir,norm} \cos \phi (W/m^2) \quad (7.322)$$

where f_{sunlit} is the fraction of the window that is sunlit (determined by the shadowing calculations), $I_{dir,norm}$ is the direct normal solar irradiance, and ϕ is the angle of incidence.

Let $I_{sky,inc}$ be the irradiance on the window due to diffuse solar radiation from the sky (W/m^2) and let $I_{gnd,inc}$ be the irradiance on the window due to diffuse solar radiation from the ground (W/m^2).

Then we have the following expressions for different classes of transmitted and absorbed solar radiation for the window/screen system, all in W/m^2 :

Direct and diffuse solar entering zone from incident direct solar:

$$I_{dir,inc} T_{sys}^{dir,all} (\alpha', \varphi') \quad (7.323)$$

Direct solar absorbed by screen:

$$I_{dir,inc} \alpha_{sc}^{dir,sys} (\alpha', \varphi') \quad (7.324)$$

Direct solar absorbed by glass layers:

$$I_{dir,inc} A_{gl,j,f}^{dir,sys}(\phi, \phi_s), \quad j = 1, N \quad (7.325)$$

Diffuse solar entering zone from incident diffuse solar:

$$(I_{sky,inc} + I_{gnd,inc}) T_{sys}^{dif,dif} \quad (7.326)$$

Diffuse solar absorbed by screen:

$$(I_{sky,inc} + I_{gnd,inc}) \alpha_{sc}^{dif,sys} \quad (7.327)$$

Diffuse solar absorbed by glass layers:

$$(I_{sky,inc} + I_{gnd,inc}) A_{gl,j,f}^{dif,sys}, \quad j = 1, N \quad (7.328)$$

7.7.11 Complex Fenestration Calculation Module

This section describes detailed method for modeling complex fenestration systems, including shading devices and general fenestration attachments. This detailed method primarily refers to the optical side of modeling complex fenestration systems. Thermal modeling is done according to ISO 15099 standard, which is described in the Window Heat Balance Calculation section with the addition of deflection and vacuum glazing systems modeling and some modifications to shading layer algorithms, which is described in Shading Device Thermal Model section. Optical calculations in this method are done using Bidirectional Scattering Distribution Function (BSDF) approach. The concept behind BSDF is based on the definition of discrete set of incident and outgoing angles, which fully describes optical performance of any system, simple or complex, limited only by the resolution of angular discretization. In this method each layer, as well as the whole system is described by a matrix of incident and outgoing angles.

7.7.11.1 Complex Fenestration Solar-Optical Calculations

7.7.11.1.1 Solar radiation calculation outline

For solar radiation calculations, each of the layers as well as entire glazing system can be represented with the set of Bi-directional Scattering Distribution Functions or BSDF, consisting of Bi-directional Reflectance Distribution Function or BRDF and Bi-directional Transmittance Distribution Function or BTDF. Each function is a matrix 145 x 145 that describes reflectance or transmittance distribution in the outgoing hemisphere for each incident angle in the incidence hemisphere. For each function there is forward and back matrix, for a total of 4 145 x 145 matrices. Depending on the purpose of calculations, description of entire glazing system is divided into solar and visible spectrum, which means that there can be 8 matrices describing visible and complete solar spectrums. Reflectance and transmittance being non-dimensional ratios of reflected or transmitted energy over incident energy, in order to get total reflected and transmitted energy it is necessary to supply vector of incident solar energy, which usually consists of direct and diffuse radiation. Specifics of calculations of direct and diffuse solar radiation is described in some detail in oncoming chapters.

Scattering (Non-Specular) Glazing and Shading Devices

A general scattering fenestration system is characterized by BTDFs and BRDFs, which were described above. Given an incident direction $\mathbf{p}^{(I)}$, and an incident irradiance $E(\mathbf{p}^{(I)})$, the transmitted radiance in the outgoing direction $\mathbf{p}^{(T)}$ is:

$$S(\mathbf{p}^{(T)}) = \mathcal{T}(\mathbf{p}^{(T)}, \mathbf{p}^{(I)}) dE(\mathbf{p}^{(I)}) \quad (7.329)$$

where the function \mathcal{T} is the BTDF. In the absence of a source of effectively plane-parallel incident radiation (such as direct sunlight) $dE(\mathbf{p}^{(I)})$ is an infinitesimal quantity, and the right side of the equation must be summed over the irradiance from all incident directions to produce the outgoing radiance:

$$S(\mathbf{p}^{(T)}) = \int \mathcal{T}(\mathbf{p}^{(T)}, \mathbf{p}^{(I)}) \frac{dE(\mathbf{p}^{(I)})}{d\Omega} d\Omega \quad (7.330)$$

A similar equation gives the reflected radiance in the direction $\mathbf{p}^{(R)}$:

$$S(\mathbf{p}^{(R)}) = \int \mathcal{R}(\mathbf{p}^{(R)}, \mathbf{p}^{(I)}) \frac{dE(\mathbf{p}^{(I)})}{d\Omega} d\Omega \quad (7.331)$$

We can express the irradiance in terms of the exterior luminance, S , in that direction:

$$dE(\mathbf{p}^{(I)}) dA = S^{(I)}(\mathbf{p}^{(I)}) (-\mathbf{p}^{(I)} \cdot \mathbf{n}) d\Omega^{(I)} dA \quad (7.332)$$

which allows one to express the transmittance of exterior radiation to produce the total outgoing radiance from the fenestration into the room in a particular direction:

$$S(\mathbf{p}^{(T)}) = \int_{\Omega^{(I)}} \mathcal{T}(\mathbf{p}^{(T)}, \mathbf{p}^{(I)}) S^{(I)}(\mathbf{p}^{(I)}) (-\mathbf{p}^{(I)} \cdot \mathbf{n}) d\Omega^{(I)} \quad (7.333)$$

The negative sign is added to account for the fact that $\mathbf{p}^{(I)}$ and \mathbf{n} have opposite sign for incoming radiation.

The radiance in Equation 7.333 is emitted from the back side of the element of area shown in Figure 7.34. Considering a second surface, viewing the back side of the fenestration system, we can use Equation 7.332 to calculate the irradiance on surface 2:

$$E^{(2)}(\mathbf{p}^{(T)}) dA^{(2)} = S^{(T)}(\mathbf{p}^{(T)}) (-\mathbf{p}^{(T)} \cdot \mathbf{n}^{(2)}) d\Omega^{(I,2)} dA^{(2)} \quad (7.334)$$

This expression, however, contains a number of new quantities, such as $d\Omega^{(I,2)}$, the element of solid angle for incoming radiation as seen from surface 2. We can sort this out by referring to Figure 7.35 and making some changes and clarifications in notation.

In this figure, we consider that surface 1 is the back side of the fenestration system, and surface 2 is some other surface in the room that receives the transmitted solar radiation through the fenestration system. We consider infinitesimal elements $dA^{(1)}$ and $dA^{(2)}$ of the two surfaces, and define vector surface elements by $d\mathbf{A}^{(1)} = dA^{(1)} \mathbf{n}^{(1)}$ and $d\mathbf{A}^{(2)} = dA^{(2)} \mathbf{n}^{(2)}$. The quantity \mathbf{r} in the figure denotes a vector pointing from surface 1 to surface 2, the magnitude of which is the distance r between the two surface elements. This is used to define two unit vectors: $\hat{\mathbf{r}}^{(1)} = \mathbf{r}/r$ is a unit vector pointing from surface element 1 to surface element 2, and $\hat{\mathbf{r}}^{(2)} = -\mathbf{r}/r$ is a unit vector pointing from surface element 2 back to surface element 1. The unit vector $\mathbf{p}^{(T)}$ in Equation 7.333

Figure 7.34: Irradiance geometry

Figure 7.35: Radiation exchange between two surface elements

is in fact $\hat{\mathbf{r}}^{(1)}$. The shaded quadrilaterals in the figure are the projected area elements normal to \mathbf{r} . Since the areas are infinitesimal, all the radiation leaving one surface element and arriving at the other will be in the direction \mathbf{r} , so that all radiation will be contained within the parallelepiped defined by the dashed lines (parallel to \mathbf{r}) joining the corners of the two surface elements. It follows that the area $dA^{(2)}$ is not independent of $dA^{(1)}$. The figure also shows the solid angle that has been denoted $d\Omega^{(I,2)}$ above, which is the solid angle subtended by $dA^{(1)}$ as seen from $dA^{(2)}$ and is given by:

$$d\Omega^{(I,2)} = \frac{d\mathbf{A}^{(1)} \cdot \mathbf{r}^{(1)}}{r^2} \quad (7.335)$$

The net power from surface element 1 to surface element 2 is:

$$W^{(1 \rightarrow 2)} = (S^{(1)}(\hat{\mathbf{r}}^{(1)}) - S^{(2)}(\hat{\mathbf{r}}^{(2)})) \frac{(d\mathbf{A}^{(1)} \cdot \hat{\mathbf{r}}^{(1)}) (d\mathbf{A}^{(2)} \cdot \hat{\mathbf{r}}^{(2)})}{r^2} \quad (7.336)$$

where $S^{(1)}(\hat{\mathbf{r}}^{(1)})$ is the radiance leaving surface element 1 in the direction of surface element 2, and vice-versa for $S^{(2)}(\hat{\mathbf{r}}^{(2)})$. In this case, the latter is zero and the former is the quantity called $S^{(T)}(\mathbf{p}^{(T)})$ above. Given Equation 7.335, we can recognize the quantity multiplying the radiance as the solid angle $d\Omega^{(I,2)}$ times the projected area of surface element 2 perpendicular to \mathbf{r} . But the expression is symmetrical in the two surface elements, so we could also express it as:

$$W^{(1 \rightarrow 2)} = S^{(T)}(\mathbf{p}^{(T)}) (d\mathbf{A}^{(1)} \cdot \hat{\mathbf{r}}^{(1)}) d\Omega^{(T)} \quad (7.337)$$

where

$$d\Omega^{(T)} = \frac{(d\mathbf{A}^{(2)} \cdot \hat{\mathbf{r}}^{(2)})}{r^2} \quad (7.338)$$

The superscript (T) is used here because the solid angle element pertains to the direction $\mathbf{p}^{(T)}$. In the particular case under discussion that restricts attention to those directions for which the outgoing radiation strikes surface element 2. We can now rewrite Equation 7.334 as:

$$E^{(2)}(\mathbf{p}^{(T)}) dA^{(2)} = S^{(T)}(\mathbf{p}^{(T)}) (\mathbf{n}^{(1)} \cdot \hat{\mathbf{r}}^{(1)}) d\Omega^{(T)} dA^{(1)} \quad (7.339)$$

and since, as can readily be seen from Figure 7.35, $(d\mathbf{A}^{(1)} \cdot \hat{\mathbf{r}}^{(1)}) = (d\mathbf{A}^{(2)} \cdot \hat{\mathbf{r}}^{(2)})$, this becomes:

$$E^{(2)}(\mathbf{p}^{(T)}) = S^{(T)}(\mathbf{p}^{(T)}) (-\mathbf{p}^{(T)} \cdot \mathbf{n}^{(2)}) d\Omega^{(T)} \quad (7.340)$$

Substituting Equation 7.333 for $S^{(T)}(\mathbf{p}^{(T)})$, we obtain a propagation equation for outside radiation passing through the window and arriving at surface element 2:

$$E^{(2)}(\mathbf{p}^{(T)}) = \int_{(\Omega)} T(\mathbf{p}^{(T)}, \mathbf{p}^{(I)}) S^{(I)}(\mathbf{p}^{(I)}) (-\mathbf{p}^{(I)} \cdot \mathbf{n}^{(I)}) d\Omega^{(I)} (-\mathbf{p}^{(T)} \cdot \mathbf{n}^{(2)}) d\Omega^{(T)} \quad (7.341)$$

or, in terms involving only irradiance:

$$E^{(2)}(\mathbf{p}^{(T)}) = \int_{\Omega^{(I)}} T(\mathbf{p}^{(T)}, \mathbf{p}^{(I)}) E(\mathbf{p}^{(I)}) d\Omega^{(I)} (-\mathbf{p}^{(T)} \cdot \mathbf{n}^{(2)}) d\Omega^{(T)} \quad (7.342)$$

Comparing these two equations with Equations 7.329 and 7.331, we can see that physically they represent the processes of (a) propagation of radiation outgoing at one surface (initially, the sky

“surface”), where it is characterized by radiance, to incidence on a second surface, characterized by irradiance, followed (b) transmittance, which converts incoming radiation traveling in a given direction to outgoing radiation in a different set of directions, characterized again by radiance. We can make the former of these processes explicit by defining a propagation function. Considering the first surface element to be located at a position specified by the vector $\mathbf{x}^{(1)}$ and the second at $\mathbf{x}^{(2)}$, then radiation leaving surface 1 in a direction $\mathbf{p}^{(1)}$ and arriving at surface 2 in a direction $\mathbf{p}^{(2)}$ produces an irradiance given by:

$$E^{(2)}(\mathbf{p}^{(2)}) = \int \mathcal{L}(\mathbf{x}^{(2)}, \mathbf{p}^{(2)}; \mathbf{x}^{(1)}, \mathbf{p}^{(1)}) S^{(1)}(\mathbf{p}^{(1)}) d\Omega^{(1)} \quad (7.343)$$

where the propagation function \mathcal{L} is defined by:

$$\mathcal{L}(\mathbf{x}^{(2)}, \mathbf{p}^{(2)}; \mathbf{x}^{(1)}, \mathbf{p}^{(1)}) = (-\mathbf{p}^{(2)} \cdot \mathbf{n}^{(2)}) d\Omega^{(2)} \delta(\mathbf{p}^{(2)}, \mathbf{p}^{(1)}) \delta(\mathbf{x}^{(2)}, \mathbf{x}^{(1)} + \mathbf{r}) \quad (7.344)$$

The spatial dependence is inserted to guarantee that the geometrical relations in Figure 7.35 are preserved. The delta functions in direction and spatial vectors are the mathematically standard δ -distributions defined so that:

$$\int \delta(\mathbf{p}^{(2)}, \mathbf{p}^{(1)}) f(\mathbf{p}^{(1)}) d\Omega^{(1)} = f(\mathbf{p}^{(2)}) \quad (7.345)$$

$$\int_{\Omega} \delta(\mathbf{p}^{(2)}, \mathbf{p}^{(1)}) d\Omega^{(1)} = \begin{cases} 1 & \mathbf{p}^{(2)} \in \Omega \\ 0 & \mathbf{p}^{(2)} \notin \Omega \end{cases} \quad (7.346)$$

$$\int \delta(\mathbf{x}^{(2)}, \mathbf{x}^{(1)}) f(\mathbf{x}^{(1)}) dA^{(1)} = f(\mathbf{x}^{(2)}) \quad (7.347)$$

$$\int_A \delta(\mathbf{x}^{(2)}, \mathbf{x}^{(1)}) dA^{(1)} = \begin{cases} 1 & \mathbf{x}^{(2)} \in A \\ 0 & \mathbf{x}^{(2)} \notin A \end{cases} \quad (7.348)$$

for an arbitrary function f . [In Equations 7.345 and 7.346, the integration is assumed to be over all possible values of either direction or position, so that the vectors $\mathbf{p}^{(2)}$ and $\mathbf{x}^{(2)}$ are necessarily within the domain of integration.]

Physical Caveats

In Equations 7.330 and 7.331, the functions \mathcal{T} and \mathcal{R} pertain to the overall glazing system, and are assumed to be averaged over both wavelength and polarization with appropriate weightings. [EnergyPlus considers wavelength only in that it distinguishes between radiation in the longwave thermal IR region and in the shortwave solar/visible region. (In considering daylighting, there is a further limitation to the visible region.) In this discussion we are concerned solely with the shortwave solar/visible region.] While fenestration properties may depend on both wavelength and polarization, for externally incident radiation this dependence is taken into account in the calculation and averaging of \mathcal{T} and \mathcal{R} . However, both the wavelength distribution (within the solar region) and the polarization state of the outgoing radiation will generally be different from that of the incident radiation. This is not a feature peculiar to non-specular fenestration systems; it is also true of specular ones, and may in fact be more important there. For most interior surfaces, where the radiation is either absorbed or diffusely reflected (and where both processes are assumed

wavelength and polarization independent), this is of no importance, but in the case of either interior windows or the back-reflectance from exterior windows, it could in principle cause errors, unless proper account is taken in specifying \mathcal{T} and \mathcal{R} for these cases.

Discretization: The LBNL Method

A series of 6 papers (Papamichael, Klems et al. 1988; Klems 1994A; Klems 1994B; Klems and Warner 1995; Klems and Kelley 1996; Klems, Warner et al. 1996) formulated the LBNL method of characterizing scattering fenestration systems. The relevant aspects of that method will be summarized here. This method has been incorporated into the WINDOW (from LBNL 2012) computer program.

The method begins by approximating the integrals in Equations 7.332 and 7.343 by finite sums. It does this by defining a set of finite solid angle elements $\{\Delta\Omega_i\}$ that covers the relevant solid angle hemisphere (whether incident, transmitted or reflected directions). Each solid angle element is characterized by a direction \mathbf{p}_i , and it is assumed that this may be substituted for any direction within the solid angle element. This set of solid angle elements and corresponding directions is termed a basis. Note that, since \mathbf{p}_i is a two-dimensional vector, enumerating the solid angle elements with a single index i implicitly includes specifying an ordering of the direction vectors. Equation 7.333 then becomes:

$$S(\mathbf{p}_j^{(T)}) = \sum_i \mathcal{T}(\mathbf{p}_j^{(T)}, \mathbf{p}_i^{(I)}) S^{(I)}(\mathbf{p}_i^{(I)}) (-\mathbf{p}_i^{(I)} \cdot \mathbf{n}) \Delta\Omega_i^{(I)} \quad (7.349)$$

and Equation 7.343 becomes:

$$E^{(2)}(\mathbf{p}_j^{(2)}) = \sum_i \int_{\Delta\Omega_i} \mathcal{L}(\mathbf{x}^{(2)}, \mathbf{p}_j^{(2)}; \mathbf{x}^{(1)}, \mathbf{p}_i^{(1)}) S^{(1)}(\mathbf{p}_i^{(1)}) d\Omega^{(1)} \quad (7.350)$$

Referring to the definition of the propagation function in Equation 7.344 and properties of the δ -distribution in Equation 7.346, we see that the integrals in the summation will all be zero, except when $\mathbf{p}_j^{(2)}$ is contained in the solid angle element $\Delta\Omega_i$. In that case the integration produces $\mathbf{p}_i^{(1)} = \mathbf{p}_j^{(2)}$. We can retain the formal summation by utilizing the finite-dimensional form of the δ -distribution, known as the Kronecker delta, δ_{ij} :

$$\delta_{ij} = \begin{cases} 1 & i = j \\ 0 & i \neq j \end{cases} \quad (7.351)$$

Then, the integral becomes:

$$\int_{\Delta\Omega_i} \mathcal{L}(\mathbf{x}^{(2)}, \mathbf{p}_j^{(2)}; \mathbf{x}^{(1)}, \mathbf{p}_i^{(1)}) S^{(1)}(\mathbf{p}_i^{(1)}) d\Omega^{(1)} = \lambda(-\mathbf{p}_j^{(2)}) \delta_{ij} \cdot \delta(\mathbf{x}^{(2)}, \mathbf{x}^{(1)} + \mathbf{r}) \quad (7.352)$$

where the function λ is defined as:

$$\lambda^{(s)}(\mathbf{p}_j) = (\mathbf{p}_j \cdot \mathbf{n}^{(s)}) \Delta\Omega_j \quad (7.353)$$

and the superscript (s) refers to the surface.

The LBNL method, which focuses on glazing systems consisting of plane-parallel layers, makes particular assumptions that allow one to ignore the spatial dependence of \mathcal{L} . Since the only

effect of the function $\delta(\mathbf{x}^{(2)}, \mathbf{x}^{(1)} + \mathbf{r})$ in Equation 7.344 is to require that if the expression is formally integrated over two separate surface areas, only the parts of the integration that satisfy the geometric constraints will contribute (in effect, the integration is over only one of the surfaces), we will drop the spatial dependence in the present discussion and replace it later when we consider the total energy transfer between different surfaces.

Equations 7.352 (without the delta distribution in \mathbf{x}) and 7.353 are then considered to define the components of a diagonal matrix:

$$^{(s)} = (\Lambda^{(s)}_{ij}) \quad \text{where} \quad \Lambda^{(s)}_{ij} = (\mathbf{p}_j \cdot \mathbf{n}^{(s)}) \Delta\Omega_j \delta_{ij} \quad (7.354)$$

Considering the radiance in the various basis directions to be the components of a vector:

$$\mathbf{S} = \begin{pmatrix} S_1 \\ \cdots \\ S_j \\ \cdots \end{pmatrix} \quad \text{where} \quad \mathbf{S}_j = \mathbf{S}(\mathbf{p}_j) \quad (7.355)$$

Equation 7.333 becomes:

$$S^{(T)}_j = \sum_i T_{ji} \sum_k \Lambda_{ik} S_k \quad \text{where} \quad T_{ji} = \mathcal{T}(\mathbf{p}_j^{(T)}, \mathbf{p}_i^{(I)}) \quad (7.356)$$

which has the obvious character of a series of matrix multiplications. (Note that the superscript (T) here means transmitted, not the matrix operation transpose.) Similarly, the reflectance matrix elements are:

$$R_{ij} = \mathcal{R}(\mathbf{p}^{(R)}, \mathbf{p}^{(I)}) \quad (7.357)$$

The method then identifies the infinitesimal directional irradiances in Equation 7.329 with the components of an irradiance vector:

$$\mathbf{E} = \begin{pmatrix} E_1 \\ \cdots \\ E_i \\ \cdots \end{pmatrix} \quad \text{where} \quad E_i = \frac{dE(\mathbf{p}_j)}{d\Omega} \quad (7.358)$$

and Equations 7.329 - 7.332 can be rewritten as matrix equations:

$$\mathbf{S}^{(T)} = \mathbf{T} \cdot \mathbf{E}^{(I)} \quad (7.359)$$

$$\mathbf{S}^{(R)} = \mathbf{R} \cdot \mathbf{E}^{(I)} \quad (7.360)$$

$$\mathbf{E}^{(I)} = {}^{(I)} \cdot \mathbf{S}^{(I)} \quad (7.361)$$

$$\mathbf{S}^{(T)} = \mathbf{T} \cdot {}^{(I)} \cdot \mathbf{S}^{(I)} \quad (7.362)$$

Table 7.12: Fenestration properties needed for the calculation

Exterior Window	T_{ij}^F	Front Transmittance matrix elements
	R_{ij}^F	Back Reflectance matrix elements
	$A_i^{F,n}$	In-situ absorptance of n^{th} layer for front incidence
	$A_i^{B,n}$	In-situ absorptance of n^{th} layer for back incidence
Interior Window	T_{ij}^F	Front Transmittance matrix elements
	T_{ij}^B	Back Transmittance matrix elements
	R_{ij}^F	Front Reflectance matrix elements
	R_{ij}^B	Back Reflectance matrix elements
	$A_i^{F,n}$	In-situ absorptance of n^{th} layer for front incidence
	$A_i^{B,n}$	In-situ absorptance of n^{th} layer for back incidence

(These are for radiation incident on the front surface of the fenestration; there is a similar set of equations for radiation incident on the back surface and propagating in an opposite sense to that in the above equations.)

In the LBNL method, these equations are used extensively to calculate the overall properties of a fenestration system from those of its component layers. Here we will assume that the components of the system property matrices are given at input. These may be from a calculation by WINDOW or determined by some other method. The quantities needed for each fenestration are:

The transmittance and reflectance are overall system properties. (For daylighting calculations, one also needs the transmittance and reflectance averaged over the visible spectrum only; the quantities indicated in the table pertain to the entire solar spectrum.) For the optical calculations we do not need to know anything about the individual layers making up the fenestration. However, the thermal calculation of heat flow through the fenestration requires knowledge of the amount of radiation absorbed in each of the fenestration layers. As indicated in the table, we therefore need the in-situ layer absorptance for each layer, referenced to the incident surface. This is denoted $A_i^{F,n}$ for the fraction of the i^{th} component of the irradiance incident on the front surface of the fenestration that is absorbed in layer n , with a similar quantity, $A_i^{B,n}$, for irradiance incident on the back surface. The term “in-situ layer absorptance” is used because these are not simply the absorptance of the layer, but include the transmittance and interreflection by other layers of the system prior to the absorptance in layer n . The absorptance is a row vector, having possibly a different value for each direction of the incident irradiance, so that for an irradiance E_i^F on the front surface of a fenestration and E_i^B on the back surface, the power Q^n absorbed per unit area in layer n would be

$$Q^n = \sum_i A_i^{F,n} E_i^F + \sum_j A_j^{B,n} E_j^B \quad (7.363)$$

(In the vector/matrix language, $Q^n = \mathcal{A}^{F,n} \cdot \mathbf{E}^F + \mathcal{A}^{B,n} \cdot \mathbf{E}^B$)

Bases and Coordinate Systems

The introduction of a basis or multiple bases is a bit more complicated than indicated in the text preceding Equation 7.349. There for transmission we need coordinates describing incoming

radiation on one surface of the physical layer and outgoing radiation at the second (opposite) surface, while reflection adds the need for coordinates describing outgoing radiation at the first surface. Back transmittance and reflectance add the requirement for coordinates describing incoming radiation at the second surface. The usual way of assigning coordinates to radiation involves specifying its line of propagation relative to the local surface normal. This means that there are separate coordinate systems for the first and second surfaces, and that, moreover, the description is different for incoming and outgoing radiation: for incoming radiation one is specifying a unit vector pointing toward the source of the radiation (*i.e.*, antiparallel to the direction of propagation), while for outgoing radiation one is specifying a unit vector in the direction of propagation of the radiation. In principle, then, one needs four coordinate systems or bases (for each physical layer), and the process of transmission or reflection involves a discontinuous transition between an input basis and an output basis.

The LBNL method used by WINDOW uses a particular choice of coordinate systems in which incoming radiation at the first surface and outgoing radiation at the second are described by one coordinate system, while the same coordinate system reflected through the layer is used to describe incoming radiation at the second surface and outgoing radiation at the first. The reason for this choice is that it greatly simplifies the matrix representations: specular transmittance or reflectance is always represented by a diagonal matrix, one can mix matrices representing forward or backward incidence processes, and all of the coordinate systems have propagation matrices with the same representation, so in effect there is one L matrix rather than four.

The point of this discussion is that the components of the transmittance and reflectance matrices, and the layer absorptance vectors, depend on the definition of these four bases. If they were generated by WINDOW, then they assume the particular coordinate system described above. (If they were produced by some other means, they may be specified in yet some other coordinate system.) While the LBNL coordinate system gives an intuitive description of outgoing radiation, as a description of incoming radiation it is very unintuitive. And in any case, the coordinate system is different from that of EnergyPlus. It will be necessary to translate the matrices and vectors into the correct EnergyPlus coordinate system.

Matching the WINDOW6 Calculation to EnergyPlus

It is useful to have some sense of how well the basis normally used in WINDOW calculations matches the requirements of EnergyPlus. In using a BSDF window, a user would presumably be interested in the directionality of the transmitted radiation; if the size of the solid angle bins in the basis is large compared to the solid angle subtended by the typical surface in a zone, then that directional information will be lost. On the other hand, if the bins are very small compared to this solid angle, then (since EnergyPlus does not consider the spatial variations within a surface) the directions are being oversampled. Since the calculation time will be proportional to the number of matrix elements, which is the square of the number of basis directions, oversampling is to be avoided.

Because of the great variety of buildings that may be modeled with EnergyPlus, and because the user has control over the basis for the BSDF properties, it is not possible to answer this question in a definitive way. Here we consider the effect of the normal WINDOW basis in a typical perimeter office space, 10 ft wide, 15 ft deep and 11 ft high. It is assumed to have a window 9 ft wide by 6 ft high, with the sill height 3 ft. The window is placed to have a 4 in inner reveal.

The normal WINDOW “full” basis has 145 output directions. Figure 7.36 shows how the window and the solid angle bin project onto the inner surfaces for three of those directions. In each case the solid angle bin is projected from the window center, and the window edges are projected

along the central ray.

In general, the basis appears to be reasonably matched to the calculation, with neither a loss of angular detail nor great oversampling.

Complex Fenestrations in EnergyPlus

Exterior

EnergyPlus models the exterior radiance in two parts, a moving sun radiance $S^{(\text{Sun})}(t)\Delta\Omega^{(\text{Sun})}$ and a constant-shape direction-dependent sky radiance $S^{(\text{Sky})}(\mathbf{p}, t)$. The intensities of these vary with time. For the solar radiation there is a single sky radiance model. For daylight calculations the treatment is similar for exterior luminance, except that there are a number of user-selectable sky luminance models. Here we will discuss radiance; the treatment of luminance is analogous.

The direct normal solar intensity (at a given time) is:

$$I^{(\text{D})}(t) = S^{(\text{Sun})}(t)\Delta\Omega^{(\text{Sun})} \quad (7.364)$$

and if we let:

$$S^{(\text{Sky})}(\mathbf{p}, t) = I^{(\text{Sky})}(t)s(\mathbf{p}) \quad (7.365)$$

where the shape function for the sky radiance model, s , is defined so that:

$$\int_{2\pi} s(\mathbf{p})d\Omega = 1 \quad (7.366)$$

then the global solar irradiance on a horizontal surface at a given time is:

$$I^{(\text{G})}(t) = I^{(\text{Sky})}(t) \left(1 - \int_{\Delta\Omega^{(\text{Sun})}} s(\mathbf{p})d\Omega \right) + I^{(\text{D})}(t) \cos \theta^{(\text{Sun})}(t) \quad (7.367)$$

It must be understood that in Equation 7.366 the integration region 2π means integration over the sky hemisphere and that $s(\mathbf{p})$ is zero for upward-going directions.

With the sky radiance shape $s(\mathbf{p})$ specified in the EnergyPlus code, the angular size of the sun $\Delta\Omega^{(\text{Sun})}$ known, and the solar zenith angle $\theta^{(\text{Sun})}(t)$ calculated in the code, the two hourly input quantities $I^{(\text{D})}(t)$ and $I^{(\text{G})}(t)$ determine the exterior radiance for any given hour.

In this context, the transmitted radiance for a complex fenestration system given in Equation 7.332 becomes:

$$\begin{aligned} S(\mathbf{p}^{(\text{T})}) = & I^{(\text{Sky})}(t) \int_{\Omega^{(\text{Sky})}} \mathcal{T}(\mathbf{p}^{(\text{T})}, \mathbf{p}^{(\text{I})}) s(\mathbf{p}^{(\text{I})}) (-\mathbf{p}^{(\text{I})} \cdot \mathbf{n}) d\Omega^{(\text{I})} \\ & + \int_{\Omega^{(\text{Gnd})}} \mathcal{T}(\mathbf{p}^{(\text{T})}, \mathbf{p}^{(\text{I})}) S^{(\text{Gnd})}(\mathbf{p}^{(\text{I})}, t) (-\mathbf{p}^{(\text{I})} \cdot \mathbf{n}) d\Omega^{(\text{I})} \\ & + H(\Delta\Omega^{(\text{Sun})}(t) \not\subset \Omega^{(\text{Sf})}) \int_{\Delta\Omega^{(\text{Sun})}(t)} \mathcal{T}(\mathbf{p}^{(\text{T})}, \mathbf{p}^{(\text{I})}) S^{(\text{Sun})}(\mathbf{p}^{(\text{I})}, t) (-\mathbf{p}^{(\text{I})} \cdot \mathbf{n}) d\Omega^{(\text{I})} \\ & + \int_{\Omega^{(\text{Sf})}} \mathcal{T}(\mathbf{p}^{(\text{T})}, \mathbf{p}^{(\text{I})}) S^{(\text{Refl})}(\mathbf{p}^{(\text{I})}, t) (-\mathbf{p}^{(\text{I})} \cdot \mathbf{n}) d\Omega^{(\text{I})} \end{aligned} \quad (7.368)$$

where the incoming hemisphere viewed by the fenestration has been broken up into four parts. The viewed sky (excluding the part containing the sun) is $\Omega^{(\text{Sky})}$, the viewed ground is

Figure 7.36: Transmitted Radiation in Three Directions for a Perimeter Office. (a) $\theta = 0^\circ$; (b) $\theta = 40^\circ$, $\phi = 15^\circ$; (c) $\theta = 70^\circ$, $\phi = 67.5^\circ$. θ and ϕ are the normal spherical angle coordinates in a right-handed coordinate system where y points up and z is normal to the window p

$\Omega^{(\text{Gnd})}$, the part subtended by the sun is $\Delta\Omega^{(\text{Sun})}$, and the part subtended by one or more exterior surfaces (shading or reflecting objects) is $\Omega^{(\text{Sf})}$. These solid angles must exclude the exterior surfaces. The symbol H represents a Helmholtz function: Its value is one if its logical argument is true, zero otherwise. It has been inserted into the equation to account for those times when the sun is behind an exterior object. Where there are multiple exterior shading or reflecting objects, $\Omega^{(\text{Sf})}$ may consist of several regions that may be disjoint or connected, depending on the exterior geometry. As indicated in the equation, $\Delta\Omega^{(\text{Sun})}$ is time-dependent, to account for the sun's movement; $\Omega^{(\text{Gnd})}$ and $\Omega^{(\text{Sf})}$ are fixed, but as written $\Omega^{(\text{Sky})}$ has a time dependence induced by the exclusion of the solid angle subtended by the sun. So that we can discuss the parts separately, we break the outgoing radiance down by source:

$$S(\mathbf{p}^{(\text{T})}) = S^{(\text{Sky})}(\mathbf{p}^{(\text{T})}) + S^{(\text{Gnd})}(\mathbf{p}^{(\text{T})}) + S^{(\text{Sun})}(\mathbf{p}^{(\text{T})}) + S^{(\text{Sf})}(\mathbf{p}^{(\text{T})}) \quad (7.369)$$

By subtracting the radiation from the part of the sky hidden by the sun from $S^{(\text{Sun})}$ and adding it back into $S^{(\text{Sky})}$ we can remove the time dependence of $\Omega^{(\text{Sky})}$:

$$\begin{aligned} S^{(\text{Sun})}(\mathbf{p}^{(\text{T})}) &= H(\Delta\Omega^{(\text{Sun})}(t) \not\subset \Omega^{(\text{Sf})}) \\ &\times \int_{\Delta\Omega^{(\text{Sun})}(t)} \mathcal{T}(\mathbf{p}^{(\text{T})}, \mathbf{p}^{(\text{I})}) [S^{(\text{Sun})}(\mathbf{p}^{(\text{I})}, t) - I^{(\text{Sky})}(t)s(\mathbf{p}^{(\text{I})})] (-\mathbf{p}^{(\text{I})} \cdot \mathbf{n}) d\Omega^{(\text{I})} \end{aligned} \quad (7.370)$$

$$S^{(\text{Sky})}(\mathbf{p}^{(\text{T})}) = I^{(\text{Sky})}(t) \int_{\Omega^{(\text{Sky})}} \mathcal{T}(\mathbf{p}^{(\text{T})}, \mathbf{p}^{(\text{I})}) s(\mathbf{p}^{(\text{I})}) (-\mathbf{p}^{(\text{I})} \cdot \mathbf{n}) d\Omega^{(\text{I})} \quad (7.371)$$

Now in Equation 7.371 the integral is to be evaluated without regard to the sun position, and therefore $\Omega^{(\text{Sky})}$ is time-independent.

We can further simplify Equation 7.369 by noting that the angular size of the sun is small, and both $s(\mathbf{p}^{(\text{I})})$ and $\mathcal{T}(\mathbf{p}^{(\text{T})}, \mathbf{p}^{(\text{I})})$ can be considered as constant over the range of directions in $\Delta\Omega^{(\text{Sun})}$. We can therefore evaluate them at the direction $\mathbf{p}^{(\text{Sun})}(t)$ of the center of the sun and move them out of the integration, resulting in:

$$S^{(\text{Sun})}(\mathbf{p}^{(\text{T})}) = \mathcal{T}(\mathbf{p}^{(\text{T})}, \mathbf{p}^{(\text{Sun})}) [I^{(\text{D})} - I^{(\text{Sky})}s(\mathbf{p}^{(\text{Sun})})\Delta\Omega^{(\text{Sun})}] \cos\theta^{(\text{Sun})} H(\mathbf{p}^{(\text{Sun})} \not\subset \Omega^{(\text{Sf})}) \quad (7.372)$$

In this equation we have dropped the explicit time dependence, but $\mathbf{p}^{(\text{Sun})}$, $q^{(\text{Sun})}$, $I^{(\text{D})}$, and $I^{(\text{Sky})}$ are time-varying, while $\Delta\Omega^{(\text{Sun})}$ is simply the constant angular size of the sun.

We separate the reflected radiance $S^{(\text{Sf})}$ into separate components for each surface:

$$S^{(\text{Sf})} = \sum_n S^{(\text{Sf},n)} \quad (7.373)$$

The individual shading surface reflected radiances are then:

$$S^{(\text{Sf},n)}(\mathbf{p}^{(\text{T})}) = \int_{\Omega^{(\text{Sf},n)}} \mathcal{T}(\mathbf{p}^{(\text{T})}, \mathbf{p}^{(\text{I})}) S^{(\text{Refl},n)}(\mathbf{p}^{(\text{I})}, t) (-\mathbf{p}^{(\text{I})} \cdot \mathbf{n}) d\Omega^{(\text{I})} \quad (7.374)$$

The solid angle of integration in this expression is subtended by the portion of the exterior reflecting surface n viewed by the fenestration; if one surface lies behind another, the hidden part of its surface is removed from the solid angle it subtends. This is summarized by the requirement:

$$\begin{aligned}\Omega^{(\text{Sf})} &= \bigcup_n \Omega^{(\text{Sf},n)} \\ \bigcap_n \Omega^{(\text{Sf},n)} &= 0\end{aligned}\quad (7.375)$$

(This requirement will need to be modified to handle the case of transmitting exterior surfaces.) $S^{(\text{Refl},n)}$ is time dependent because the incident radiation on the surface depends on the sun position. Equation 7.371 must be evaluated after the exterior surface shading or reflectance calculations, in order to enforce the requirement that:

$$\Omega^{(\text{Sky})} \cap \Omega^{(\text{Sf})} = 0 \quad (7.376)$$

Finally, the transmitted radiance from the ground-reflected exterior radiation is:

$$S^{(\text{Gnd})}(\mathbf{p}^{(\text{T})}) = \int_{\Omega^{(\text{Gnd})}} \mathcal{T}(\mathbf{p}^{(\text{T})}, \mathbf{p}^{(\text{I})}) S^{(\text{Gnd})}(\mathbf{p}^{(\text{I})}, t) (-\mathbf{p}^{(\text{I})} \cdot \mathbf{n}) d\Omega^{(\text{I})} \quad (7.377)$$

Here, not only is there the requirement that:

$$\Omega^{(\text{Gnd})} \cap \Omega^{(\text{Sf})} = 0 \quad (7.378)$$

but also the incident radiation on the ground may be affected by shading or reflection from exterior surfaces. Since this is dependent on the sun position, $S^{(\text{Gnd})}$ is time dependent, as indicated in Equation 7.377.

Applying the discretization of the previous section and the definitions in Equations 7.354 - 7.357, we can rewrite Equation 7.371 as:

$$S_j^{(\text{T},\text{Sky})} = I^{(\text{Sky})}(t) \sum_{i \in \Omega^{(\text{Sky})}} T_{ji} \Lambda_{ii} s_i \quad (7.379)$$

where

$$s_i = s(\mathbf{p}_i^{(\text{I})}) \quad (7.380)$$

is the sky radiance shape factor evaluated at the central direction of the i^{th} solid angle bin. A “T” superscript has been added on the left-hand side of the equation to denote that S is the transmitted outgoing radiance (due to incident sky radiation for the fenestration under discussion). The stipulation $i \in \Omega^{(\text{Sky})}$ on the summation means that the sum is to include only those solid angle elements for which the sky is viewed by the fenestration. This is essentially a shading calculation, in addition to a restriction to downward-going incident directions. We anticipate the result of this calculation by defining a sky geometric factor:

$$V_i^{(\text{Sky})} = \begin{cases} 1 & \text{all of } \Delta\Omega_i \text{ views sky for all of fenestration} \\ \text{viewed fraction} & \text{some of } \Delta\Omega_i, \text{ fenestration views sky} \\ 0 & \text{none of } \Delta\Omega_i \text{ views sky for any part of fenestration} \end{cases} \quad (7.381)$$

Then we can carry out the summation over all downward directions and write:

$$S_j^{(T, Sky)} = I^{Sky}(t) \sum_{i \text{ down}} T_{ji} \Lambda_{ii} V_i^{(Sky)} s_i \quad (7.382)$$

Similarly, Equation 7.374 becomes:

$$S_j^{(T, Sf, n)} = \sum_{i \text{ down}} T_{ji} \Lambda_{ii} V_i^{(Sf, n)} S^{(Refl, n)}(\mathbf{p}_i^{(I)}, t) \quad (7.383)$$

where $V_i^{(Sf, n)}$ is another geometric view factor, defined analogously to Equation 7.381, giving the fraction of the solid angle $\Delta\Omega_i$ that views the exterior surface n . Note that:

$$V_i^{(Sky)} + \sum_n V_i^{(Sf, n)} = 1 \quad (7.384)$$

The quantity $S^{(Refl, n)}(\mathbf{p}_i^{(I)}, \mathbf{t})$ is in fact the reflected radiance at a particular location on the n^{th} exterior surface — the location where the direction $\mathbf{p}_i^{(I)}$ intersects the surface. (This statement will become more precise when the spatial dependence dropped from Equation 7.352 is re-inserted.) This surface is assumed to have either a diffuse reflectance $\rho^{(n)}$ or a specular reflectance $\rho^{(sp, n)}$. (Both properties are possible simultaneously, but EnergyPlus assumes that an exterior surface is either diffusing or specular, but not both.) The reflectance is assumed uniform over the surface, but the particular location (effectively, the image of the fenestration projected onto surface n) may or may not view the sky, or, at a particular time, the sun. We denote the incident irradiance of the surface n by E_i^n . This irradiance pertains only to the surface n (in the present EnergyPlus calculation) and is independent of the fenestration or its basis. We attach the subscript i simply as a reminder that the irradiance pertains to the portion of the surface that is viewed by the solid angle element $\Delta\Omega_i$ of the fenestration f (which would become important if the EnergyPlus shading calculations were modified to relax the assumption of uniform incident irradiance on exterior surfaces) and that the irradiance pertains only to those surfaces n that are viewed by the solid angle element i . For specularly reflecting surfaces, we make the following definitions: First, within the set of basis solid angles $\Delta\Omega_i$, let $s(t)$ identify the one containing the sun direction at time t , and let $r(t)$ identify the one containing the specular reflection direction of the sun at time t . We then define a contingent direct beam irradiance, which we denote by $E_{ir(t)}^{(D, n)}$. This irradiance is non-zero only if $i = r(t)$ this direction is such that i is the specularly reflected direction for the surface n . If this is the case, then $E_{i=r(t)}^{(D, n)}$ is the incident direct beam irradiance. With this definition:

$$S^{(Refl, n)}(\mathbf{p}_i^{(I)}, t) = \rho^{(sp, n)} E_{ir(t)}^{(D, n)} + \rho^{(n)} E_i^n \quad (7.385)$$

If we then define normalized irradiance factors U by $E_i^n = U_i^{(Sky, n)} I^{(Sky)}(t) + U_{iSun(tsh)}^{(D, n)} I^{(D)}(t)$ and $E_{ir(t)}^{(D, n)} = U_{ir(t)}^{(D, n)} I^{(D)}(t)$, where $U_{iSun(tsh)}^{(D, n)}$ denotes the fraction of the beam solar that irradiates the surface for a given sun direction. It is evaluated during the shading calculation, as indicated by the notation $Sun(tsh)$. With these definitions we can rewrite the equation as:

$$S^{(Refl, n)}(\mathbf{p}_i^{(I)}, \mathbf{t}) = \mathbf{I}^{(D)}(\mathbf{t}) \mathbf{U}_{ir(t)}^{(D, n)} \rho^{(sp, n)} + \mathbf{I}^{(D)}(\mathbf{t}) \mathbf{U}_{iSun(tsh)}^{(D, n)} \rho^{(n)} + \mathbf{I}^{(sky)}(\mathbf{t}) \mathbf{U}_i^{(Sky, n)} \rho^{(n)} \quad (7.386)$$

and Equation 7.383 becomes, in terms of the incident irradiances:

$$S_j^{(T,Sf,n)} = \sum_{idown} T_{ji} \Lambda_{ii} V_i^{(Sf,n)} \left(\rho^{(sp,n)} E_{ir(t)}^{(D,n)} + \rho^{(n)} E_i^n \right) \quad (7.387)$$

and in terms of the normalized irradiance factors,

$$S_j^{(T,Sf,n)} = \sum_{idown} T_{ji} \Lambda_{ii} V_i^{(Sf,n)} I^{(D)}(t) U_{ir(t)}^{(D,n)} \rho^{(sp,n)} \\ + \sum_{idown} T_{ji} \Lambda_{ii} V_i^{(Sf,n)} \left[I^{(D)}(t) U_{iSun(tsh)}^{(D,n)} \rho^{(n)} + I^{(Sky)}(t) U_i^{(Sky,n)} \rho^{(n)} \right] \quad (7.388)$$

The specularly reflected term can be removed from the sum, since only one value of i can contribute:

$$S_j^{(T,Sf,n)} = T_{jr(t)} \Lambda_{r(t)r(t)} V_{r(t)}^{(Sf,n)} E_{r(t)r(t)}^{(D,n)} \rho^{(sp,n)} + \rho^{(n)} \sum_{idown} T_{ji} \Lambda_{ii} V_i^{(Sf,n)} E_i^n \quad (7.389)$$

and

$$S_j^{(T,Sf,n)} = T_{jr(t)} \Lambda_{r(t)r(t)} V_{r(t)}^{(Sf,n)} U_{r(t)r(t)}^{(D,n)} I^{(D)}(t) \rho^{(sp,n)} \\ + \rho^{(n)} \sum_{idown} T_{ji} \Lambda_{ii} V_i^{(Sf,n)} \left(I^{(D)}(t) U_{iSun(tsh)}^{(D,n)} + U_i^{(Sky,n)} I^{(Sky)}(t) \right) \quad (7.390)$$

which separates specular and diffuse reflectance from the exterior surfaces.

With respect to shading and reflection of exterior radiation into the fenestration, the exterior reveal surfaces can be treated as additional diffusely reflecting exterior surfaces.

Ground radiation is treated in the same way as radiation reflected from interior surfaces, except that one sums only over upward-going incident directions and the ground is assumed to be diffusely reflecting. The transmitted radiance from ground reflectance is:

$$S_j^{(T,Gnd)} = \rho^{(Gnd)} \sum_{iup} T_{ji} \Lambda_{ii} V_i^{(Gnd)} E_i^{(Gnd)} \quad (7.391)$$

In this equation, the symbol $E_i^{(Gnd)}$ is shorthand for a spatial calculation. The solid angle region $\Delta\Omega_i$ views (from various points over the fenestration area) some spatial region of the ground. The symbol $E_i^{(Gnd)}$ denotes the incident irradiance on the ground over this spatial region. In the absence of shading, this would be simply $I^{(G)} = I^{(Sky)} + I^{(D)} \cos \theta_{Sun}$; shading requires a more complex calculation. Currently the EnergyPlus code does a Monte-Carlo calculation: rays are randomly generated from the window, when they strike the ground a calculation is made to determine whether that point receives direct solar radiation and what portion of the sky it views (reflected radiation from surfaces is neglected). Here we would perform that calculation for each region of the ground i viewed by a basis solid angle element, instead of generating random rays from the window. We denote the results of that calculation by $E_i^{(Gnd)} = U_{iSun(tsh)}^{(D,Gnd)} I^{(D)}(t) + U_i^{(Sky,Gnd)} I^{(Sky)}(t)$, where the U 's are average viewing factors for the sun and sky, calculated as part of the shading calculation (which is indicated by the subscript tsh : $Sun(tsh)$ is the sun direction as specified by the shading calculation. This then gives:

$$S_j^{(T,Gnd)} = \rho^{(Gnd)} \sum_{iup} T_{ji} \Lambda_{ii} V_i^{(Gnd)} \left(U_{iSun(tsh)}^{(D,Gnd)} I^{(D)}(t) + U_i^{(Sky,Gnd)} I^{(Sky)}(t) \right) \quad (7.392)$$

The transmitted radiance from direct beam radiation is:

$$S_j^{(T, \text{Sun})} = T_{js(t)} \cos \theta^{(\text{Sun})} I^{(D)}(t) V_{is(t)}^{(D)} \quad (7.393)$$

This introduces yet one more geometric view factor: $V_{is(t)}^{(D)}$ is zero if the sun direction $s(t)$ is not i ; if $i = s(t)$ it is the fraction of the fenestration area irradiated by the direct sun. Equation 7.393 uses the fact that the angular size of the sun is smaller than any basis solid angle element, and that EnergyPlus treats the sun and circumsolar region as a point source [hence the absence of the sky correction in Equation 7.370].

At this point we have developed separate expressions for a fenestration's transmitted radiance in a particular direction depending on the exterior source of the radiation. These expressions utilize the discretized BTDF of the fenestration in the form of transmittance matrix elements over an angular basis. The exterior geometry is re-expressed in the form of geometric view factors in this basis. In the process, the explicit time dependence of the exterior radiation has been reduced to the time-varying direct and diffuse solar intensities and the solar position. The time dependence of the solar position, however, consists merely in specifying, for a particular time, which of the basis solid angle elements contains the solar direction. The entire exterior geometry necessary for the fenestration transmittance calculation can therefore be pre-calculated.

Interior

We begin with the discretized form of Equation 7.339, in which we also modify the surface notation. In that equation, the surfaces involved are termed (1) and (2), where radiation is outgoing from surface 1 and incoming to surface 2. Here radiation is outgoing from the inner surface of the fenestration, so we label that surface (f). The receiving surface is one of the surfaces of the zone in which the fenestration is located. We number those surfaces with the index k , so the receiving surface is labeled (k). Equation 7.339 then becomes:

$$dW_j^{(f \rightarrow k)} = E^{(k)}(\mathbf{p}_j^{(T)}) dA^{(k)} = S_j^{(T)} \cdot (\mathbf{n}^{(f)} \cdot \mathbf{p}_j^{(T)}) \Delta\Omega_j^{(T)} dA^{(f)} \quad (7.394)$$

or, noting that $(\mathbf{n}^{(f)} \cdot \mathbf{p}_j^{(T)}) \Delta\Omega_j^{(T)} = \Lambda_{jj}^{(T)}$ (where the superscript T is retained in case the incoming and outgoing bases are defined differently),

$$dW_j^{(f \rightarrow k)} = E^{(k)}(\mathbf{p}_j^{(T)}) dA^{(k)} = S_j^{(T)} \Lambda_{jj}^{(T)} dA^{(f)} \quad (7.395)$$

If we integrate this expression over the fenestration area $A^{(f)}$ we obtain the total power leaving the fenestration surface in direction j ; however, all of that power may not reach surface k : some may strike the inner window reveal or a different zone surface. If we define a spatial projection operator by:

$$\mathbf{x}^{(k)} = \mathcal{P}^{(k)}(\mathbf{p}_j^{(T)}, \mathbf{x}^{(f)}) \equiv \mathcal{P}_j^{(k)}(\mathbf{x}^{(f)}) \quad (7.396)$$

where $\mathbf{x}^{(k)}$ is in the plane of surface k , and a geometric form factor by:

$$F_j^{(k)} = \frac{1}{A^{(f)}} \int_{\mathcal{P}_j^{(k)}(\mathbf{x}^{(f)}) \in A^{(k)}} dA^{(f)} \quad (7.397)$$

then:

$$dW_j^{(f \rightarrow k)} = S_j^{(T)} \Lambda_{jj}^{(T)} F_j^{(k)} A^{(f)} \quad (7.398)$$

The total power leaving the fenestration (in any direction) and arriving at surface k is then

$$W_j^{(f \rightarrow k)} = \sum_j S_j^{(T)} \Lambda_{jj}^{(T)} F_j^{(k)} A^{(f)} \quad (7.399)$$

Substituting Equations 7.370, 7.382, 7.388, and 7.391 into Equation 7.399 yields a series of expressions for the total power arriving at surface k (by transmission through fenestration f) from each of the sources of exterior radiation. However, the equations for transmitted radiation describe an infinitesimal region, which means that the radiation in a given direction will always come from one source. When one integrates the transmitted power over the fenestration surface, one encounters the problem that for this direction different parts of the fenestration area may receive radiation from different sources. Also, for a given outgoing direction, the projection of a receiving surface back onto the fenestration may produce an image that covers only part of the fenestration area, and this image may not be identical with the part of the area that receives incident radiation from a particular source. The most important origin of this problem is the existence of inner and outer window reveals, as illustrated in Figure 7.37.

Figure 7.37: Mismatch of irradiated and viewed fenestration areas for different incident and outgoing directions

In this figure, the portion of the fenestration area not viewed by the plane of surface k is instead viewed by one or more of the inner window reveals. Similarly, the portion of the fenestration not irradiated in the figure is in fact irradiated by diffusely reflected radiation from the outer window reveals. We can account for this by replacing the area $A^{(f)}$ in Equation 7.399 with the overlap area $A_{ji}^{(f,Src),k}$ (dark shaded in the figure), where “Src” stands for the source of the incident radiation. This area is defined by:

$$A_{ji}^{(f,Src),k} = A_i^{(f,Src)} \Big| A_j^{(f),k} \quad (7.400)$$

The total power at the interior surface k for each source of radiation then becomes:

$$W^{(Sky),k} = I^{(Sky)}(t) \sum_j \Lambda_{jj}^{(T)} F_j^{(k)} \sum_{idown} T_{ji} \Lambda_{ii} V_i^{(Sky)} A_{ji}^{(f,Sky),k} s_i \quad (7.401)$$

$$\begin{aligned} W^{(Sf,n),k} &= I^{(D)}(t) \rho^{(sp,n)} \sum_j \Lambda_{jj}^{(T)} F_j^{(k)} T_{jr(t)} \Lambda_{r(t)r(t)} V_{r(t)}^{(Sf,n)} A_{jr(t)}^{(f,Sf,n),k} U_{r(t)s(t)}^{(D,n)} \\ &+ I^{(D)}(t) \rho^{(n)} \sum_j \Lambda_{jj}^{(T)} F_j^{(k)} \sum_{idown} T_{ji} \Lambda_{ii} V_i^{(Sf,n)} A_{ji}^{(f,Sf,n),k} U_{iSun(tsh)}^{(D,n)} \\ &+ I^{(Sky)}(t) \rho^{(n)} \sum_j \Lambda_{jj}^{(T)} F_j^{(k)} \sum_{idown} T_{ji} \Lambda_{ii} V_i^{(Sf,n)} A_{ji}^{(f,Sf,n),k} U_i^{(Sky,n)} \end{aligned} \quad (7.402)$$

$$\begin{aligned} W^{(Gnd),k} &= I^{(D)}(t) \rho^{(Gnd)} \sum_j \Lambda_{jj}^{(T)} F_j^{(k)} \sum_{iup} T_{ji} \Lambda_{ii} V_i^{(Gnd)} A_{ji}^{(f,Gnd),k} U_{iSky(tch)}^{(D,Gnd)} \\ &+ I^{(Sky)}(t) \rho^{(Gnd)} \sum_j \Lambda_{jj}^{(T)} F_j^{(k)} \sum_{iup} T_{ji} \Lambda_{ii} V_i^{(Gnd)} A_{ji}^{(f,Gnd),k} U_i^{(Sky,Gnd)} \end{aligned} \quad (7.403)$$

$$W^{(Sun),k} = I^{(D)}(t) \sum_j F_j^{(k)} \Lambda_{jj}^{(T)} T_{js(t)} \cos \theta_{s(t)}^{(Sun)} V_{is(t)}^{(D)} A_{js(t)}^{(f,Sun),k} \quad (7.404)$$

If we define a series of solar irradiation factors, Z , that describe the fraction of the radiation incident on the fenestration due to a given exterior radiation source that is ultimately incident on the interior surface k :

$$Z^{(Sky),k} = \sum_j \Lambda_{jj}^{(T)} F_j^{(k)} \sum_{idown} T_{ji} \Lambda_{ii} V_i^{(Sky)} A_{ji}^{(f,Sky),k} s_i \quad (7.405)$$

$$Z_{r(t)}^{(sp,Sf,n),k} = \sum_j \Lambda_{jj}^{(T)} F_j^{(k)} T_{jr(t)} \Lambda_{r(t)r(t)} V_{r(t)}^{(Sf,n)} A_{jr(t)}^{(f,Sf,n),k} U_{r(t)s(t)}^{(D,n)} \quad (7.406)$$

$$Z_{s(t)}^{(Sun,Sf,n),k} = \sum_j \Lambda_{jj}^{(T)} F_j^{(k)} \sum_{idown} T_{ji} \Lambda_{ii} V_i^{(Sf,n)} A_{ji}^{(f,Sf,n),k} U_{iSun(tsh)}^{(D,n)} \quad (7.407)$$

$$Z^{(Sky,Sf,n),k} = \sum_j \Lambda_{jj}^{(T)} F_j^{(k)} \sum_{idown} T_{ji} \Lambda_{ii} V_i^{(Sf,n)} A_{ji}^{(f,Sf,n),k} U_i^{(Sky,n)} \quad (7.408)$$

$$Z_{s(t)}^{(D,Gnd),k} = \sum_j \Lambda_{jj}^{(T)} F_j^{(k)} \sum_{iup} T_{ji} \Lambda_{ii} V_i^{(Gnd)} A_{ji}^{(f,Gnd),k} U_{iSun(tsh)}^{(D,Gnd)} \quad (7.409)$$

$$Z^{(Sky,Gnd),k} = \sum_j \Lambda_{jj}^{(T)} F_j^{(k)} \sum_{iup} T_{ji} \Lambda_{ii} V_i^{(Gnd)} A_{ji}^{(f,Gnd),k} U_i^{(Sky,Gnd)} \quad (7.410)$$

$$Z_{s(t)}^{(\text{Sun}),k} = \sum_j F_j^{(k)} \Lambda_{jj}^{(\text{T})} T_{js(t)} \cos \theta_{s(t)}^{(\text{Sun})} V_{is(t)}^{(\text{D})} A_{js(t)}^{(\text{f,Sun}),k} \quad (7.411)$$

then Equations 7.405 through 7.411 become:

$$W^{(\text{Sky}),k} = I^{(\text{Sky})}(t) Z^{(\text{Sky}),k} \quad (7.412)$$

$$W^{(\text{Sf,n}),k} = I^{(\text{D})}(t) \rho^{(\text{sp,n})} Z_{r(t)}^{(\text{sp,Sf,n}),k} + I^{(\text{D})}(t) \rho^{(\text{n})} Z_{s(t)}^{(\text{Sun,Sf,n}),k} + I^{(\text{Sky})}(t) \rho^{(\text{n})} Z^{(\text{Sky,Sf,n}),k} \quad (7.413)$$

$$W^{(\text{Gnd}),k} = I^{(\text{D})}(t) \rho^{(\text{Gnd})} Z_{s(t)}^{(\text{D,Gnd}),k} + I^{(\text{Sky})}(t) \rho^{(\text{Gnd})} Z^{(\text{Sky,Gnd}),k} \quad (7.414)$$

$$W^{(\text{Sun}),k} = I^{(\text{D})}(t) Z_{s(t)}^{(\text{Sun}),k} \quad (7.415)$$

The notation $s(t)$ appearing in a subscript in several of the above equations refers to the basis direction for which the sun direction is contained in the basis solid angle element. This is of course time dependent. What is meant here is that at any given time the particular basis element containing the sun is to be picked out. (If no basis element for the fenestration contains the sun at a given time, then the corresponding view factor—and therefore irradiance or absorption factor—is zero.) It is therefore necessary to tabulate those quantities with an $s(t)$ subscript for all basis directions s that could possibly contain the sun direction (and for $r(t)$, all basis directions that could possibly contain the reflected sun angle for the surface n). This is a set considerably smaller than that of all incoming basis directions. Figure 7.38 illustrates this point for direct irradiation of fenestrations in three different orientations in a building at a particular latitude, using the W6 full basis, which has 145 incoming directions. In the worst case (west-facing) one only needs to consider around 50 of these, with much fewer needed in other orientations. The specific numbers for a given fenestration will depend on the choice of basis, orientation and latitude. The basis direction values can of course be interpolated where greater directional resolution is warranted. In equation the specular direction $r(t)$ is uniquely determined by the sun direction $s(t)$, so the Z factor does not need an additional index for s .

The reason for the definition of the Z factors is that to a great extent they can be precalculated, so that within the hourly calculation only Equations 7.412 - 7.415 need to be used. In addition, there are fewer Z factors to be stored than transmittance matrix elements. The storage determinants for the foregoing calculations are summarized in the following table.

Table 7.13: Determination of array sizes

Parameters	
N_{Basis}	Number of elements in the (incoming or outgoing) basis
N_{Sun}	Number of basis directions that may be sun directions (depends on fenestration orientation)
$N_{\text{Sun}}^{(\text{Gnd})}$	Number of sun directions that give significantly different ground irradiation conditions, as seen by fenestration
N_{Sf}	Number of reflecting surfaces viewable by fenestration (depends on fenestration orientation)

Table 7.13: Determination of array sizes

$N_{Sun}^{(Sf,n)}$	Number of time steps for which surface n is sunlit (depends on orientation of surface n ; determined during shading calculation)
$N_{Refl}^{(Sf,n)}$	Number of basis directions that may be reflected sun directions from surface n (depends on orientation of fenestration and surface n).
$N_{IntSurf}$	Number of interior surfaces in the zone containing the fenestration
N_{Layers}	Number of thermal layers in the fenestration system
Arrays	
$\mathcal{A}_i^{F,l}, \mathcal{A}_i^{B,l}$	Absorptance vector element; N_{Basis}
T_{ij}	Transmittance matrix element; $N_{Basis} \times N_{Basis}$
$V_i^{(Sky)}$	Sky viewed fraction; one-dimensional, N_{Basis}
$V_i^{(Sf,n)}$	Fraction of surface n viewed; $N_{Basis} \times N_{Sf}$
$\rho^{(n)}, \rho^{(sp,n)}$	Surface n diffuse, specular reflectance; N_{Sf} (already stored by E+)
$U_{iSun(tsh)}^{(D,n)}$	Fraction of the image of $\Delta\Omega_i$ on surface n that views the sun when it is in direction Sun(tsh); $N_{Basis} \times N_{Sf} \times N_{Sun}^{(Sf,n)}$
$V_i^{(Gnd)}$	Fraction of $\Delta\Omega_i$ that views ground; N_{Basis}
$U_i^{(Sky,Gnd)}$	Fraction of sky radiation received by the image of $\Delta\Omega_i$ on the ground; N_{Basis}
$U_{iSun(tsh)}^{(D,Gnd)}$	Fraction of direct solar radiation for sun direction Sun(tsh) received by image of $\Delta\Omega_i$ on ground; $N_{Sim}^{Gnd} \times N_{Basis}$
$V_{is(t)}^{(D)}$	Fraction of fenestration area irradiated by direct solar radiation for direction i , given that sun angle is $s(t)$; $N_{Sun} \times N_{Basis}$
$F_j^{(k)}$	Fraction of radiation in direction j leaving fenestration interior that arrives at surface k ; $N_{Basis} \times N_{IntSurf}$
$Z^{(Sky),k}$	Sky irradiation factor; $N_{IntSurf}$
$Z_{r(t)}^{(sp,Sf,n),k}$	Exterior surface specular irradiation factor; $N_{Sun}^{(Sf,n)} \times N_{Sf} \times N_{IntSurf}$
$Z_{s(t)}^{(Sun,Sf,n),k}$	Exterior surface direct-diffuse irradiation factor; $N_{Sun}^{(Sf,n)} \times N_{Sf} \times N_{IntSurf}$
$Z^{(Sky,Sf,n),k}$	Exterior surface sky irradiation factor; $N_{Sf} \times N_{IntSurf}$
$Z_{s(t)}^{(D,Gnd),k}$	Ground-reflected direct solar irradiation factor (given sun direction $s(t)$); $N_{Sun}^{(Gnd)} \times N_{IntSurf}$
$Z^{(Sky,Gnd),k}$	Ground-reflected diffuse solar irradiation factor; $N_{IntSurf}$
$Z_{s(t)}^{(Sun),k}$	Direct solar irradiation factor; $N_{Sun} \times N_{IntSurf}$
$K^{(Sky),l}$	Sky absorption factor; N_{Layers}

Table 7.13: Determination of array sizes

$K_{r(t)}^{(sp,Sf,n),l}$	Exterior surface specular absorption factor; $N_{Sf} \times N_{Refl}^{(Sf,n)} \times N_{Layers}$
$K_{s(t)}^{(Sun,Sf,n),l}$	Exterior surface diffusely reflected direct sun absorption factor; $N_{Sf} \times N_{Sun}^{(Sf,n)} \times N_{Layers}$
$K^{(Sky,Sf,n),l}$	Exterior surface reflected sky radiation absorption factor; $N_{Sf} \times N_{Layers}$
$K_{s(t)}^{(D,Gnd),l}$	Ground-reflected direct solar absorption factor; $N_{Sun}^{(Gnd)} \times N_{Layers}$
$K^{(Sky,Gnd),l}$	Ground-reflected sky radiation absorption factor; N_{Layers}
$K_{s(t)}^{(Sun),l}$	Direct sunlight absorption factor; $N_{Sun} \times N_{Layers}$

Absorption

For thermal calculations, it is necessary to know the energy absorbed in each layer of the fenestration. This depends only on the incident geometry, but otherwise is calculated in the same manner as the solar flux incident on interior surfaces. For a given layer l of a fenestration f , we define a source-referenced absorption factor, $K(\text{source}),l$. This is the amount of energy absorbed in layer l divided by the relevant solar intensity (which might be beam, diffuse, or reflected beam or diffuse, depending on the source of the radiation). These absorption factors and the resultant source-specific absorbed solar powers are calculated by the analogs [see Equation 7.363 or Equations 7.405 through 7.411]:

$$K^{(\text{Sky}),l} = A^{(f)} \sum_{i \text{ down}} \mathcal{A}_i^{F,l} \Lambda_{ii} V_i^{(\text{Sky})} s_i \quad (7.416)$$

$$Q^{(\text{Sky}),l} = I^{(\text{Sky})}(t) K^{(\text{Sky}),l} \quad (7.417)$$

$$K_{r(t)}^{(\text{sp},Sf,n),l} = A^{(f)} \mathcal{A}_{r(t)}^{F,l} \Lambda_{r(t)r(t)} V_{r(t)}^{(Sf,n)} U_{r(t)s(t)}^{(D,n)} \quad (7.418)$$

$$K_{s(t)}^{(\text{Sun},Sf,n),l} = A^{(f)} \sum_{i \text{ down}} \mathcal{A}_i^{F,l} \Lambda_{ii} V_i^{(Sf,n)} U_{iSun(tsh)}^{(D,n)} \quad (7.419)$$

$$K^{(\text{Sky},Sf,n),l} = A^{(f)} \sum_{i \text{ down}} \mathcal{A}_i^{F,l} \Lambda_{ii} V_i^{(Sf,n)} U_i^{(\text{Sky},n)} \quad (7.420)$$

$$Q^{(Sf,n),l} = I^{(D)}(t) \rho^{(\text{sp},n)} K_{r(t)}^{(\text{sp},Sf,n),l} + I^{(D)}(t) \rho^{(n)} K_{s(t)}^{(\text{Sun},Sf,n),l} + I^{(\text{Sky})}(t) \rho^{(n)} K^{(\text{Sky},Sf,n),l} \quad (7.421)$$

$$K_{s(t)}^{(D,Gnd),l} = A^{(f)} \sum_{i \text{ up}} \mathcal{A}_i^{F,l} \Lambda_{ii} V_i^{(Gnd)} U_{iSun(tsh)}^{(D,Gnd)} \quad (7.422)$$

$$K^{(\text{Sky},Gnd),l} = A^{(f)} \sum_{i \text{ up}} \mathcal{A}_i^{F,l} \Lambda_{ii} V_i^{(Gnd)} U_i^{(\text{Sky},Gnd)} \quad (7.423)$$

$$Q^{(Gnd),l} = I^{(D)}(t) \rho^{(Gnd)} K_{s(t)}^{(D,Gnd),l} + I^{(\text{Sky})}(t) \rho^{(Gnd)} K^{(\text{Sky},Gnd),l} \quad (7.424)$$

Figure 7.38: Sun Paths and Incident Basis for Three Window Orientations, 38° N. Latitude. The nodal positions (blue dots) for a W6 full basis are compared with the summer solstice (red curve) and winter solstice (green curve) solar paths. Solar paths for other days of the year will lie between these two extremes. (Note: the basis points are to be interpreted as the direction of a vector pointing from the fenestration to the sun.) (a) South facing. (b) West facing. (c) North facing (the winter path is off the figure (i.e., the window is shaded); allowed paths will be outside the red path.

$$K_{s(t)}^{(\text{Sun}),l} = A^{(f)} \mathcal{A}_{s(t)}^{F,l} \cos \theta_{s(t)}^{(\text{Sun})} V_{is(t)}^{(D)} \quad (7.425)$$

$$Q^{(\text{Sun}),l} = I^{(D)}(t) K_{s(t)}^{(\text{Sun}),l} \quad (7.426)$$

Comment on Bases

Use of the basis in the above discussion has been mostly implicit, but it should nevertheless be clear that the essential feature of the basis is that it is a two-element list (i.e., a 2 X N array): it associates with an incident (i) or outgoing (j) direction index a vector \mathbf{p}_i (or \mathbf{p}_j) that is a unit vector giving the direction of the radiation, the specification of which is two angles in some coordinate system. The incident and outgoing bases of course must match the matrix elements of the fenestration properties. These bases will (certainly in the case of WINDOW program; probably in the case of other input sources) have a structure: ordering of the elements, etc. However, after the initialization of the hourly loop calculation, this structure will be irrelevant: EnergyPlus will retain only those incoming and outgoing directions that are essential to the calculation with (one would hope, most of) the others combined into irradiation factors. At this point, the basis will truly be an arbitrary list. It follows that the specification of the basis in the EnergyPlus input should be determined by (1) the source of fenestration property data, and (2) user convenience.

A related point concerns the specification of a basis for specular glazings, i.e., multiple layers of glass. These fenestrations are both specular (input direction = output direction) and axially symmetric. These properties have different effects on the calculation.

The specular property means that one should not be using Equation 7.329 at all to describe the transmittance. Instead, one should use the equation:

$$S(\mathbf{p}^{(T)}) = \tau(\mathbf{p}^{(T)}) \cdot E(\mathbf{p}^{(T)}) \quad (7.427)$$

This equation is shoehorned into the integral calculation of equation through the use of a delta function in the incident direction vector, resulting (after the discretization) in a diagonal matrix for the transmittance (or reflectance). The outgoing radiance element on the diagonal would be calculated as $T_{ii}\Lambda_{ii}$, where multiplication by Λ_{ii} substitutes for integration over the basis solid angle element. For a specular glazing, $T_{ii} = \tau(\mathbf{p}_i^{(T)})/\Omega_i$, so one recovers the correct transmittance when one does the multiplication. However, there is still a problem in principle: For a specular fenestration, the angular spread of the outgoing radiation will be that of the source, which for direct sunlight is very small; the calculation, however, assumes the angular spread of the basis element. This problem disappears in the geometric approximation to be used in EnergyPlus: by considering only the central direction of each basis element, the outgoing radiation in that direction is essentially assumed to be specular, so the blurring in the discretization is undone.

The axial symmetry of conventional glazings means that the transmittance (or reflectance) depends on only the incident angle, not the azimuthal angle about the normal to the fenestration plane. So if one specifies the diagonal elements of the matrix, all of the terms with the same incident angles but different azimuthal angles will be the same. One could alternatively specify only the specular transmittance at each of the incident angle values, provided one also indicated that it was for an axially symmetric fenestration. Since expanding this set of values to the equivalent diagonal elements is a trivial calculation, how one specifies a specular glazing is completely a question of user convenience. For example, if one were dealing with the WINDOW full basis, would it be more user-friendly to specify

- (1) $T_{ii} = \tau(\mathbf{p}_i^{(T)})/\Omega_i$, for 145 values, 135 of which are repeats of the previous value
- (2) $\tau(\theta_i)$ for 9 values of incident angle, θ_i ?

Interior Solar Radiation Transmitted by Complex Fenestration

Diffuse Solar Radiation Transmitted by Complex Fenestration

Distribution of solar radiation transmitted through exterior window is divided on diffuse and direct part.

Diffuse solar transmitted through exterior complex fenestration and absorbed in interior walls is calculated and treated in same way as described in the section on Initial Distribution of Diffuse Solar Transmitted through Exterior and Interior Windows. Even though that BSDF is given for various directions, for purpose of diffuse solar radiation, transmittance and reflectances of fenestration system is integrated over incoming and outgoing hemisphere. Because incoming diffuse solar radiation is divided on ground and sky parts, integration of incoming hemisphere is also performed over ground and sky part (see Equation 7.374).

Direct Solar Radiation Transmitted by Complex Fenestration

Direct solar (beam) transmitted through exterior window is using same overlap calculations (see Figure 5.14) for each outgoing basis direction. For certain sun position, algorithm calculates equivalent incoming beam number. The inside beam solar irradiance is calculated in similar manner as described in the section titled Interior Beam Radiation.

$$\begin{aligned}
 AISurf(SurfNum) = & \frac{AbsIntSurf(SurfNum)}{A(SurfNum)} \\
 & \cdot \sum_{i=1}^{N_{extwin}} \left(\sum_{j=1}^{N_{out}} TBm_{k,j} \cdot \Lambda_{k,j} \cdot Aoverlap_{k,j}(SurfNum) \right) \cdot CosInc_i
 \end{aligned} \tag{7.428}$$

i = exterior window number

N_{extwin} = number of exterior windows in zone

N_{out} = Beam number of exterior windows in zone

$CosInc_i$ = cosine of angle of incidence of beam on exterior window i

$TBm_{k,j}$ = beam-to-beam transmittance of exterior window i at incidence direction k outgoing direction j

$\Lambda_{k,j}$ = lambda value of exterior window i at incidence direction k for outgoing direction j

$A_{overlap_{k,j}}(SurfNum)$ = beam solar irradiated area of surface $SurfNum$ projected back onto the plane of exterior window i for incoming direction k and outgoing direction j (the $A_{overlap}$'s for an exterior window sum up to the glazed area of the window)

$AbsIntSurf(SurfNum)$ = inside face solar absorptance of surface $SurfNum$

$A(SurfNum)$ = area of surface $SurfNum$ [m²]

Equation 7.428 is valid as long as surface which is hit by transmitted solar radiation is not another complex fenestration. In that case, for beam which is transmitted from other exterior window and reaches back surface of this window, angle of incidence needs to be taken into account.

Interior Solar Absorbed by Complex Fenestration

Solar radiation absorbed in window layers is coming from three sources: Diffuse radiation from sky and ground, direct radiation from the sun and beam radiation coming from the sun and it is transmitted through other exterior windows.

Diffuse Radiation from Sky and Ground

Energy absorbed in the layers and which originates from diffuse radiation from sky and ground is represented by following equation:

$$SurfWinQRadSWwinAbs(Surf, Lay) =$$

$$\sum_{i=1}^{N_{layers}} (WinSkyFtAbs(Surf, Lay) \cdot SkySolarInc + WinSkyGndAbs(Surf, Lay) \cdot GndSolarInc) \quad (7.429)$$

where

$WinSkyFtAbs(Lay)$ = front absorptance averaged over sky for layer (Lay) and window belonging to Surf

$WinSkyGndAbs(Lay)$ = front absorptance averaged over ground for layer (Lay) and window belonging to Surf

$SkySolarInc$ = incident diffuse solar from the sky

$GndSolarInc$ = incident diffuse solar from the ground

Direct Radiation from the Sun

Energy absorbed in the layers and which originates from direct solar radiation is given by following equation:

$$SurfWinQRadSWwinAbs(SurfNum, Lay) = AWinSurf(SurfNum, Lay) \cdot BeamSolar \quad (7.430)$$

where

$AWinSurf(SurfNum, Lay)$ – is time step value of factor for beam absorbed in fenestration glass layers

$BeamSolar$ – Current beam normal solar irradiance

Factor for time step value is given by equation:

$$AWinSurf(SurfNum, Lay) = WinBmFtAbs(Lay, HourOfDay, TimeStep) \cdot CosInc \cdot SunLitFract \cdot OutProjSLFracMult(HourOfDay) \quad (7.431)$$

where

$WinBmFtAbs(Lay, HourOfDay, TimeStep)$ – is front directional absorptance for given layer and time

$CosInc$ – cosine of beam solar incident angle

$SunLitFract$ – sunlit fraction without shadowing effects of frame and divider

$OutProjSLFracMult(HourOfDay)$ - Multiplier on sunlit fraction due to shadowing of glass by frame and divider outside projections.

Direct Solar Radiation Coming from Sun and it is Transmitted Through Other Windows

Direct solar radiation transmitted through other windows is using solar overlap calculations described in the section on Overlapping Shadows. Overlapping is used to determine amount of energy transferred through the window is hitting certain surface. That is used to calculate energy absorbed in walls and same approach will be used to calculate energy absorbed in window layers (Equation 7.428). In case when receiving surface is complex fenestration, it is not enough just to apply Equation 7.428 because factor $AbsIntSurf$ is now depending of incoming angle which is defined through front and back directional absorptance matrices. It would mean that for each outgoing directions of transmitting complex fenestration, algorithm would need to determine what is best matching basis direction of receiving surface. Best receiving direction is used to determine absorptance factors which will be used in Equation 7.428. It is important to understand that for basis definition, each unit vector defining one beam is going towards surface, which would mean that best matching directions from surface to surface will actually have minimal dot product.

$$Best_{in} = \min(dot(out_p, in_1), dot(out_p, in_2), \dots, dot(out_p, in_N)) \quad (7.432)$$

where

$Best_{in}$ – is best matching receiving direction basis dot product (in_k)

out_p – current transmitting complex fenestration direction

in_1, \dots, in_N – set of receiving complex fenestration basis directions

Result of Equation 7.432 is minimal dot product, which corresponds to best matching direction of receiving surface. If we mark that direction with index k , then Equation 7.428 becomes:

$$AWinSurf(SurfNum, Lay) = \frac{1}{A(SurfNum)} \cdot \sum_{i=1}^{N_{extwin}} \left(\sum_{j=1}^{N_{out}} AbsIntSurf_k(SurfNum) \cdot TBm_{k,j} \cdot A_{k,j} \cdot Aoverlap_{k,j}(SurfNum) \right) \cdot CosInc_i \quad (7.433)$$

where

$AbsIntSurf_k(SurfNum)$ – directional absorptance for the receiving surface for the best matching direction.

Everything else is same as described in Equation 7.428.

$\Delta\theta_i$	Difference in temperature of face i between successive iterations	K	-

7.8.1 The Glazing Heat Balance Equations

The window glass face temperatures are determined by solving the heat balance equations on each face every time step. For a window with N glass layers there are $2N$ faces and therefore $2N$ equations to solve. Figure 7.39 shows the variables used for double glazing ($N = 2$).

The following assumptions are made in deriving the heat balance equations:

- 1) The glass layers are thin enough (a few millimeters) that heat storage in the glass can be neglected; therefore, there are no heat capacity terms in the equations.
- 2) The heat flow is perpendicular to the glass faces and is one dimensional. See “Edge of Glass Corrections,” below, for adjustments to the gap conduction in multi-pane glazing to account for 2-D conduction effects across the pane separators at the boundaries of the glazing.
- 3) The glass layers are opaque to IR. This is true for most glass products. For thin plastic suspended films this is not a good assumption, so the heat balance equations would have to be modified to handle this case.

Figure 7.39: Glazing system with two glass layers showing variables used in heat balance equations.

4) The glass faces are isothermal. This is generally a good assumption since glass conductivity is very high.

5) The short wave radiation absorbed in a glass layer can be apportioned equally to the two faces of the layer.

The four equations for double-glazing are as follows. The equations for single glazing ($N = 1$) and for $N = 3$ and $N = 4$ are analogous and are not shown.

$$E_o \varepsilon_1 - \varepsilon_1 \sigma \theta_1^4 + k_1 (\theta_2 - \theta_1) + h_o (T_o - \theta_1) + S_1 = 0 \quad (7.434)$$

$$k_1 (\theta_1 - \theta_2) + h_1 (\theta_3 - \theta_2) + \sigma \frac{\varepsilon_2 \varepsilon_3}{1 - (1 - \varepsilon_2)(1 - \varepsilon_3)} (\theta_3^4 - \theta_2^4) + S_2 = 0 \quad (7.435)$$

$$h_1 (\theta_2 - \theta_3) + k_2 (\theta_4 - \theta_3) + \sigma \frac{\varepsilon_2 \varepsilon_3}{1 - (1 - \varepsilon_2)(1 - \varepsilon_3)} (\theta_2^4 - \theta_3^4) + S_3 = 0 \quad (7.436)$$

$$E_i \varepsilon_4 - \varepsilon_4 \sigma \theta_4^4 + k_2 (\theta_3 - \theta_4) + h_i (T_i - \theta_4) + S_4 = 0 \quad (7.437)$$

7.8.1.1 Absorbed Radiation

S_i in Equations 7.434 to 7.437 is the radiation (short-wave and long-wave from zone lights and equipment) absorbed on the i^{th} face. Short-wave radiation (solar and short-wave from lights) is assumed to be absorbed uniformly along a glass layer, so for the purposes of the heat balance calculation it is split equally between the two faces of a layer. Glass layers are assumed to be opaque to IR so that the thermal radiation from lights and equipment is assigned only to the inside (room-side) face of the inside glass layer. For N glass layers S_i is given by

$$S_{2j-1} = S_{2j} = \frac{1}{2} \left(I_{bm}^{ext} \cos \phi A_j^f(\phi) + I_{dif}^{ext} A_j^{f,dif} + I_{sw}^{int} A_j^{b,dif} \right), \quad j = 1 \text{ to } N \quad (7.438)$$

$$S_{2N} = S_{2N} + \varepsilon_{2N} I_{lw}^{int} \quad (7.439)$$

Here

I_{bm}^{ext} = exterior beam normal solar irradiance

I_{dif}^{ext} = exterior diffuse solar incident on glazing from outside

I_{sw}^{int} = interior short-wave radiation (from lights and from reflected diffuse solar) incident on glazing from inside

I_{lw}^{int} = long-wave radiation from lights and equipment incident on glazing from inside

ε_{2N} = emissivity (thermal absorptance) of the room-side face of the inside glass layer

7.8.2 Room-Side Convection

The correlation for room-side convection coefficient, h_i , is from ISO 15099 section 8.3.2.2. (Prior to EnergyPlus version 3.1, the value for h_i was modeled using the “Detailed” algorithm for opaque surface heat transfer, e.g. for a vertical surface $h_i = 1.31|\Delta T|^{1/3}$; see section Detailed Natural Convection Algorithm). The ISO 15099 correlation is for still room air and is determined in terms of the Nusselt number, Nu , is:

$$h_i = Nu \left(\frac{\lambda}{H} \right) \quad (7.440)$$

where

λ is the thermal conductivity of air, and

H is the height of the window.

The Rayleigh number based on height, Ra_H , is calculated using:

$$Ra_H = \frac{\rho^2 H^3 g c_p |T_{surf,i} - T_{air}|}{T_{m,f} \mu \lambda} \quad (7.441)$$

where

ρ is the density of air

g is the acceleration due to gravity,

c_p is the specific heat of air,

μ is the dynamic viscosity of air, and

$T_{m,f}$ is the mean film temperature in Kelvin given by,

$$T_{m,f} = T_{air} + \frac{1}{4} (T_{surf,i} - T_{air}) \quad (7.442)$$

There are four cases for the Nusselt correlation that vary by the tilt angle in degrees, γ , and are based on heating conditions. For cooling conditions (where $T_{surf,i} > T_{air}$), the tilt angle is complemented so that $\gamma = 180 - \gamma$.

Case A. $0^\circ \leq \gamma < 15^\circ$

$$Nu = 0.13 Ra_H^{1/3} \quad (7.443)$$

Case B. $15^\circ \leq \gamma \leq 90^\circ$

$$Ra_{cv} = 2.5 \times 10^5 \left(\frac{e^{0.72\gamma}}{\sin \lambda} \right)^{1/5} \quad (7.444)$$

$$Nu = 0.56 (Ra_H \sin \gamma)^{1/4}; \text{ for } Ra_H \leq Ra_{CV} \quad (7.445)$$

$$Nu = 0.13 \left(Ra_H^{1/3} - Ra_{CV}^{1/3} \right) + 0.56 (Ra_{CV} \sin \gamma)^{1/4}; \text{ } Ra_H > Ra_{CV} \quad (7.446)$$

Case C. $90^\circ < \gamma \leq 179^\circ$

$$Nu = 0.56 (Ra_H \sin \gamma)^{1/4}; \text{ } 10^5 \leq Ra_H \sin \gamma < 10^{11} \quad (7.447)$$

Case D. $179^\circ < \gamma \leq 180^\circ$

$$Nu = 0.58 Ra_H^{1/5}; \text{ } Ra_H \leq 10^{11} \quad (7.448)$$

The material properties are evaluated at the mean film temperature. Standard EnergyPlus psychrometric functions are used for ρ and c_p . Thermal conductivity is calculated using:

$$\lambda = 2.873 \times 10^{-3} + 7.76 \times 10^{-5} T_{m,f} \quad (7.449)$$

Kinematic viscosity is calculated using:

$$\mu = 3.723 \times 10^{-6} + 4.94 \times 10^{-8} T_{m,f} \quad (7.450)$$

This correlation depends on the surface temperature of the room-side glazing surface and is therefore included inside the window heat balance iteration loop.

7.8.3 Solving the Glazing Heat Balance Equations

The equations are solved as follows:

- 1) Linearize the equations by defining $h_{r,i} = \varepsilon_i \sigma \theta_i^3$. For example, Equation 7.434 becomes

$$E_o \varepsilon_1 - h_{r,1} \theta_1 + k_1 (\theta_2 - \theta_1) + h_o (T_o - \theta_1) + S_1 = 0 \quad (7.451)$$

- 2) Write the equations in the matrix form $A\theta = B$
- 3) Use previous time step's values of θ_i as initial values for the current time step. For the first time step of a design day or run period the initial values are estimated by treating the layers as a simple RC network.
- 4) Save the θ_i for use in the next iteration: $\theta_{prev,i} = \theta_i$
- 5) Using θ_{2N} , reevaluate the room-side face surface convection coefficient h_i
- 6) Using the θ_i to evaluate the radiative conductances $h_{r,i}$
- 7) Find the solution $\theta = A^{-1}B$ by LU decomposition
- 8) Perform relaxation on the the new θ_i : $\theta_i \rightarrow (\theta_i + \theta_{prev,i}) / 2$
- 9) Go to step 4

Repeat steps 4 to 9 until the difference, $\Delta\theta_i$, between values of the θ_i in successive iterations is less than some tolerance value. Currently, the test is:

$$\frac{1}{2N} \sum_{i=1}^{2N} |\Delta\theta_i| < 0.02K \quad (7.452)$$

If this test does not pass after 100 iterations, the tolerance is increased to 0.2K. If the test still fails the program stops and an error message is issued.

The value of the inside face temperature, θ_{2N} , determined in this way participates in the zone heat balance solution (see Outdoor/Exterior Convection) and thermal comfort calculation (see Occupant Thermal Comfort).

7.8.4 Edge-Of-Glass Effects

Table 7.15: C++ Variables used in Edge of Glass calculations

Mathematical variable	Description	Units	C++ variable
\bar{h}	Area-weighted net conductance of glazing including edge-of-glass effects	W/m ² -K	-
A_{cg}	Area of center-of-glass region	m ²	CenterGlArea
A_{fe}	Area of frame edge region	m ²	FrameEdgeArea
A_{de}	Area of divider edge region	m ²	DividerEdgeArea
A_{tot}	Total glazing area	m ²	Surface%Area
h_{cg}	Conductance of center-of-glass region (without air films)	W/m ² -K	-
h_{fe}	Conductance of frame edge region (without air films)	W/m ² -K	-
h_{de}	Conductance of divider edge region (without air films)	W/m ² -K	-
h_{ck}	Convective conductance of gap k	W/m ² -K	-
h_{rk}	Radiative conductance of gap k	W/m ² -K	-
η	Area ratio	-	-
α	Conductance ratio	-	FrEdgeToCenterGlCondRatio, DivEdgeToCenterGlCondRatio

Because of thermal bridging across the spacer separating the glass layers in multi-pane glazing, the conductance of the glazing near the frame and divider, where the spacers are located, is higher than it is in the center of the glass. The area-weighted net conductance (without inside and outside air films) of the glazing in this case can be written

$$\bar{h} = (A_{cg}h_{cg} + A_{fe}h_{fe} + A_{de}h_{de}) / A_{tot} \quad (7.453)$$

where

h_{cg} = conductance of center-of-glass region (without air films)

h_{fe} = conductance of frame edge region (without air films)

h_{de} = conductance of divider edge region (without air films)

A_{cg} = area of center-of-glass region

A_{fe} = area of frame edge region

A_{de} = area of divider edge region

A_{tot} = total glazing area = $A_{cg} + A_{fe} + A_{de}$

The different regions are shown in Figure 7.40:

Equation 7.453 can be rewritten as:

Figure 7.40: Different types of glass regions.

$$\bar{h} = h_{cg} (\eta_{cg} + \alpha_{fe} \eta_{fe} + \alpha_{de} \eta_{de}) \quad (7.454)$$

where

$$\eta_{cg} = A_{cg}/A_{tot} \quad (7.455)$$

$$\eta_{fe} = A_{fe}/A_{tot} \quad (7.456)$$

$$\eta_{de} = A_{de}/A_{tot} \quad (7.457)$$

$$\alpha_{fe} = h_{fe}/h_{cg} \quad (7.458)$$

$$\alpha_{de} = h_{de}/h_{cg} \quad (7.459)$$

The conductance ratios α_{fe} and α_{de} are user inputs obtained from Window 5. They depend on the glazing construction as well as the spacer type, gap width, and frame and divider type.

In the EnergyPlus glazing heat balance calculation effective gap convective conductances are used to account for the edge-of-glass effects. These effective conductances are determined as follows for the case with two gaps (triple glazing). The approach for other numbers of gaps is analogous.

Neglecting the very small resistance of the glass layers, the center-of-glass conductance (without inside and outside air films) can be written as:

$$h_{cg} = \left((h_{r,1} + h_{c,1})^{-1} + (h_{r,2} + h_{c,2})^{-1} \right)^{-1} \quad (7.460)$$

where

$h_{c,k}$ = convective conductance of the k^h gap

$h_{r,k}$ = radiative conductance of the k^h gap or:

$$h_{r,k} = \frac{1}{2} \sigma \frac{\varepsilon_i \varepsilon_j}{1 - (1 - \varepsilon_i)(1 - \varepsilon_j)} (\theta_i + \theta_j)^3 \quad (7.461)$$

$\varepsilon_i, \varepsilon_j$ = emissivity of the faces bounding the gap

θ_i, θ_j = temperature of faces bounding the gap (K)

Equation 7.454 then becomes:

$$\bar{h} = (\eta_{cg} + \alpha_{fe} \eta_{fe} + \alpha_{de} \eta_{de}) \left((h_{r,1} + h_{c,1})^{-1} + (h_{r,2} + h_{c,2})^{-1} \right)^{-1} \quad (7.462)$$

We can also write \bar{h} in terms of effective convective conductances of the gaps as:

$$\bar{h} = \left((h_{r,1} + \bar{h}_{c,1})^{-1} + (h_{r,2} + \bar{h}_{c,2})^{-1} \right)^{-1} \quad (7.463)$$

Comparing Equations 7.462 and 7.463, we obtain:

$$h_{r,k} + \bar{h}_{c,k} = (\eta_{cg} + \alpha_{fe} \eta_{fe} + \alpha_{de} \eta_{de}) (h_{r,k} + h_{c,k}) \quad (7.464)$$

Using $\eta_{cg} = 1 - \eta_{fe} - \eta_{de}$ gives:

$$\bar{h}_{c,k} = h_{r,k} (\eta_{fe} (\alpha_{fe} - 1) + \eta_{de} (\alpha_{de} - 1)) + h_{c,k} (1 + \eta_{fe} (\alpha_{fe} - 1) + \eta_{de} (\alpha_{de} - 1)) \quad (7.465)$$

This is the expression used by EnergyPlus for the gap convective conductance when a frame or divider is present.

7.8.5 Apportioning of Absorbed Short-Wave Radiation in Shading Device Layers

If a shading device has a non-zero short-wave transmittance then absorption takes place throughout the shading device layer. The following algorithm is used to apportion the absorbed short-wave radiation to the two faces of the layer. Here f_1 is the fraction assigned to the face closest to the incident radiation and f_2 is the fraction assigned to the face furthest from the incident radiation.

$$f_1 = 1, f_2 = 0 \text{ if } \tau_{sh} = 0 \quad (7.466)$$

Otherwise:

$$\left. \begin{aligned} f_1 &= 0, f_2 = 0 && \text{if } \alpha_{sh} \leq 0.01 \\ f_1 &= 1, f_2 = 0 && \text{if } \alpha_{sh} > 0.999 \\ f_1 &= \frac{1 - e^{0.5 \ln(1 - \alpha_{sh})}}{\alpha_{sh}} \\ f_2 &= 1 - f_1 \end{aligned} \right\} \text{ if } 0.01 < \alpha_{sh} \leq 0.999 \quad (7.467)$$

7.8.6 Window Frame and Divider Calculation

For the zone heat balance calculation the inside surface temperature of the frame and that of the divider are needed. These temperatures are determined by solving the heat balance equations on the inside and outside surfaces of the frame and divider.

Table 7.16: C++ Variables used in Window/Frame and Divider calculations

Mathematical variable	Description	Units	C++ variable
$Q_{ExtIR,abs}$	IR from the exterior surround absorbed by outside frame surfaces	W	-
$Q_{IR,emitted}$	IR emitted by outside frame surfaces	W	-
Q_{conv}	Convection from outside air to outside frame surfaces	W	-
Q_{cond}	Conduction through frame from inside frame surfaces to outside frame surfaces	W	-
Q_{abs}	Solar radiation plus outside glass IR absorbed by outside of frame	W	-

Table 7.16: C++ Variables used in Window/Frame and Divider calculations

Mathematical variable	Description	Units	C++ variable
$Q_{abs,sol}^{dif}$	Diffuse solar absorbed by outside frame surfaces, per unit frame face area	W/m ²	-
$Q_{abs,sol}^{bm}$	Beam solar absorbed by outside frame surfaces, per unit frame face area	W/m ²	-
I_{ext}^{dif}	Diffuse solar incident on window	W/m ²	-
I_{ext}^{bm}	Direct normal solar irradiance	W/m ²	-
α_{sol}^{fr}	Solar absorptance of frame	-	FrameSolAbsorp
$R_{gl}^{f,dif}$	Front diffuse solar reflectance of glazing	-	
$R_{gl}^{f,bm}$	Front beam solar reflectance of glazing	-	
$\cos(\beta_{face})$	Cosine of angle of incidence of beam solar on frame outside face		CosIncAng
$\cos(\beta_h)$	Cosine of angle of incidence of beam solar on frame projection parallel to window x-axis	-	CosIncAngHorProj
$\cos(\beta_v)$	Cosine of angle of incidence of beam solar on frame projection parallel to window y-axis	-	CosIncAngVertProj
$f_{sunlight}$	Fraction of window that is sunlit	-	SunlitFrac
A_f	Area of frame's outside face (same as area of frame's inside face)	m ²	-
A_{p1}, A_{p2}	Area of frame's outside and inside projection faces	m ²	-
F_f	Form factor of frame's outside or inside face for IR	-	-
F_{p1}, F_{p2}	Form factor of frame outside projection for exterior IR; form factor of frame inside projection for interior IR	-	-
E_o	Exterior IR incident on window plane	W/m ²	outir
E_i	Interior IR incident on window plane	W/m ²	SurroundIRfromParentZone

Table 7.16: C++ Variables used in Window/Frame and Divider calculations

Mathematical variable	Description	Units	C++ variable
$\varepsilon_1, \varepsilon_2$	Outside, inside frame surface emissivity	-	FrameEmis
θ_1, θ_2	Frame outside, inside surface temperature	K	FrameTempSurfOut, FrameSurfTempIn
T_o, T_i	Outdoor and indoor air temperatures	K	tout, tin
$h_{o,c}, h_{i,c}$	Frame outside and inside air film convective conductance	W/m ² -K	HOutConv, HInConv
k	Effective inside-surface to outside-surface conductance of frame per unit area of frame projected onto window plane	W/m ² -K	FrameConductance, FrameCon
S_1	Q_{abs}/A_f	W/m ² -K	FrameQRadOutAbs
S_2	Interior short-wave radiation plus interior IR from internal sources absorbed by inside of frame divided by A_f	W/m ² -K	FrameQRadInAbs
η_1, η_2	$A_{p1}/A_f, A_{p2}/A_f$	-	-
H	Height of glazed portion of window	m	Surface%Height
W	Width of glazed portion of window	m	Surface%Width
w_f, w_d	Frame width, divider width	m	FrameWidth, DividerWidth
p_{f1}, p_{f2}	Frame outside, inside projection	m	FrameProjectionOut, FrameProjectionIn
N_h, N_v	Number of horizontal, vertical dividers	-	HorDividers, VertDividers
$T_{o,r}, T_{i,r}$	Frame outside, inside radiative temperature	K	TOutRadFr, TInRadFr
$h_{o,r}, h_{i,r}$	Frame outside, inside surface radiative conductance	W/m ² -K	HOutRad, HInRad
A	Intermediate variable in frame heat balance solution	K	Afac
C	Intermediate variable in frame heat balance solution	-	Efac
B, D	Intermediate variables in frame heat balance solution	-	Bfac, Dfac

7.8.6.1 Frame Temperature Calculation

Figure 7.41 shows a cross section through a window showing frame and divider. The outside and inside frame and divider surfaces are assumed to be isothermal. The frame and divider profiles are approximated as rectangular since this simplifies calculating heat gains and losses (see “Error Due to Assuming a Rectangular Profile,” below).

Figure 7.41: Cross section through a window showing frame and divider (exaggerated horizontally).

7.8.6.2 Frame Outside Surface Heat Balance

The outside surface heat balance equation is:

$$Q_{ExtIR,abs} - Q_{IR,emitted} + Q_{conv} + Q_{cond} + Q_{abs} = 0 \quad (7.468)$$

where

$Q_{ExtIR,abs}$ = IR from the exterior surround (sky and ground) absorbed by outside frame surfaces

$Q_{IR,emitted}$ = IR emitted by outside frame surfaces

Q_{conv} = convection from outside air to outside frame surfaces

Q_{cond} = conduction through frame from inside frame surfaces to outside frame surfaces

Q_{abs} = solar radiation (from sun, sky and ground) plus IR from outside window surface absorbed by outside frame surfaces (see “Calculation of Absorbed Solar Radiation,” below).

The first term can be written as the sum of the exterior IR absorbed by the outside face of the frame and the exterior IR absorbed by the frame’s outside projection surfaces.

$$Q_{ExtIR,abs} = \varepsilon_1 E_o A_f F_f + \varepsilon_1 E_o A_{p1} F_{p1} \quad (7.469)$$

where ε_1 is the outside surface emissivity.

The exterior IR incident on the plane of the window, E_o , is the sum of the IR from the sky, ground and obstructions. For the purposes of the frame heat balance calculation it is assumed to be isotropic. For isotropic incident IR, $F_f = 1.0$ and $F_{p1} = 0.5$, which gives:

$$Q_{ExtIR,abs} = \varepsilon_1 E_o (A_f + \frac{1}{2} A_{p1}) \quad (7.470)$$

The IR emitted by the outside frame surfaces is:

$$Q_{ExtIR,emitted} = \varepsilon_1 \sigma (A_f + A_{p1}) \theta_1^4 \quad (7.471)$$

The convective heat flow from the outside air to the outside frame surfaces is:

$$Q_{conv} = h_{o,c} (A_f + A_{p1}) (T_o - \theta_1) \quad (7.472)$$

The conduction through the frame from inside to outside is:

$$Q_{cond} = k A_f (\theta_2 - \theta_1) \quad (7.473)$$

Note that A_f is used here since the conductance, k , is, by definition, per unit area of frame projected onto the plane of the window.

Adding these expressions for the Q terms and dividing by A_f gives:

$$E_o \varepsilon_1 \left(1 + \frac{1}{2} \eta_1 \right) - \varepsilon_1 (1 + \eta_1) \theta_1^4 + h_{o,c} (1 + \eta_1) (T_o - \theta_1) + k (\theta_2 - \theta_1) + S_1 = 0 \quad (7.474)$$

where $S_1 = Q_{abs}/A_f$ and

$$\eta_1 = \frac{A_{p1}}{A_f} = \left(\frac{p_{f,1}}{w_f} \right) \frac{H + W - (N_h + N_v) w_d}{H + W + 2w_f} \quad (7.475)$$

We linearize Equation 7.474 as follows. Write the first two terms as:

$$\varepsilon_1 (1 + \eta_1) [E_o (1 + \frac{1}{2} \eta_1) / (1 + \eta_1) - \theta_1^4] \quad (7.476)$$

and define a radiative temperature:

$$T_{o,r} = [E_o (1 + \frac{1}{2} \eta_1) / (1 + \eta_1)]^{1/4} \quad (7.477)$$

This gives:

$$\varepsilon_1 (1 + \eta_1) [T_{o,r}^4 - \theta_1^4] \quad (7.478)$$

which, within a few percent, equals:

$$\varepsilon_1(1 + \eta_1) \frac{(T_{o,r} + \theta_1)^3}{2} (T_{o,r} - \theta_1) \quad (7.479)$$

Defining an outside surface radiative conductance as follows:

$$h_{o,r} = \varepsilon_1(1 + \eta_1) \frac{(T_{o,r} + \theta_1)^3}{2} \quad (7.480)$$

then gives:

$$h_{o,r}(T_{o,r} - \theta_1) \quad (7.481)$$

The final outside surface heat balance equation in linearized form is then:

$$h_{o,r}(T_{o,r} - \theta_1) + h_{o,c}(1 + \eta_1)(T_o - \theta_1) + k(\theta_2 - \theta_1) + S_1 = 0 \quad (7.482)$$

7.8.6.3 Frame Inside Surface Heat Balance

A similar approach can be used to obtain the following linearized *inside* surface heat balance equation:

$$h_{i,r}(T_{i,r} - \theta_2) + h_{i,c}(1 + \eta_2)(T_i - \theta_2) + k(\theta_1 - \theta_2) + S_2 = 0 \quad (7.483)$$

where

$$T_{i,r} = [E_i(1 + \frac{1}{2}\eta_2)/(1 + \eta_2)]^{1/4} \quad (7.484)$$

$$\eta_2 = \frac{A_{p2}}{A_f} = \left(\frac{p_{f,2}}{w_f} \right) \frac{H + W - (N_h + N_v)w_d}{H + W + 2w_f} \quad (7.485)$$

and E_i is the interior IR irradiance incident on the plane of the window.

Solving Equations 7.482 and 7.483 simultaneously gives:

$$\theta_2 = \frac{D + CA}{1 - CB} \quad (7.486)$$

with

$$A = \frac{h_{o,r}T_{o,r} + h_{o,c}T_o + S_1}{h_{o,r} + k + h_{o,c}} \quad (7.487)$$

$$B = \frac{k}{h_{o,r} + k + h_{o,c}} \quad (7.488)$$

$$C = \frac{k}{h_{i,r} + k + h_{i,c}} \quad (7.489)$$

$$D = \frac{h_{i,r}T_{i,r} + h_{i,c}T_i + S_2}{h_{i,r} + k + h_{i,c}} \quad (7.490)$$

7.8.6.4 Calculation of Solar Radiation Absorbed by Frame

The frame outside face and outside projections and inside projections absorb beam solar radiation (if sunlight is striking the window) and diffuse solar radiation from the sky and ground. For the outside surfaces of the frame, the absorbed diffuse solar per unit frame face area is:

$$Q_{abs,sol}^{dif} = I_{ext}^{dif} \alpha_{fr,sol} (A_f + F_{p1} A_{p1}) / A_f = I_{ext}^{dif} \alpha_{fr,sol} \left(1 + 0.5 \frac{A_{p1}}{A_f} \right) \quad (7.491)$$

If there is no exterior window shade, I_{ext}^{dif} includes the effect of diffuse solar reflecting off of the glazing onto the outside frame projection, i.e.,

$$I_{ext}^{dif} \rightarrow I_{ext}^{dif} \left(1 + R_{gl}^{f,dif} \right) \quad (7.492)$$

The beam solar absorbed by the outside face of the frame, per unit frame face area is:

$$Q_{abs,sol}^{bm,face} = I_{ext}^{bm} \alpha_{fr,sol} \cos \beta_{face} f_{sunlit} \quad (7.493)$$

The beam solar absorbed by the frame outside projection parallel to the window x-axis is:

$$Q_{abs,sol}^{bm,h} = I_{ext}^{bm} \alpha_{fr,sol} \cos \beta_h p_{f1} (W - N_v w_d) f_{sunlit} / A_f \quad (7.494)$$

Here it is assumed that the sunlit fraction, f_{sunlit} , for the window can be applied to the window frame. Note that at any given time beam solar can strike only one of the two projection surfaces that are parallel to the window x-axis. If there is no exterior window shade, I_{ext}^{bm} includes the effect of beam solar reflecting off of the glazing onto the outside frame projection, i.e.,

$$I_{ext}^{bm} \rightarrow I_{ext}^{bm} \left(1 + R_{gl}^{f,bm} \right) \quad (7.495)$$

The beam solar absorbed by the frame outside projection parallel to the window y-axis is:

$$Q_{abs,sol}^{bm,v} = I_{ext}^{bm} \alpha_{fr,sol} \cos \beta_v p_{f1} (H - N_h w_d) f_{sunlit} / A_f \quad (7.496)$$

Using a similar approach, the beam and diffuse solar absorbed by the *inside* frame projections is calculated, taking the transmittance of the glazing into account.

7.8.6.5 Error Due to Assuming a Rectangular Profile

Assuming that the inside and outside frame profile is rectangular introduces an error in the surface heat transfer calculation if the profile is non-rectangular. The percent error in the calculation of convection and emitted IR is approximately $100|L_{profile,rect} - L_{profile,actual}| / L_{profile,rect}$, where $L_{profile,rect}$ is the profile length for a rectangular profile ($w_f + p_{f1}$ for outside of frame or $w_f + p_{f2}$ for inside of frame) and $L_{profile,actual}$ is the actual profile length. For example, for a circular profile *vs* a square profile the error is about 22%. The error in the calculation of absorbed beam radiation is close to zero since the beam radiation intercepted by the profile is insensitive to the shape of the profile. The error in the absorbed diffuse radiation and absorbed IR depends on details of the shape of the profile. For example, for a circular profile *vs.* a square profile the error is about 15%.

7.8.6.6 Divider Temperature Calculation

The divider inside and outside surface temperatures are determined by a heat balance calculation that is analogous to the frame heat balance calculation described above.

7.8.7 Beam Solar Reflection from Window Reveal Surfaces

This section describes how beam solar radiation that is reflected from window reveal surfaces is calculated. Reflection from outside reveal surfaces—which are associated with the setback of the glazing from the outside surface of the window’s parent wall—increases the solar gain through the glazing. Reflection from inside reveal surfaces—which are associated with the setback of the glazing from the inside surface of the window’s parent wall—decreases the solar gain to the zone because some of this radiation is reflected back out of the window.

The amount of beam solar reflected from reveal surfaces depends, among other things, on the extent to which reveal surfaces are shadowed by other reveal surfaces. An example of this shadowing is shown in Figure 7.42. In this case the sun is positioned such that the top reveal surfaces shadow the left and bottom reveal surfaces. And the right reveal surfaces shadow the bottom reveal surfaces. The result is that the left/outside, bottom/outside, left/inside and bottom/inside reveal surfaces each have sunlit areas. Note that the top and right reveal surfaces are facing away from the sun in this example so their sunlit areas are zero.

The size of the shadowed areas, and the size of the corresponding illuminated areas, depends on the following factors:

- The sun position relative to the window
- The height and width of the window
- The depth of the outside and inside reveal surfaces

We will assume that the reveal surfaces are perpendicular to the window plane and that the window is rectangular. Then the above factors determine a unique shadow pattern. From the geometry of the pattern the shadowed areas and corresponding illuminated areas can be determined. This calculation is done in subroutine `CalcBeamSolarReflectedFromWinRevealSurface` in the `SolarShading` module. The window reveal input data is specified in the `WindowProperty:FrameAndDivider` object expect for the depth of the outside reveal, which is determined from the vertex locations of the window and its parent wall.

If an exterior shading device (shade, screen or blind) is in place it is assumed that it blocks beam solar before it reaches outside or inside reveal surfaces. Correspondingly, it is assumed that an interior or between-glass shading device blocks beam solar before it reaches inside reveal surfaces.

Representative shadow patterns are shown in Figures 7.43 and 7.44 for a window with no shading device, and without and with a frame. The case with a frame has to be considered separately because the frame can cast an additional shadow on the inside reveal surfaces.

The patterns shown apply to both vertical and horizontal reveal surfaces. It is important to keep in mind that, for a window of arbitrary tilt, if the left reveal surfaces are illuminated the right surfaces will not be, and vice versa. And if the bottom reveal surfaces are illuminated the top surfaces will not be, and vice versa. (Of course, for a vertical window, the top reveal surfaces will never be illuminated by beam solar if the reveal surfaces are perpendicular to the glazing, as is being assumed.

Figure 7.42: Example of shadowing of reveal surfaces by other reveal surfaces.

For each shadow pattern in Figures 7.43 and 7.44, equations are given for the shadowed areas $A_{1,sh}$ and $A_{2,sh}$ of the outside and inside reveal surfaces, respectively. The variables in these equations are the following (see also Figure 7.45):

d_1 = depth of outside reveal, measured from the outside plane of the glazing to the edge of the reveal, plus one half of the glazing thickness.

d_2 = depth of inside reveal (or, for illumination on bottom reveal surfaces, inside sill depth), measured from the inside plane of the glazing to the edge of the reveal or the sill, plus one half of the glazing thickness.

L = window height for vertical reveal surfaces or window width for horizontal reveal surfaces

α = vertical solar profile angle for shadowing on vertical reveal surfaces or horizontal solar profile angle for shadowing on horizontal reveal surfaces.

$p_1(p_2)$ = distance from outside (inside) surface of frame to glazing midplane.

d_2' = depth of shadow cast by top reveal on bottom reveal, or by left reveal on right reveal, or by right reveal on left reveal.

d_2'' = depth of shadow cast by frame.

For simplicity it is assumed that, for the case without a frame, the shadowed and illuminated areas extend into the glazing region. For this reason, d_1 and d_2 are measured from the midplane of the glazing. For the case with a frame, the beam solar absorbed by the surfaces formed by the frame outside and inside projections perpendicular to the glazing is calculated as described in “Window Frame and Divider Calculation: Calculation of Solar Radiation Absorbed by Frame.”

The following logic gives expressions for the shadowed areas for all possible shadow patterns. Here:

$$d1 = d_1$$

$$d2 = d_2$$

$$P1 = p_1$$

$$P2 = p_2$$

$$f1 = d_1 - p_1$$

$$f2 = d_2 - p_2$$

$$d2prime = d_2'$$

$$d2prime2 = d_2''$$

$$d12 = d_1 + d_2 - d_2'$$

$$\text{TanAlpha} = \tan \alpha$$

$$A1sh = A_{1,sh}$$

$$A2sh = A_{2,sh}$$

$$L = L$$

$L1$ = average distance to frame of illuminated area of outside reveal (used to calculate view factor to frame).

$L2$ = average distance to frame of illuminated area of inside reveal (used to calculate view factor to frame).

```

The beam solar reflected from a sunlit region of area A is given by:

$$R = I_B A \cos \beta (1 - a) \quad (7.497)$$

where

R = reflected solar radiation [W]

I_B = beam normal irradiance [W/m²]

A = sunlit area [m²]

β = beam solar angle of incidence on reveal surface

a = solar absorptance of reveal surface

All reflected radiation is assumed to be isotropic diffuse. For outside reveal surfaces it is assumed that $R/2$ goes toward the window and $R/2$ goes to the exterior environment. Of the portion that goes toward the window a fraction F_1 goes toward the frame, if present, and $1 - F_1$ goes toward the glazing.

The view factor F_1 to the frame calculated by assuming that the illuminated area can be considered to be a line source. Then the area-weighted average distance, L_1 , of the source to the frame is calculated from the shape of the illuminated area (see above psuedo-code). Then F_1 is related as follows to the average angle subtended by the frame of width w_f :

$$F_1 = \frac{\tan^{-1}(w_f/L_1)}{\pi/2} \quad (7.498)$$

For the portion going towards the frame, $(R/2)F_1a_f$ is absorbed by the frame (where a_f is the

solar absorptance of the frame) and contributes to the frame heat conduction calculation. The rest, $(R/2)F_1(1 - a_f)$, is assumed to be reflected to the exterior environment.

If the glazing has diffuse transmittance τ_{diff} , diffuse front reflectance ρ_{diff}^f , and layer front absorptance $\alpha_{l,diff}^f$, then, of the portion, $(R/2)(1 - F_1)$, that goes toward the glazing, $(R/2)(1 - F_1)\tau_{diff}$ is transmitted to the zone, $(R/2)(1 - F_1)\alpha_{l,diff}^f$ is absorbed in glass layer l and contributes to the glazing heat balance calculation, and $(R/2)(1 - F_1)\rho_{diff}^f$ is reflected to the exterior environment.

The beam solar absorbed by an outside reveal surface is added to the other solar radiation absorbed by the outside of the window's parent wall.

For inside reveal surfaces it is assumed that $R/2$ goes towards the window and $R/2$ goes into the zone. Of the portion that goes toward the window a fraction $(R/2)F_2$ goes toward the frame, if present, and $(R/2)(1 - F_2)$ goes toward the glazing (F_2 is calculated using a method analogous to that used for F_1). For the portion going towards the frame, $(R/2)F_2a_f$ is absorbed by the frame and contributes to the frame heat conduction calculation. The rest, $(R/2)F_2(1 - a_f)$, is assumed to be reflected back into the zone.

If the glazing has diffuse back reflectance ρ_{diff}^b , and layer back absorptance $\alpha_{l,diff}^b$, then, of the portion $(R/2)(1 - F_2)$ that goes toward the glazing, $(R/2)(1 - F_2)\tau_{diff}$ is transmitted back out the glazing, $(R/2)(1 - F_2)\alpha_{l,diff}^b$ is absorbed in glass layer l and contributes to the glazing heat balance calculation, and $(R/2)(1 - F_2)\rho_{diff}^b$ is reflected into the zone.

The beam solar absorbed by an inside reveal surface is added to the other solar radiation absorbed by the inside of the window's parent wall.

7.8.8 Shading Device Thermal Model

Shading devices in EnergyPlus can be on the exterior or interior sides of the window or between glass layers. The window shading device thermal model accounts for the thermal interactions between the shading layer (shade, screen or blind) and the adjacent glass, and between the shading layer and the room (for interior shading) or the shading layer and the outside surround (for exterior shading).

An important feature of the shading device thermal model is calculating the natural convection airflow between the shading device and glass. This flow affects the temperature of the shading device and glazing and, for interior shading, is a determinant of the convective heat gain from the shading layer and glazing to the zone air. The airflow model is based on one described in the ISO Standard 15099, "Thermal Performance of Windows, Doors and Shading Devices—Detailed Calculations" [ISO15099, 2001]. (Between-glass forced airflow is also modeled; see "Airflow Windows.")

The following effects are considered by the shading device thermal model:

- For interior and exterior shading device: Long-wave radiation (IR) from the surround absorbed by shading device, or transmitted by the shading device and absorbed by the adjacent glass. For interior shading the surround consists of the other zone surfaces. For exterior shading the surround is the sky and ground plus exterior shadowing surfaces and exterior building surfaces "seen" by the window.
- Inter-reflection of IR between the shading device and adjacent glass.
- Direct and diffuse solar radiation absorbed by the shading device.
- Inter-reflection of solar radiation between shading layer and glass layers.

- Convection from shading layer and glass to the air in the gap (or, for between-glass shading, gaps) between the shading layer and adjacent glass, and convection from interior shading layer to zone air or from exterior shading layer to outside air.
- Natural convection airflow in the gap (or, for between-glass shading, gaps) between shading layer and adjacent glass induced by buoyancy effects, and the effect of this flow on the shading-to-gap and glass-to-gap convection coefficients.
- For interior shading, convective gain (or loss) to zone air from gap airflow.

In the following it is assumed that the shading device, when in place, covers the glazed part of the window (and dividers, if present) and is parallel to the glazing. For interior and exterior shading devices it is assumed that the shading layer is separated from the glazing by an air gap. A between-glass shading layer is assumed to be centered between two glass layers and separated from the adjacent glass layers by gaps that is filled with the same gas. If the window has a frame, it is assumed that the shading device does *not* cover the frame.

7.8.9 Heat Balance Equations for Shading Device and Adjacent Glass

If a window shading device is deployed the heat balance equations for the glass surfaces facing the shading layer are modified, and two new equations, one for each face of the shading layer, are added. Figure 7.46 illustrates the case of double glazing with an interior shading device.

Figure 7.46: Glazing system with two glass layers and an interior shading layer showing variables used in heat balance equations.

The heat balance equation for the glass surface facing the gap between glass and shading layer (called in the following, “gap”) is:

$$\frac{E_i \epsilon_4 \tau_{sh}}{1 - \rho_4 \rho_{sh}} + \frac{\sigma \epsilon_4}{1 - \rho_4 \rho_{sh}} [\theta_5^4 \epsilon_{sh} - \theta_4^4 (1 - \rho_{sh})] + k_2 (\theta_3 - \theta_4) + h_{cv} (T_{gap} - \theta_4) + S_4 = 0 \quad (7.499)$$

where

τ_{sh} = IR diffuse transmittance of shading device

ε_{sh} = diffuse emissivity of shading device

ρ_{sh} = IR diffuse reflectance of shading device (= 1 - ($\tau_{sh} + \varepsilon_{sh}$))

θ_5 = temperature of the surface of the shading layer that faces the gap (K).

The term $1 - \rho_4\rho_{sh}$ accounts for the inter-reflection of IR radiation between glass and shading layer.

The convective heat transfer from glass layer #2 to the air in the gap is:

$$q_{c,gl} = h_{cv}(\theta_4 - T_{gap}) \quad (7.500)$$

where

T_{gap} = effective mean temperature of the gap air (K).

h_{cv} = convective heat transfer coefficient from glass or shading layer to gap air (W/m²K).

The corresponding heat transfer from shading layer to gap air is:

$$q_{c,sh} = h_{cv}(\theta_5 - T_{gap}) \quad (7.501)$$

The convective heat transfer coefficient is given by:

$$h_{cv} = 2h_c + 4v \quad (7.502)$$

where

h_c = surface-to-surface heat transfer coefficient for non-vented (closed) cavities (W/m²K)

v = mean air velocity in the gap (m/s).

The quantities h_{cv} and T_{gap} depend on the airflow velocity in the gap, which in turn depends on several factors, including height of shading layer, glass/shading layer separation (gap depth), zone air temperature for interior shading or outside air temperature for exterior shading, and shading layer and glass face temperatures. The calculation of h_{cv} and T_{gap} is described in the following sections.

The heat balance equation for the shading layer surface facing the gap is:

$$\frac{E_i\tau_{sh}\rho_4\varepsilon_{sh}}{1 - \rho_4\rho_{sh}} + \frac{\sigma\varepsilon_{sh}}{1 - \rho_4\rho_{sh}} [\varepsilon_4\theta_4^4 - \theta_5^4(1 - \rho_4(\varepsilon_{sh} + \rho_{sh}))] + k_{sh}(\theta_6 - \theta_5) + h_{cv}(T_{gap} - \theta_5) + S_{sh,1} = 0 \quad (7.503)$$

where

k_{sh} = shading layer conductance (W/m²K).

θ_6 = temperature of shading layer surface facing the zone air (K).

$S_{sh,l}$ = solar radiation plus short-wave radiation from lights plus IR radiation from lights and zone equipment absorbed by the gap-side face of the shading layer (W/m²K).

The heat balance equation for the shading layer surface facing the zone air is:

$$E_i\varepsilon_{sh} - \varepsilon_{sh}\sigma\theta_6^4 + k_{sh}(\theta_5 - \theta_6) + h_i(T_i - \theta_6) + S_{sh,2} = 0 \quad (7.504)$$

where

$S_{sh,2}$ = solar radiation plus short-wave radiation from lights plus IR radiation from lights and zone equipment absorbed by the zone-side face of the shading layer (W/m²K).

7.8.10 Solving for Gap Airflow and Temperature

For interior and exterior shading devices a pressure-balance equation is used to determine gap air velocity, gap air mean equivalent temperature and gap outlet air temperature given values of zone air temperature (or outside temperature for exterior shading), shading layer face temperatures and gap geometry. The pressure balance equates the buoyancy pressure acting on the gap air to the pressure losses associated with gap airflow between gap inlet and outlet [ISO15099, 2001]. The variables used in the following analysis of the interior shading case are shown in Figure 7.47.

Figure 7.47: Vertical section (a) and perspective view (b) of glass layer and interior shading layer showing variables used in the gap airflow analysis. The opening areas A_{bot} , A_{top} , A_l , A_r and A_h are shown schematically.

7.8.10.1 Pressure Balance Equation

The pressure balance equation for airflow through the gap is:

$$\Delta p_T = \Delta p_B + \Delta p_{HP} + \Delta p_Z \quad (7.505)$$

Here, Δp_T is the driving pressure difference between room air and gap air. It is given by:

$$\Delta p_T = \rho_0 T_0 g H \sin \phi \frac{|T_{gap} - T_{gap,in}|}{T_{gap} T_{gap,in}} \quad (7.506)$$

where

ρ_0 = density of air at temperature T_0 (kg/m³)

T_0 = reference temperature (283K)

g = acceleration due to gravity (m/s²)

H = height of shading layer (m)

ϕ = tilt angle of window (vertical = 90°)

T_{gap} = effective mean temperature of the gap air (K)

$T_{gap,in}$ = gap inlet temperature (= zone air temperature for interior shading) (K)

The Δp_B term is due to the acceleration of air to velocity v (Bernoulli's law). It is given by:

$$\Delta p_B = \frac{\rho}{2} v^2 (\text{Pa}) \quad (7.507)$$

where ρ is the gap air density evaluated at T_{gap} (kg/m³).

The Δp_{HP} term represents the pressure drop due to friction with the shading layer and glass surfaces as the air moves through the gap. Assuming steady laminar flow, it is given by the Hagen-Poiseuille law for flow between parallel plates [Munson et al. 1998]:

$$\Delta p_{HP} = 12\mu \frac{H}{s^2} v (\text{Pa}) \quad (7.508)$$

where μ is the viscosity of air at temperature T_{gap} (Pa-s).

The Δp_Z term is the sum of the pressure drops at the inlet and outlet openings:

$$\Delta p_Z = \frac{\rho v^2}{2} (Z_{in} + Z_{out}) (\text{Pa}) \quad (7.509)$$

Here, the inlet pressure drop factor, Z_{in} , and the outlet pressure drop factor, Z_{out} , are given by:

$$\begin{aligned} Z_{in} &= \left(\frac{A_{gap}}{0.66A_{eq,in}} - 1 \right)^2 \\ Z_{out} &= \left(\frac{A_{gap}}{0.60A_{eq,out}} - 1 \right)^2 \end{aligned} \quad (7.510)$$

where

$A_{eq,in}$ = equivalent inlet opening area (m²)

$A_{eq,out}$ = equivalent outlet opening area (m²)

A_{gap} = cross-sectional area of the gap = sW (m²)

If $T_{gap} > T_{gap,in}$:

$$\begin{aligned} A_{eq,in} &= A_{bot} + \frac{A_{top}}{2(A_{bot} + A_{top})} (A_l + A_r + A_h) \\ A_{eq,out} &= A_{top} + \frac{A_{bot}}{2(A_{bot} + A_{top})} (A_l + A_r + A_h) \end{aligned} \quad (7.511)$$

If $T_{gap} \leq T_{gap,in}$:

$$\begin{aligned} A_{eq,in} &= A_{top} + \frac{A_{bot}}{2(A_{bot} + A_{top})} (A_l + A_r + A_h) \\ A_{eq,out} &= A_{bot} + \frac{A_{top}}{2(A_{bot} + A_{top})} (A_l + A_r + A_h) \end{aligned} \quad (7.512)$$

Here, the area of the openings through which airflow occurs (see Figure 7.47 and Figure 7.48) are defined as follows:

A_{bot} = area of the bottom opening (m²)

A_{top} = area of the top opening (m²)

A_l = area of the left-side opening (m^2)

A_r = area of the right-side opening (m^2)

A_h = air permeability of the shading device expressed as the total area of openings (“holes”) in the shade surface (these openings are assumed to be uniformly distributed over the shade) (m^2)

Figure 7.48 shows examples of A_{bot} , A_{top} , A_l and A_r for different shading device configurations. These areas range from zero to a maximum value equal to the associated shade/screen/blind-to-glass cross-sectional area; i.e., A_{bot} and $A_{top} \leq sW$, A_l and $A_r \leq sH$.

Figure 7.48: Examples of openings for an interior shading layer covering glass of height H and width W . Not to scale. (a) Horizontal section through shading layer with openings on the left and right sides (top view). (b) Vertical section through shading layer with openings at the top and bottom (side view).

Expression for the Gap Air Velocity

Expressing Equation 7.505 in terms of v yields the following quadratic equation:

$$\frac{\rho v^2}{2} (1 + Z_{in} + Z_{out}) + \frac{12\mu H}{s^2} v - \rho_0 T_0 g H \sin \phi \frac{|T_{gap,in} - T_{gap}|}{T_{gap,in} T_{gap}} = 0 \quad (7.513)$$

Solving this gives:

$$v = \frac{\left[\left(\frac{12\mu H}{s^2} \right)^2 + \frac{2\rho^2(1+Z_{in}+Z_{out})\rho_0 T_0 g H \sin \phi |T_{gap,in} - T_{gap}|}{T_{gap,in} T_{gap}} \right]^{1/2} - \frac{12\mu H}{s^2}}{\rho(1 + Z_{in} + Z_{out})} \quad (7.514)$$

The choice of the root of the quadratic equation is dictated by the requirement that $v = 0$ if $T_{gap,in} = T_{gap}$.

Gap Outlet Temperature and Equivalent Mean Air Temperature

The temperature of air in the gap as a function of distance, h , from the gap inlet (Figure 7.49) is:

$$T_{gap}(h) = T_{ave} - (T_{ave} - T_{gap,in})e^{-h/H_0} \quad (7.515)$$

where

$$T_{ave} = \frac{T_{gl} + T_{sh}}{2} \quad (7.516)$$

is the average temperature of the glass and shading layer surfaces facing the gap (K).

H_0 = characteristic height (m), given by:

$$H_0 = \frac{\rho C_p s}{2h_{cv}} v \quad (7.517)$$

where C_p is the heat capacity of air.

The gap outlet temperature is given by:

$$T_{gap,out} = T_{ave} - (T_{ave} - T_{gap,in})e^{-H/H_0} \quad (7.518)$$

The thermal equivalent mean temperature of the gap air is:

$$T_{gap} = \frac{1}{H} \int_0^H T_{gap}(h) dh = T_{ave} - \frac{H_0}{H} (T_{gap,out} - T_{gap,in}) \quad (7.519)$$

Solution Sequence for Gap Air Velocity and Outlet Temperature

The routine WinShadeGapFlow is called within the glazing heat balance iterative loop in SolveForWindowTemperatures to determine v and $T_{gap,out}$. The solution sequence in WinShadeGapFlow is as follows:

At start of iteration, guess T_{gap} as $((T_{gl} + T_{sh})/2 + T_{gap,in})/2$. Thereafter use value from previous iteration.

Get still-air conductance, h_c , by calling WindowGasConductance and NusseltNumber.

Get v from Equation 7.514.

Get h_{cv} from Equation 7.502.

Get T_{ave} from Equation 7.516.

Get $T_{gap,out}$ from Equation 7.518.

Get new value of T_{gap} from Equation 7.519.

The values of h_{cv} and T_{gap} so determined are then used in the window heat balance equations to find new values of the face temperatures of the glass and shading layers. These temperatures are used in turn to get new values of h_{cv} and T_{gap} until the whole iterative process converges.

Convective Heat Gain to Zone from Gap Airflow

The heat added (or removed) from the air as it passes through the gap produces a convective gain (or loss) to the zone air given by:

$$q_v = LW [h_{cv} (T_{gl} - T_{gap}) + h_{cv} (T_{sh} - T_{gap})] = 2h_{cv} LW (T_{ave} - T_{gap}) \text{ (W)} \quad (7.520)$$

Figure 7.49: Variation of gap air temperature with distance from the inlet for upward flow.

This can also be expressed as:

$$q_v = \dot{m}C_p (T_{gap,out} - T_{gap,in}) \text{ (W)} \quad (7.521)$$

where the air mass flow rate in the gap is given by:

$$\dot{m} = \rho A_{gap} v \text{ (kg/s)} \quad (7.522)$$

7.8.11 Improved Airflow Equations for Window Screens and Horizontal Louvered Blind Systems

Several different approaches to simulate windows with attachments have been studied and developed. The primary focus of these works has been the experimental measurement, simulation, and simplified model development of solar heat gain for horizontal louvered blinds (venetian blinds) located between-glass and room-side. Relatively little research has been done to characterize the night-time (zero solar load) U-factor impacts of attachment products other than venetian blinds, including in-plane products such as solar screens, roller shades, cellular shades, insect screens, and drapes.

Surface openness of shade systems, $d_{surface}$ in Figure 7.50, has primarily been studied for highly porous surfaces such as insect screens. The inlet and outlet pressure loss of a cavity open to the indoor room, ΔP_z , is calculated with Equations 7.523, where the use of in/out and top/bot are dependent on the direction of flow, as determined by the glass surface temperature relative to the indoor temperature.

$$\begin{aligned} \Delta P_z &= 0.5\rho v^2(Z_{in} + Z_{out}) \\ Z_{in/out} &= \left(\frac{A_s}{0.6A_{eq,in/out}} - 1\right)^2 \\ A_{eq,in/out} &= A_{top/bot} + \frac{1}{2}\frac{A_{bot/top}}{A_{bot}+A_{top}}(A_l + A_r + A_h) \\ A_h &= d_{surface}WH \\ A_s &= d_{gap}W \end{aligned} \quad (7.523)$$

Where ρ is the fluid density, v is the fluid velocity, $Z_{in/out}$ is the pressure loss factor of the cavity, A_s is the cross-section area of the cavity, d_{gap} is the glass-to-shade cavity depth, $d_{surface}$ is the openness fraction (0 - 1), W is the window width, H is the window height, A_{eq} , is the equivalent inlet/outlet area of the cavity, and A_l , A_r , A_{top} , A_{bot} , A_h are the areas of the left, right, top, bottom, and front surface ventilation gaps respectively.

The set of equations 7.523 include an inherent minimum of pressure loss coefficient, Z , when the calculated inlet or outlet area, A_{eq} , equals 5/3 the cross section area, A_s . This limits the validity of the model to A_{eq} less than 5/3 of A_s . Figure 7.51 illustrates this minimum with a surface map of calculated Z values ($\log(Z)$ plotted to show contours) over a range of A_{eq} based on a 1m x 1m window. Figure 7.51 shows a slice of the surface plot at a typical $d_{gap} = 15mm$. Window surface area, A_w , is typically one to two orders of magnitude larger than the cross-section area, A_s . This means that A_{eq} exceeds A_s at relatively low surface openness. For a typical glass-to-shade gap, $d_{gap} = 15mm$, the local minimum in Z , and in turn valid openness range of the algorithm, occurs at an openness of $d_{surface} \cong 0.1$.

Figure 7.50: Illustration of ISO 15099 ventilated shade layer opening locations.

Figure 7.51: Pressure loss factor, Z , as a function of A_{eq} at $A_s = 0.015m^2$; and (b) surface plot of Z as a function of A_s and A_{eq} for a 1m x 1m window. The minimum follows the predicted ratio of 5/3 between A_{eq} and A_s .

7.8.11.1 Screen Heat Flux

To improve the simulation correlation, correlation coefficients are proposed to the five ventilated layer opening parameters defined in ISO 15099; A_h , A_{top} , A_{bot} , A_l , and A_r . This model includes two correlation constants, C_1 and C_2 that are determined based on regression analysis of the measured dataset. An additional two constants, C_3 and C_4 , are also optimized and used to correlate the to left/right and top/bottom gaps respectively as shown in Equations 7.524.

$$\begin{aligned}
 A_h &= C_1 \cdot d_{surface}^{C_2} \cdot A_w \\
 A_{l,r}^* &= C_3 \cdot A_{l,r} \\
 A_{t,b}^* &= C_4 \cdot A_{t,b}
 \end{aligned} \tag{7.524}$$

Where correlation constants are:

Coefficient	Value
C_1	0.078
C_2	1.20
C_3	1
C_4	1

7.8.11.2 Horizontal Louvered Blind

To improve the simulation correlation, correlation coefficients are proposed to the five ventilated layer opening parameters defined in ISO 15099; A_h , A_{top} , A_{bot} , A_l , and A_r . The proposed heat flux model includes parameters for the openness, $d_{surface}$, open area, A_h , tilt, ϕ , and the layer conductivity, k .

$$\begin{aligned}
A_h &= D_1 \cdot [d_{surface}(\cos\phi)^{D_2}]^{D_3} \cdot A_s \\
d_{surface} &= 1 - \frac{t}{\cos(\phi)(p-t)} \\
t^* &= D_4 \cdot w \cdot \cos\phi \\
k^* &= d_{surface} \cdot k_c + (1 - d_{surface})k_s \\
d_{top} &= 0 \\
d_{left,right} &= d_{gap}(\text{for outside mount}) \\
d_{left,right} &= 0(\text{for inside mount}) \\
d_{bottom} &= d_{gap}(\text{for outside mount}) \\
d_{bottom} &= 0(\text{for inside mount})
\end{aligned} \tag{7.525}$$

where t^* and k^* are the revised layer thickness and equivalent conductivity and k_c is the conductivity of the gas between slats at the average blind layer temperature.

Where correlation constants are:

Coefficient	Horizontal Blinds	Vertical Blinds
D_1	0.016	0.041
D_2	-0.63	-0.00
D_3	0.53	0.270
D_4	0.043	0.012

7.8.12 Heat Balance Equations for Between-Glass Shading Device

In EnergyPlus shading devices are allowed between the two glass panes of double glazing and between the two inner glass panes of triple glazing. Figure 7.52 shows the case of a between-glass shading device in double glazing.

Figure 7.52: Glazing system with two glass layers and a between-glass shading device showing variables used in the heat balance equations.

The heat balance equations for the two glass surfaces facing the shading device are the following.
For face #2:

$$h_{cv,1}(T_{gap,1} - \theta_2) + k_1(\theta_1 - \theta_2) + \frac{\sigma \varepsilon_2}{1 - \rho_2 R_1} \left[\frac{\tau_{sh}}{1 - \rho_6 \rho_3} (\varepsilon_3 \theta_3^4 + \varepsilon_6 \theta_6^4 \rho_3) + \varepsilon_5 \theta_5^4 + \varepsilon_2 \theta_2^4 R_1 \right] - \sigma \varepsilon_2 \theta_2^4 + S_2 = 0 \quad (7.526)$$

where

$$R_1 = \rho_5 + \frac{\tau_{sh}^2 \rho_3}{1 - \rho_6 \rho_3} \quad (7.527)$$

$T_{gap,1}$ = effective mean air temperature in gap 1 (K)

$h_{cv,1}$ = convective heat transfer coefficient from glass or shading layer to gas in gap 1 (W/m²K)

For face #3:

$$h_{cv,2}(T_{gap,2} - \theta_3) + k_2(\theta_4 - \theta_3) + \frac{\sigma \varepsilon_3}{1 - \rho_3 R_2} \left[\frac{\tau_{sh}}{1 - \rho_5 \rho_2} (\varepsilon_3 \theta_2^4 + \varepsilon_5 \theta_5^4 \rho_2) + \varepsilon_6 \theta_6^4 + \varepsilon_7 \theta_3^4 R_2 \right] - \sigma \varepsilon_3 \theta_3^4 + S_3 = 0 \quad (7.528)$$

where

$$R_2 = \rho_6 + \frac{\tau_{sh}^2 \rho_2}{1 - \rho_5 \rho_2} \quad (7.529)$$

$T_{gap,2}$ = effective mean air temperature in gap 2 (K)

$h_{cv,2}$ = convective heat transfer coefficient from glass or shading layer to gas in gap 2 (W/m²K)

The heat balance equations for the shading layer faces are:

For face #5:

$$h_{cv,1}(T_{gap,1} - \theta_5) + k_s h(\theta_6 - \theta_5) + \frac{\sigma \varepsilon_5}{1 - \rho_2 R_1} \left[\frac{\tau_{sh} \rho_2}{1 - \rho_5 \rho_3} (\varepsilon_3 \theta_3^4 + \varepsilon_6 \theta_6^4 \rho_3) + \varepsilon_2 \theta_2^4 + \varepsilon_5 \theta_5^4 \rho_2 \right] - \sigma \varepsilon_5 \theta_5^4 + S_5 = 0 \quad (7.530)$$

For face #6:

$$h_{cv,2}(T_{gap,2} - \theta_3) + k_2(\theta_4 - \theta_3) + \frac{\sigma \varepsilon_3}{1 - \rho_3 R_2} \left[\frac{\tau_{sh}}{1 - \rho_5 \rho_2} (\varepsilon_2 \theta_2^4 + \varepsilon_5 \theta_5^4 \rho_2) + \varepsilon_6 \theta_6^4 + \varepsilon_7 \theta_3^4 R_2 \right] - \sigma \varepsilon_3 \theta_3^4 + S_3 = 0 \quad (7.531)$$

The convective heat transfer coefficients are given by:

$$\begin{aligned} h_{cv,1} &= 2h_{c,1} + 4v \\ h_{cv,2} &= 2h_{c,2} + 4v \end{aligned} \quad (7.532)$$

where

$h_{c,1}, h_{c,2}$ = surface-to-surface heat transfer coefficients for gap #1 and #2, respectively, when these gaps are non-vented (closed).

v = air velocity in the gaps (m/s). It is assumed that the gap widths are equal, so that the velocity of flow in the gaps is equal and opposite, i.e., when the airflow is upward in gap #1 it is downward in gap #2 and vice-versa.

In analogy to the interior or exterior shading device case, the air velocity is determined by solving the following pressure balance equation:

$$\Delta p_{T,1,2} = \Delta p_{B,1} + \Delta p_{HP,1} + \Delta p_{Z,1} + \Delta p_{B,2} + \Delta p_{HP,2} + \Delta p_{Z,2} \quad (7.533)$$

where the driving pressure difference between gap #1 and #2 is:

$$\Delta p_{T,1,2} = \rho_0 T_0 g H \sin \phi \frac{|T_{gap,1} - T_{gap,2}|}{T_{gap,1} T_{gap,2}} \quad (\text{Pa}) \quad (7.534)$$

The pressure drops on the right-hand side of this equation are:

$$\begin{aligned} \Delta p_{B,i} &= \frac{\rho_{gap,i}}{2} v^2 \\ \Delta p_{HP,i} &= 12 \mu_{gap,i} \frac{H}{s^2} \\ \Delta p_{Z,i} &= \frac{\rho_{gap,i} v^2}{2} (Z_{in,i} + Z_{out,i}) \end{aligned} \quad (7.535)$$

where i = gap number (1 or 2).

It can be shown that $Z_{in,1} + Z_{out,1} = Z_{in,2} + Z_{out,2}$. Then, inserting these pressure drop expressions into Equation 7.534, we obtain the following expression for the airflow velocity:

$$v = \frac{\left[\left(\frac{12(\mu_{gap,1} + \mu_{gap,2})H}{s^2} \right)^2 + 2\Delta p_{T,1,2}(\rho_{gap,1} + \rho_{gap,2})(1 + Z_{in} + Z_{out}) \right]^{1/2} - \frac{12(\mu_{gap,1} + \mu_{gap,2})H}{s^2}}{(\rho_{gap,1} + \rho_{gap,2})(1 + Z_{in} + Z_{out})} \quad (7.536)$$

The choice of the sign of the square root term is dictated by the requirement that $v = 0$ if $\Delta p_{T,1,2} = 0$, i.e., $T_{gap,1} = T_{gap,2}$.

Given v , we can now calculate $T_{gap,1}$ and $T_{gap,2}$, which gives $\Delta p_{T,1,2}$. The procedure is as follows. We have:

$$T_{gap,1,out} = T_{ave,1} - (T_{ave,1} - T_{gap,1,in})\xi_1 \quad (7.537)$$

where $T_{ave,1} = (\theta_2 + \theta_5)/2$ and $\xi_1 = e^{-\frac{H}{H_{0,1}}}$ with $H_{0,1} = \rho_{gap,1} C_p s v / (2h_{cv,1})$. Since $T_{gap,1,in} = T_{gap,2,out}$ this gives:

$$T_{gap,1,out} = T_{ave,1} - (T_{ave,1} - T_{gap,2,out})\xi_1 \quad (7.538)$$

Similarly,

$$T_{gap,2,out} = T_{ave,2} - (T_{ave,2} - T_{gap,1,out})\xi_2 \quad (7.539)$$

Solving these simultaneous equations gives:

$$\begin{aligned} T_{gap,1,out} &= \frac{T_{ave,1}(1-\xi_1) + \xi_1 T_{ave,2}(1-\xi_2)}{1-\xi_1\xi_2} \\ T_{gap,2,out} &= \frac{T_{ave,2}(1-\xi_2) + \xi_2 T_{ave,1}(1-\xi_1)}{1-\xi_1\xi_2} \end{aligned} \quad (7.540)$$

Using these in:

$$T_{gap,1} = T_{ave,1} - \frac{H_{0,1}}{H} (T_{gap,1,out} - T_{gap,2,out}) \quad (7.541)$$

gives:

$$T_{gap,1} = T_{ave,1} - \frac{H_{0,1}}{H} \xi (T_{ave,1} - T_{ave,2}) \quad (7.542)$$

with:

$$\xi = \frac{(1 - \xi_1)(1 - \xi_2)}{1 - \xi_1 \xi_2} \quad (7.543)$$

Similarly, from:

$$T_{gap,2} = T_{ave,2} - \frac{H_{0,2}}{H} (T_{gap,2,out} - T_{gap,1,out}) \quad (7.544)$$

we get:

$$T_{gap,2} = T_{ave,2} - \frac{H_{0,2}}{H} \xi (T_{ave,2} - T_{ave,1}) \quad (7.545)$$

The overall solution sequence is as follows. At start of the iteration process, guess $T_{gap,1} = T_{ave,1}$ and $T_{gap,2} = T_{ave,2}$. Then:

- 1) Get $\rho_{gap,1}, \rho_{gap,2}, \mu_{gap,1}, \mu_{gap,2}$ using $T_{gap,1}, T_{gap,2}$.
- 2) Get still-air conductances $h_{c,1}, h_{c,2}$ by calling WindowGasConductance and NusseltNumber.
- 3) Get v from Equation 7.536.
- 4) Get $h_{cv,1}, h_{cv,2}$ from Equation 7.532.
- 5) Get $T_{ave,1}, T_{ave,2}$.
- 6) Get $H_{o,1}, H_{o,2}, \xi_1$ and ξ_2 .
- 7) Get $T_{gap,1}, T_{gap,2}$ from Equations 7.542 and 7.545.

The values $h_{cv,1}, h_{cv,2}, T_{gap,1}$ and $T_{gap,2}$ are then used in the face heat balance equations to find new values of the face temperatures $\theta_2, \theta_3, \theta_5$ and θ_6 . These are used in turn to get new values of $h_{cv,1}, h_{cv,2}, T_{gap,1}$ and $T_{gap,2}$ until the whole iterative process converges.

7.8.13 Airflow Windows

In airflow windows forced air flows in the gap between adjacent layers of glass. Such windows are also known as “heat-extract windows” and “climate windows.”

Five configurations of airflow windows are modeled (Figure 7.53) that depend on the source and destination of forced air. The allowed combinations of Airflow Source and Airflow Destination are:

InsideAir → OutsideAir
 InsideAir → InsideAir
 InsideAir → ReturnAir
 OutsideAir → InsideAir
 OutsideAir → OutsideAir

A common application of airflow windows is to reduce the zone cooling load by exhausting indoor air through the window, thereby picking up and rejecting heat from the glazing (Figure 7.53).

Figure 7.54 shows the variables used in the heat balance equations for forced airflow in a double-glazed window.

The heat balance equation for the left-hand glass surface facing the gap in Figure 7.54 is:

Figure 7.53: Gap airflow configurations for airflow windows. From "Active facades," Version no. 1, Belgian Building Research Institute, June 2002.

$$k_1(\theta_1 - \theta_2) + h_{cv}(T_{gap} - \theta_2) + \sigma \frac{\varepsilon_2 \varepsilon_3}{1 - (1 - \varepsilon_2)(1 - \varepsilon_3)} (\theta_3^4 - \theta_2^4) + S_2 = 0 \quad (7.546)$$

The corresponding equation for the right-hand glass surface facing the gap is:

$$k_2(\theta_4 - \theta_3) + h_{cv}(T_{gap} - \theta_3) + \sigma \frac{\varepsilon_2 \varepsilon_3}{1 - (1 - \varepsilon_2)(1 - \varepsilon_3)} (\theta_2^4 - \theta_3^4) + S_3 = 0 \quad (7.547)$$

Here,

T_{gap} = effective mean temperature of the gap air (K)

h_{cv} = convective heat transfer coefficient from glass to gap air (W/m²K).

The convective heat transfer coefficient is given by:

$$h_{cv} = 2h_c + 4v \quad (7.548)$$

where

h_c = glass-to-glass heat transfer coefficient for non-vented (closed) cavity (W/m²K)

v = mean air velocity in the gap (m/s).

The air velocity is determined by the gap cross-sectional area in the flow direction and the air flow rate, which is an input value that is constant or can vary according to a user-specified schedule:

$$v = \frac{F}{A_{gap}} \quad (\text{m/s}) \quad (7.549)$$

where

F = airflow rate (m³/s)

A_{gap} = gap cross-sectional area in direction of flow (m²)

It is assumed that the airflow is uniform across the width of the window.

The mean temperature of the gap air is given by the following expression, whose derivation follows that for Equation 7.519 for the case of an interior shading device:

$$T_{gap} = T_{ave} - \frac{H}{H_0}(T_{gap,out} - T_{gap,in}) \quad (7.550)$$

where

$$T_{ave} = \frac{\theta_2 + \theta_3}{2} \quad (7.551)$$

$$H_0 = \frac{\rho C_p S}{2h_{cv}} v \quad (7.552)$$

H = glazing height (m)

$T_{gap,in}$ = gap air inlet temperature (T_i if the airflow source is indoor air, T_o if the airflow source is outside air) (K).

The outlet air temperature is given by:

$$T_{gap,out} = T_{ave} - (T_{ave} - T_{gap,in})e^{-H/H_0} \quad (7.553)$$

The equations for glass face #1 and #4 are the same as those for no airflow in the gap (Equations 7.434 and 7.437).

The convective heat gain to the zone air due to the gap airflow when the airflow destination is indoor air is:

$$q_v = \dot{m}(C_{p,out}T_{gap,out} - C_{p,i}T_i) \quad (\text{W}) \quad (7.554)$$

where

$C_{p,i}$ = heat capacity of the indoor air (J/kg-K)

$C_{p,out}$ = heat capacity of the gap outlet air (J/kg-K)

and where the air mass flow rate in the gap is:

$$\dot{m} = \rho F \quad (\text{kg/s}) \quad (7.555)$$

7.8.13.1 Fan Energy

The fan energy used to move air through the gap is very small and is ignored.

7.8.13.2 Airflow Window with Between-Glass Shading Device

Figure 7.55 shows the case of a double-glazed airflow window with a between glass shading device. The heat balance equations in this case are the same as those for the between-glass shading device with natural convection (Figure 7.52 and following equations) except that now:

$$v = \frac{F/2}{A_{gap}} \quad (\text{m/s}) \quad (7.556)$$

where $A_{gap} = sW$ is the cross-sectional area of the gap on either side of the shading device. It is assumed that the shading device is centered between the two panes of glass so that the airflow, F , is divided equally between the two gaps.

The convective heat gain to the zone air due to the airflow through the two gaps when the airflow destination is indoor air is:

$$q_v = \dot{m}(C_{p,ave,out}T_{gap,ave,out} - C_{p,i}T_i)(\text{W}) \quad (7.557)$$

where the average temperature of the two outlet air streams is:

$$T_{gap,ave,out} = (T_{gap,1,out} + T_{gap,2,out})/2 \quad (7.558)$$

and

$C_{p,ave,out}$ = heat capacity of the outlet air evaluated at $T_{gap,ave,out}$ (J/kg-K)

7.8.14 Evacuated Glazing Unit (EGU)

Evacuated glazing Units (EGU) are an emerging technology, developed as a concept some 20-30 years ago, but only now approaching wide-spread commercialization and adoption.

Figure 7.55: Airflow window with between-glass shading device showing variables used in the heat balance equations.

7.8.14.1 Evacuated glazing unit (EGU): cavity thermal conductance

Thermal Conductance of the space in an evacuated glazing unit (EGU) is the sum of the conductance of the low pressure gas (air) and radiation conductance.

$$C_{gas} = C_{COND} + C_{RAD} \quad (7.559)$$

Conductance of the low-pressure gas

Conductance of low pressure gasses is calculated using formula by Corruccini (Corruccini, R. (1959)).

$$C_{COND} = \alpha \cdot \left[\frac{\gamma + 1}{\gamma - 1} \right] \cdot \left[\frac{R}{8 \cdot \pi \cdot M \cdot T} \right]^{\frac{1}{2}} \cdot P \quad (7.560)$$

$$B = \alpha \cdot \left[\frac{\gamma + 1}{\gamma - 1} \right] \cdot \left[\frac{R}{8 \cdot \pi \cdot M \cdot T} \right]^{\frac{1}{2}} \quad (7.561)$$

$$C_{COND} = B \cdot P \quad (7.562)$$

Where:

$$\alpha = \frac{\alpha_1 \alpha_2}{\alpha_2 + \alpha_1 (1 - \alpha_2)} \quad (7.563)$$

α_1, α_2 = Accommodation coefficients of the gas molecules with the two surfaces. These values depend on the temperature, surface conditions, etc. For the present configuration and conditions,

it is expected that α is approximately 0.5. If a conservative value is needed, then a value of 1.0 could be used. With $\alpha_1, \alpha_2 = 0.5$, $\alpha = 0.333$.

γ = Specific heat ratio, $\gamma_{air} = 1.40$.

R = Universal gas constant, $R = 8,314.462175 \text{ J/mol} \cdot \text{K}$

M = Molecular Weight, $M_{air} = 28.97 \text{ [mol/g]}$

$T = (T_1 + T_2)/2 \text{ [K]}$

P = Pressure of the gas $[\text{N/m}^2]$

From the paper Collins and Robinson (Collins, R., & Robinson, S. (1991)), B is set at approximately 50 for Air, if pressure is given in torr. Therefore according to Collins and Robinson, for air and approximate conditions of EGU:

$$C_{COND} \approx 50 \cdot P \quad (7.564)$$

Where P is in torr (i.e., mm Hg).

Note: Conversion from Pa to torr is accomplished by multiplying value in torr by 133.28.

Using formula 2 and assuming T_1 to be 20°C and T_2 to be -18°C (expected temperatures of glass surfaces in EGU, if one glass surface is low-e and unit is exposed to NFRC standard environmental conditions), and using SI system of units, the B is calculated as 54.4, which is very close to the value of 50, proposed by Collins and Robinson:

$$C_{COND} \approx 54.4 \cdot P \quad (7.565)$$

EnergyPlus uses an exact value, calculated by the formula, so these values will be input into the calculations, enabling a more flexible model that can account for special treatment of glass surfaces.

7.8.14.2 Radiation conductance

Radiation conductance for the two parallel plates is given by:

$$C_{RAD} = \frac{1}{\varepsilon_1^{-1} + \varepsilon_2^{-1} - 1} \sigma \frac{(T_1^4 - T_2^4)}{T_1 - T_2} \quad (7.566)$$

Where:

ε_1 = emissivity of the first facing glass surface, [-]

ε_2 = emissivity of the second facing glass surface, [-]

σ = Stefan-Boltzmann Constant, $5.67 \times 10^8, [\text{W}/(\text{m}^2 \cdot \text{K}^4)]$

T_1 = Temperature of the first facing glass surface, [K]

T_2 = Temperature of the second facing glass surface. [K]

Assuming glass surface temperatures of 20°C and -18°C, respectively, the following radiation conductances are obtained for the three different glass emissivities:

Clear Glass ($\varepsilon_1 = \varepsilon_2 = 0.84$): $C_{RAD} = 3.4 \text{ W/m}^2\text{K}$

Hard Coat Low-e (ε_1 or $\varepsilon_2 = 0.15$): $C_{RAD} = 0.68 \text{ W/m}^2\text{K}$

Soft Coat Low-e (ε_1 or $\varepsilon_2 = 0.04$): $C_{RAD} = 0.19 \text{ W/m}^2\text{K}$

Note: C_{RAD} of 0.09 is theoretically possible using the best low-e technology of present day (i.e., ε_1 or $\varepsilon_2 = 0.02$).

Note: Low-e values above are typical values, which will vary by manufacturer. Some more recent hard coat low-e values are at or below 0.1.

It should also be noted that values above are based on the fix set of temperatures, while in reality temperatures will depend on the environmental conditions and surface emissivities (e.g., it cannot be expected that clear glass will have same T_1 and T_2 as low-e glass).

Equation 7.566 is a precise formulation for two parallel plates at the constant temperature. A simplified equation under these conditions is given in the form of:

$$C_{RAD} = 4\sigma \frac{1}{\varepsilon_1^{-1} + \varepsilon_2^{-1} - 1} T_m^3 \quad (7.567)$$

Where:

T_m = mean temperature, [K]

$$T_m = \frac{(T_1 + T_2)}{2} \quad (7.568)$$

Calculation of the U-factor:

$$U = \frac{1}{R_{tot}} = \frac{1}{R_o + 2 \cdot R_{glass} + R_{gap} + R_i} \quad (7.569)$$

$$R_{gap} = \frac{1}{C_{gap}} = \frac{1}{C_{COND} + C_{RAD}} \quad (7.570)$$

$$R_{glass} = \frac{t_{glass}}{k_{glass}} \quad (7.571)$$

Where:

t_{glass} = glass thickness; [m]

k_{glass} = glass conductivity; $k_{glass} = 1 \text{ W}/(\text{m} \cdot \text{K})$

$R_{glass} = 0.003 \text{ m}^2\text{K}/\text{W}$ (for 3 mm glass pane)

$R_o \approx 0.033 \text{ m}^2\text{K}/\text{W}$

$R_i \approx 0.14 \text{ m}^2\text{K}/\text{W}$

U-factor of EGU without any pillars (pretending that this is possible) would be calculated using C_{RAD} only. From above radiation conductance calculations:

Clear Glass: $U = 2.64 \text{ W}/(\text{m}^2 \cdot \text{K}) [0.464 \text{ Btu}/(\text{hr} \cdot \text{ft}^2 \cdot ^\circ\text{F})]$

Hard Coat Low-e: $U = 0.62 \text{ W}/(\text{m}^2 \cdot \text{K}) [0.109 \text{ Btu}/(\text{hr} \cdot \text{ft}^2 \cdot ^\circ\text{F})]$

Soft Coat Low-e: $U = 0.19 \text{ W}/(\text{m}^2 \cdot \text{K}) [0.034 \text{ Btu}/(\text{hr} \cdot \text{ft}^2 \cdot ^\circ\text{F})]$

Adding conductance of the air at 0.001 torr ($C_{COND} = 0.08 \text{ W}/(\text{m}^2 \cdot \text{K})$, these values become:

Clear Glass: $U = 2.66 \text{ W}/(\text{m}^2 \cdot \text{K}) [0.468 \text{ Btu}/(\text{hr} \cdot \text{ft}^2 \cdot ^\circ\text{F})]$

Hard Coat Low-e: $U = 0.68 \text{ W}/(\text{m}^2 \cdot \text{K}) [0.120 \text{ Btu}/(\text{hr} \cdot \text{ft}^2 \cdot ^\circ\text{F})]$

Soft Coat Low-e: $U = 0.27 \text{ W}/(\text{m}^2 \cdot \text{K}) [0.048 \text{ Btu}/(\text{hr} \cdot \text{ft}^2 \cdot ^\circ\text{F})]$

In contrast, the U-factor of the same configuration with the air at atmospheric pressure will be (For the space width of 50 mm, $C_{COND} = 450 \text{ W}/\text{m}^2\text{K}$):

Clear Glass: $U = 5.52 \text{ W}/(\text{m}^2 \cdot \text{K}) [0.468 \text{ Btu}/(\text{hr} \cdot \text{ft}^2 \cdot ^\circ\text{F})]$

Hard Coat Low-e: $U = 5.52 \text{ W}/(\text{m}^2 \cdot \text{K}) [0.120 \text{ Btu}/(\text{hr} \cdot \text{ft}^2 \cdot ^\circ\text{F})]$

Soft Coat Low-e: $U = 5.52 \text{ W}/(\text{m}^2 \cdot \text{K}) [0.048 \text{ Btu}/(\text{hr} \cdot \text{ft}^2 \cdot ^\circ\text{F})]$

It is clear that emissivity of the glass surface makes no difference, because of the dominant conductance of the air space. Also, it is worth noting that the U-factor of such configuration is very close to the U-factor of single glazing.

7.8.14.3 Evacuated glazing unit (EGU): Glass support element thermal conductance

Glass panes in the EGU are separated by an array of small support elements. Typically, these support elements have a cylindrical shape and are often referred to as “pillars.” Typical geometry of the pillar is 0.5-1.0 mm diameter and 0.05 mm (50 mm) height. They are typically spaced 1-2 in. apart in a form of square or staggered matrix.

7.8.14.4 Calculation of the U-factor

The conductance of these elements can be measured or numerically modeled to determine accurate thermal performance. Approximate method also exists and is based on the combination of modeling and analytical work for the conduction through small cylinders in contact with infinite parallel plates with thickness much larger than cylinder height.

The following formula can be used to determine conductance of the single pillar, C_p (Collins and Fisher-Cripps 1991):

$$C_p = \frac{2ka}{1 + \frac{2h}{\pi a}} \quad (7.572)$$

Where:

k = conductivity of glass, W/(m · K)

a = radius of the pillar (m)

h = pillar height, m

For the square array of support pillars (Collins and Fischer-Cripps 1991) proposes the following formula for their conductance, C_{pa} :

$$C_{pa} = \frac{2ka}{\lambda^2 \left(1 + \frac{2h}{\pi a}\right)} \quad (7.573)$$

Where:

λ = pillar spacing, m

This formula is approximate and does not include effect of the conductivity of the pillar, but it gives good approximation for common materials used in this technology, since conductivity of the pillar does not play substantial role for non-insulating pillars (where “non-insulating” would mean that conductivity of the pillar is equal or higher than the conductivity of the glass pane.

The U-factor of the EGU with support pillars is then:

$$U = \frac{1}{R_{tot}} = \frac{1}{R_o + 2 \cdot R_{glass} + R_{gap} + R_i} \quad (7.574)$$

Where:

$$R_{gap} = \frac{1}{C_{gap}} = \frac{1}{C_{COND} + C_{RAD} + C_{pa}} \quad (7.575)$$

7.8.15 Thermal Performance of Deflected Insulated Glazing Unit (IGU)

7.8.15.1 Introduction

Deflection of insulated glazing unit (IGU) can result in thermal performance degradation or improvement due to the reduction or increase of gap space width. Convection of the gas fill is affected by changed gap space and due to modified convection pattern and shorter or longer thermal path at the center of the glazing unit can result in increased or decreased thermal performance. For the most part, U-factor is mostly affected as a direct result of changed thermal performance; however note that solar heat gain through the window (SHGC) can also be affected because of the effect of inward flowing fraction of absorbed solar radiation, which is affected by thermal performance of the IGU.

Deflection in sealed IGU is caused by the difference in gas pressure in IGU gap vs. outdoor/indoor pressure. Indoor and outdoor pressure can be considered equal, since indoor building environment is in pretty good contact with outdoor environment. We will call this pressure an atmospheric pressure, P_a . The differences in pressure between atmospheric and gap pressure is due to several factors, listed here:

- 1) Difference in atmospheric pressure between IGU fabrication location and end use location
- 2) Difference in temperature during fabrication and actual operating conditions for the glazing. It should be noted that initial temperature can be higher than ambient temperature during fabrication process, due to elevated sealant temperatures, which can raise local temperatures within the IGU.
- 3) Unbalanced gas fill leakage through the sealants, resulting in lower gap pressure and inward deflection.
- 4) Wind or static load pressure

Effects 1 and 2 will be modeled using equations presented below, while effect 3 does not have credible mathematical model. However, cumulative deflection, resulting from all three effects can be measured in the field and its effect on thermal performance can be modeled by specifying center glazing deflection.

Wind or static load pressure effects on deflection is not included in this model at this time, but will be considered for future versions.

Recognizing that indoor and outdoor air pressure could be different, such as in hot box test environment, future plans for the extension of the model will include option to specify different values for indoor and outdoor pressure. Another future improvement to the model will also include linking certain air gaps with indoor or outdoor environment, meaning that respective pressures in linked spaces will be set to equal.

7.8.15.2 Mathematical Model

Mathematical model described in detail here is based on the research work by Bernier and Bourret (1997) and Timoshenko and Woinowsky-Krieger (1959). Bernier and Bourret (1997) of the Ecole Polytechnique Montréal adopted Timoshenko and Woinowsky-Krieger (1959) model for calculating flat plate deflection subjected to the differential pressure field (static), while their original contribution was to develop correlations for changes in thermal performance, based on IGU deflection at

the center of glazing location. In addition to adopting Bernier and Bourret (1997) model here, we have also developed model for calculating change in thermal performance of deflected units when this deflection is measured in the field. Therefore, the mathematical formulation, presented here is divided into two sections; 1) calculation of the deflection and resulting thermal performance caused by pressure and temperature effects and 2) calculation of the thermal performance of the IGU when the deflection is measured.

7.8.15.3 Calculation of the deflection and thermal performance caused by pressure and temperature effects

If coordinate system is set as shown in Figure 7.56 and Figure 7.57, it is possible to calculate deflection distribution at each point of pane by using following equation:

$$L_{D(i)}(x, y) = \frac{16 \cdot \Delta P_{(i)}}{\pi^6 \cdot D_{(i)}} \sum_{m=1,3,5,\dots}^{\infty} \sum_{n=1,3,5,\dots}^{\infty} \frac{\sin \frac{m\pi x}{W} \sin \frac{n\pi y}{H}}{mn \left(\left(\frac{m}{W} \right)^2 + \left(\frac{n}{H} \right)^2 \right)^2} \quad (7.576)$$

where

$$D_{(i)} = \frac{E \cdot t_{(i)}^3}{12 \cdot (1 - \nu^2)} \quad (7.577)$$

and

E = Young's modulus (7.2×10^{10}) [Force per unit Area; SI: Pa, IP: psi]

t = thickness of glazing pane [Length; SI: m, IP: in.]

ν = poison's ratio (0.22 for glass) [Non-Dimensional]

$$\Delta P_i = P_{gap(i)} - P_{gap(i-1)} (\text{for } i\text{-th pane}) \quad [\text{Force per unit Area; SI: Pa, IP: psi}] \quad (7.578)$$

$$\Delta P_i = P_{gap(1)} - P_a (\text{first pane}) \quad [\text{Force per unit Area; SI: Pa, IP: psi}] \quad (7.579)$$

$$\Delta P_i = P_a - P_{gap(n-1)} (\text{last pane}) \quad [\text{Force per unit Area; SI: Pa, IP: psi}] \quad (7.580)$$

where

P_a = atmospheric pressure. [Force per unit Area; SI: Pa, IP: psi]

$$P_{gap(i)} = \frac{P_{ini} V_{ini(i)} T_{gap(i)}}{T_{ini} V_{gap(i)}} \quad (7.581)$$

where

P_{ini} = Initial pressure. Applies to all gaps as a single value (input data - measured or otherwise) [Force per unit Area; SI: Pa, IP: psi]

T_{ini} = Initial temperature. Applies to all gaps as a single value (input data - measured or otherwise) [Degree Temperature; SI: K, IP: R]

$V_{ini(i)}$ = Initial volume for i-th gap. [Length*Length*Length; SI: m³, IP: in³]

Figure 7.56: Deflection Coordinate System - 2D

Figure 7.57: Deflection Coordinate System - 3D

$$V_{ini(i)} = L_i \cdot W \cdot H \quad (7.582)$$

where

L_i = non-deflected glazing gap width (for i-th gap) [Length; SI: m, IP: in.]

W = IGU width [Length; SI: m, IP: in.]

H = IGU height [Length; SI: m, IP: in.]

$T_{gap(i)}$ = temperature of the gap between two glass panes (calculated using center of glazing thermal calculation algorithm, as described in ISO 15099 (ISO 2003). This value is first calculated using non-deflected state and is recalculated after the resulting deflection is calculated. This process is repeated until temperature at next iteration does not differ by more than 0.1 °C

$V_{gap(i)}$ = volume of the IGU gap in deflected state [Length*Length*Length; SI: m³, IP: in³]

$$V_{gap(i)} = V_{ini(i)} + W \cdot H \cdot (\overline{L_{D,i}} - \overline{L_{D,i+1}}) \quad (7.583)$$

where

$\overline{L_{D,i}}$ is mean deflection value for i-th pane. [Length; SI: m, IP: in.]

Deflection of each pane can be positive or negative and is done solely to establish reference. Current frame of reference is that positive deflection means that pane is deflecting towards left side, while negative deflection means that pane is deflecting towards right side (see Equation 7.583). Whether the deflection is in the direction of reducing the gap width or increasing it, it will be the result of pressure difference, as described in Equation 7.576. When pressure in the glazing unit is higher than surrounding environmental pressure, the deflection will be towards increasing gap width (i.e., ballooning), while the opposite situation will result in decreasing gap width (i.e., vacuuming)

The important part of calculating deflection of the IGU is to determine mean deflection value for each glazing pane. Mean deflection value is used to calculate gap volume in deflected state (see Equation 7.583). Mean deflection of glazing pane can be calculated by integrating Equation 7.576:

$$\overline{L_{D(i)}} = \frac{W}{\int_{x=0}^W} \frac{H}{\int_{y=0}^H} \frac{16 \cdot \Delta P_{(i)}}{\pi^6 \cdot D_{(i)}} \sum_{m=1,3,5,\dots}^{\infty} \sum_{n=1,3,5,\dots}^{\infty} \frac{\sin \frac{m\pi x}{W} \sin \frac{n\pi y}{H}}{mn \left(\left(\frac{m}{W} \right)^2 + \left(\frac{n}{H} \right)^2 \right)^2} \quad (7.584)$$

This is identical to the following expression:

$$\overline{L_{D(i)}} = \frac{16 \cdot \Delta P_{(i)}}{\pi^6 \cdot D_{(i)}} \sum_{m=1,3,5,\dots}^{\infty} \sum_{n=1,3,5,\dots}^{\infty} \frac{\int_{x=0}^W \int_{y=0}^H \sin \frac{m\pi x}{W} \sin \frac{n\pi y}{H}}{mn \left(\left(\frac{m}{W} \right)^2 + \left(\frac{n}{H} \right)^2 \right)^2} \quad (7.585)$$

and because the integral of sin(x) is equal to -cos(x), the above equation will become:

$$\overline{L_{D(i)}} = \frac{16 \cdot \Delta P_{(i)}}{\pi^6 \cdot D_{(i)}} \sum_{m=1,3,5,\dots}^{\infty} \sum_{n=1,3,5,\dots}^{\infty} \frac{(1 - \cos(m\pi))(1 - \cos(n\pi))}{mn \left(\left(\frac{m}{W} \right)^2 + \left(\frac{n}{H} \right)^2 \right)^2} \quad (7.586)$$

Finally, because $\cos(m\pi)$ and $\cos(n\pi)$ values are always equal to -1 for the given range of m and n, the above equation will become:

$$\overline{L_{D(i)}} = \frac{16 \cdot \Delta P_{(i)}}{\pi^6 \cdot D_{(i)}} \sum_{m=1,3,5,\dots}^{\infty} \sum_{n=1,3,5,\dots}^{\infty} \frac{4}{m^2 n^2 \pi^2 \left(\left(\frac{m}{W} \right)^2 + \left(\frac{n}{H} \right)^2 \right)^2} \quad (7.587)$$

Figure 7.58: Deflection Direction Convention

After calculating the mean pane deflection, the following equation is used to calculate mean gap width:

$$L_{r(i)} = L + (\overline{L_{D,(i)}} - \overline{L_{D,(i+1)}}) \quad (7.588)$$

where

$L_{r(i)}$ = Mean gap “i” width after incorporating glazing deflection. This mean gap width is used to recalculate thermal performance of deflected IGU.

$\overline{L_{D,i}}$ = mean glazing deflection for each pane “i”.

Calculation of the deflection at the center of glazing and mean glazing deflection for each pane is an iterative process, where the initial temperature distribution is calculated for non-deflected state, then deflection is calculated based on this temperature distribution, new temperature distribution is calculated for this deflected state, then temperatures from previous iteration are compared to the current iteration and the process is repeated until the difference is no larger than 0.1°C.

At the end of calculations, program will calculate and return maximum deflection value for each pane (i.e., center of glazing deflection). If we label maximum deflection of each pane as $L_{D(i),max}$, we can calculate this value by substituting $x = W/2$ and $y = H/2$ in Equation 7.576 to determine deflection at the center point. Therefore:

$$L_{D(i),max} = \frac{16 \cdot \Delta P_{(i)}}{\pi^6 \cdot D_{(i)}} \sum_{m=1,3,5,\dots}^{\infty} \sum_{n=1,3,5,\dots}^{\infty} \frac{\sin \frac{m\pi}{2} \sin \frac{n\pi}{2}}{mn \left(\left(\frac{m}{2} \right)^2 + \left(\frac{n}{2} \right)^2 \right)^2} \quad (7.589)$$

For glazing systems with more than two glazing layers, meaning multiple gas filled gaps, the deflection will be calculated for each glazing pane assuming that the pressure in a gap is independent from each other and calculated separately, unless spaces are “linked” together (e.g., stretched film middle glazing that has hole for equalizing pressure).

7.8.15.4 Non-Linked Gaps in 3 or more glazing layer system:

The procedure shown above generally applies to the 3 or more layer glazing system, with the exception that neighboring pressures are no longer P_a , but rather could be P_a on one side and P_{gap} on the other, or have P_{gap} on both sides, as shown in Figure 7.58 for gap “i”. Center of glazing thermal calculation will determine new temperature distribution, after deflection is calculated for each glazing and will be used to determine new P_{gap} , as per the procedure above.

7.8.15.5 Linked Gaps in 3 or more glazing layer system:

When one or more gaps are linked together, their pressure is assumed to be identical (e.g., in triple glazing IGU $P_{gap,1} = P_{gap,2}$). This pressure is calculated from temperatures of bounding glazing for linked gaps (e.g., for triple glazing IGU, glazing 1 and 3) and using neighboring pressures outside of those bounding glazing (e.g., for triple glazed IGU, P_a on both sides).

Note: This feature is not implemented in WINDOW 7.1. It is considered for future enhancements to the program.

7.8.15.6 Gap(s) Linked to Indoor or Outdoor Environment:

If one or more glazing gaps are linked to either indoor or outdoor environment its pressure is fixed to P_a . In combination situations, such as two or more gaps linked together with one of them being linked to indoor or outdoor environment, they will all have fixed pressure of P_a .

7.8.15.7 Calculation of the thermal performance caused by measured deflection

When deflection is measured, it is normally measured at the point of maximum deflection. Maximum deflection occurs at the center of the IGU (at $W/2$ and $H/2$).

Measured value is typically gap width at the point of maximum deflection, which we can label $L_{G(i)}$. For the i -th measured gap, the width is equal to:

$$L_{G(i)} = L_{(i)} + (L_{D(i),max} - L_{D(i+1),max}) \quad (7.590)$$

If we label the ratio of mean deflection and maximum deflection as $R_{(i)}$, then:

$$R_{(i)} = \frac{\overline{L_{D(i)}}}{L_{D(i),max}} = \sum_{m=1,3,5,\dots}^{\infty} \sum_{n=1,3,5,\dots}^{\infty} \frac{4}{m^2 n^2 \pi^2 \left(\left(\frac{m}{W} \right)^2 + \left(\frac{n}{H} \right)^2 \right)} \quad (7.591)$$

An important thing to note is that the ratios ($R_{(i)}$) for all gaps in glazing system are equal.

$$R_{(1)} = R_{(2)} = \dots = R_{(i)} = \dots = R_{(n-1)} = R \quad (7.592)$$

Substituting Equations 7.591 and 7.592 into Equation 7.588, the following equation is obtained:

$$L_{r(i)} = L_{(i)} + R (L_{D(i),max} - L_{D(i+1),max}) \quad (7.593)$$

Combining Equation 7.593 with Equation 7.590, we get the following expression for the mean gap width:

$$L_{r(i)} = L_{(i)} + R (L_{G(i)} - L_{(i)}) \quad (7.594)$$

The number of equations given in Equation 7.590 is equal to $n-1$, where n is number of panes. Therefore, we need one more equation to complete the system of equations that would allow us to solve for all independent variables. To get the last equation, we can rewrite Equation 7.589 in slightly different manner:

$$L_{D(i),max} = \frac{\Delta P_{(i)}}{D_{(i)}} \cdot K \quad (7.595)$$

where coefficient K combines all constant terms, while $D_{(i)}$ is given by Equation 7.577 and $\Delta P_{(i)}$ is calculated by Equations 7.578, 7.579 and 7.580. Summing over all deflections, $L_{D(i),max}$, the following equation is obtained:

$$\sum_{i=1}^n \frac{D_{(i)}}{K} \cdot L_{D(i),max} = \sum_{i=1}^n \Delta P_{(i)} = 0 \quad (7.596)$$

Note that sum of all $\Delta P_{(i)}$ is equal to zero since the outside pressure is equal to the inside pressure. Therefore, the remaining equation that completes the set of equations is:

Figure 7.59: Sketch of the non-symmetrically Deflected Glazing Panes

$$\sum_{i=1}^n D_{(i)} \cdot L_{D(i),max} = 0 \quad (7.597)$$

7.8.15.8 Solving system of equations

In order to solve this system of equations, we will present Equation 7.590 in a slightly different manner:

$$0 = L_{(i)} - L_{G(i)} + L_{D(i),max} - L_{D(i+1),max} \quad (7.598)$$

which in developed form will look like this:

$$0 = L_{(1)} - L_{G(1)} + L_{D(1),max} - L_{D(2),max} \quad (7.599)$$

$$0 = L_{(2)} - L_{G(2)} + L_{D(2),max} - L_{D(3),max} \quad (7.600)$$

$$0 = L_{(i)} - L_{G(i)} + L_{D(i),max} - L_{D(i+1),max} \quad (7.601)$$

$$0 = L_{(n-1)} - L_{G(n-1)} + L_{D(n-1),max} - L_{D(n),max} \quad (7.602)$$

In order to express each $L_{D(i),max}$ and its dependence on $L_{D(n),max}$ (deflection of inside/last pane), we will need to make the sum from first to last, then from second to last, third to last and so on. This procedure will create the following set of equations:

$$L_{D(1),max} = \sum_{k=1}^{k=n-1} (L_{G(k)} - L_{(k)}) + L_{D(n),max} \quad (7.603)$$

$$L_{D(2),max} = \sum_{k=2}^{k=n-1} (L_{G(k)} - L_{(k)}) + L_{D(n),max} \quad (7.604)$$

$$L_{D(i),max} = \sum_{k=i}^{k=n-1} (L_{G(k)} - L_{(k)}) + L_{D(n),max} \quad (7.605)$$

$$L_{D(n-1),max} = \sum_{k=n-1}^{k=n-1} (L_{G(k)} - L_{(k)}) + L_{D(n),max} \quad (7.606)$$

Now substituting this set of equations back into Equation 7.597:

$$\sum_{i=1}^{n-1} D_{(i)} \cdot \left(\sum_{k=i}^{k=n-1} (L_{G(k)} - L_{(k)}) + L_{D(n),max} \right) + D_{(n)} \cdot L_{D(n),max} = 0 \quad (7.607)$$

Solving for $L_{D(n),max}$ leads to the following equation:

$$L_{D(n),max} = \frac{\sum_{i=1}^{n-1} (D_{(i)} \cdot \sum_{k=i}^{k=n-1} (L_{(k)} - L_{G(k)}))}{\sum_{i=1}^n D_{(i)}} \quad (7.608)$$

Calculating $L_{D(n),max}$ from this equation and substituting it into Equations 7.603 - 7.606 will enable calculation of the deflection of the remaining panes.

7.8.16 Equivalent Layer Fenestration Model

The section describes the equivalent layer fenestration optical and thermal model. The Equivalent Layer fenestration model can have four types of attachments: drapes, venetian blinds, roller blinds and insect screens. In this model shading layers are assumed to be uniform and can be represented by an equivalent homogenous layer that has spatially-averaged “effective” optical and thermal properties (ASHRAE 1311-RP). Likewise, venetian blinds can be characterized using effective optical and thermal properties. When solar radiation strikes a window surface some fraction of the incident solar radiation passes unobstructed through openings in a shading layer and the remaining fraction is intercepted by the structure of the layer. The intercepted radiation is partly absorbed, partly reflected and partly transmitted. These reflected and transmitted components of the scattered solar radiation are assumed to be uniformly diffuse. Shading layers, because of their openness, generally transmit longwave radiation, and the effective infrared properties of shades account for that. Using effective optical properties and a beam/diffuse split of solar radiation at each layer, the equivalent layer approach can represent multi-layer systems. This representation provides virtually unlimited flexibility to combine different types of shading layers in a fenestration. The equivalent layer window model requires a few set of optical data to characterize a particular layer and this set of data is used to calculate effective layer properties. For instance, the effective solar optical properties of a venetian blind can be calculated as a function of slats optical properties and geometry. Also, it is possible to adjust slat angle at each time step in response to the changing angular position of the sun. Moreover, the model provides control strategies as a function of slat angle that can be changed at each time step as needed. Likewise, effective properties of a pleated drape are calculated as a function of fabric properties and a specified value of fullness. The only input data needed to fully characterize drapery fabrics, roller blinds and insect screens are material openness as area fraction, and the transmittance and reflectance at normal incidence. Shade openness area fraction is the same as the beam-beam transmittance at normal incidence. In multilayer fenestration, each layer is separated by a gap. A gap in equivalent layer model is defined by specifying the fill gas and the gap spacing. Currently five gas types are allowed: Air, Argon, Xenon, Krypton and Custom. The convective heat transfer coefficient in a gap is calculated depending on the spacing, the temperatures of the layers and the fill gas properties. Equivalent-layer concept – offers wide range of multiple glazing and shading layers combination and can simulate multi-layer complex fenestration systems. The effective layer properties of venetian blinds, pleated drapes, roller blinds, and insect screens are calculated from geometric layer models and material properties. A set of empirical correlations for estimating off-normal material properties were developed under ASHRAE research project (ASHRAE 1311-RP). The equivalent layer window model supports many layers of glazing and shade combination in any order but does not support WindowShadingControl. However, the venetian blind model of equivalent layer window model provides three types of blind slat angle control.

7.8.16.1 The Equivalent Layer Analysis

The equivalent layer windows system is treated as a series of parallel layers separated by gaps as shown in Figure 7.60. This multi-layer structure has been used in several computer programs and the underlying theory has been documented (ASHRAE 1311-RP).

Equivalent layer fenestration model uses two-step analysis. First, the flux of absorbed solar radiation at each layer, S_i , caused by the incident radiation flux, I_{sol} , is determined using net radiation analysis. Second, an energy balance is applied at each layer, accounting for heat transfer

Figure 7.60: Multi-layer fenestration analysis structure (ASHRAE 1311-RP)

and the known set of absorbed solar radiations S_i values, in order to solve for the set of layer temperatures, T_i , and the corresponding heat fluxes. The fenestration model also accounts for the diathermanous shade layers in the longwave radiant exchange. The latter can be significant for shading layers. Glass is considered opaque with respect to longwave radiation.

7.8.16.2 Equivalent Layer Optical Model

The multilayer optical model is based on an algorithm originally developed by Edwards (1977) and extended by Wright and Kotey (2006). The algorithm models the interaction of incident solar radiation with a glazing system composed of any number of parallel, planar, specular glazing layers. The shading layers scatter portion of the incident solar radiation diffusely, and the model tracks the beam and diffuse components of solar radiation as they interact with a multi-layer system of glazing and shading layers. The conceptual arrangement for tracking beam and diffuse solar flux components is illustrated in Figure 7.61.

Analysis yields beam-beam, beam-diffuse and diffuse-diffuse fluxes, providing full detail concerning the quantities of reflected, transmitted and absorbed radiation.

The beam and diffuse characterization of solar radiation demands an expanded set of solar optical properties (Wright and Kotey 2006). The quantities of interest for single layer are shown in Figure 7.62.

where

τ	=	transmittance of a glazing or a shading layer, (-)
ρ	=	reflectance of a glazing or a shading layer, (-)
ϵ	=	thermal emissivity of a glazing or a shading layer, (-)
θ	=	incident angle, (degree)
ϕ	=	slat angle, (degree)
Ω	=	profile angle, (degree)
J	=	radiosity of a layer surface, (W/m ²)

Figure 7.61: Solar analysis of the multi-layer glazing/shading system showing beam and diffuse fluxes (ASHRAE 1311-RP)

T = temperature of a layer, (C)

Subscripts

f = front side of a layer

b = back side of a layer

bb = beam-beam optical property. Represents a fraction of the beam radiation incident at a given layer and leaves the layer without being scattered.

bd = beam-diffuse optical property. Represents a fraction of the beam radiation incident at a given layer and leaves the layer diffusely

dd = diffuse-diffuse optical property. Represents a diffuse radiation incident at a given layer and leaves the layer as diffuse

i = layer index, (-)

Superscripts

m = represents material property (e.g., fabric material)

str = represents an apparent material structure property of roller blinds

w = represents an apparent wire property

Each glazing or shading layer, in general, require eleven set of solar properties (Wright and Kotey 2006). Only beam-beam properties are needed for common glazing layers. Each shading layer is represented by a few set of component properties and geometries that are converted to the full set of layer optical and thermal properties by equivalent layer models (ASHRAE 1311-RP). The models also make account for off-normal incidence of solar radiation and can calculate the diffuse component from normal incidence values using numerical integration.

Figure 7.62: Twelve solar properties assigned at each layer (ASHRAE 1311-RP)

7.8.16.3 Equivalent Layer Thermal Model

A surface energy balance is applied at each layer and the resulting set of equation is solved for layer temperatures and heat transfer fluxes. A schematic drawing of the multi-layer illustration and variables designation is shown in Figure 7.63. The net radiation formulation based on the radiosities, $J_{f,i}$ and $J_{b,i}$ the radiant flux leaving the front and back surfaces of the i^{th} layer, respectively, is the used as a solution technique. The net radiant heat flux across a gap can be expressed as the difference between the radiosities of the bounding surfaces. The net radiation model analysis yields the layer temperatures and corresponding heat transfer coefficients that are used to determine U-factor and SHGC. The thermal analysis is done in “ASHWAT_Thermal” routine.

Figure 7.63: Radiosity model used in thermal analysis of the multi-layer glazing/shading system (ASHRAE 1311-RP)

7.8.16.4 Glazing Layer Analysis

The Equivalent-Layer window model allows a wide range of options regarding the selection of glazing layers and gaps combinations. It also allows mixing glazing and shading layers in any sequence. For instance, it allows placing a venetian blind or a roller blind in between glazing layers. Only beam-beam solar properties at normal incidence, infrared transmittance and infrared emissivity are required for common glazing types. Off-normal solar properties at a given sun position are estimated by adjusting the normal incidence values in “ASHWAT_OffNormalProperties” routine. The model assumes that the ratio between normal and off-normal transmittance is the same for the glazing layer in question and a reference piece of uncoated 6 mm glass with a moderate tint (ASHRAE 1311-RP). A similar procedure is used to convert solar reflectance from normal to off-normal.

7.8.16.5 Gap Layer Analysis

Gaps can be specified as sealed, vented indoors or vented outdoors. The sealed gap is considered as enclosed cavity. Vented gaps is specified for inner and outer most gaps only and when the gas type is AIR. The vented gap model assumes that air flow at the perimeter of the window is not restricted. Any fill gas can be specified by molecular mass and thermo-physical properties of viscosity, specific heat and thermal conductivity. This is done by providing “a”, “b” and “c” coefficients of the

quadratic equation of the form, $p = a + bT + cT^2$, where the $T(K)$ is temperature and p is the property being evaluated. EnergyPlus has builtin-data available for common fill gas components including Air, Argon, Krypton and Xenon. Users specify CUSTOM gas by defining the coefficients as an input.

7.8.16.6 Shade Layer Analysis

Equivalent layer fenestration model has a complete set of solar and longwave models for the four shading layer types: drapes, venetian blinds, roller blinds and insect screens developed under ASHRAE 1311-RP. And semi-empirical models are used to evaluate the off-normal properties of drape, roller blind and insect screen materials. The effective layer properties of venetian blinds and the effect of pleating in drapes are determined using a more fundamental net radiation scheme. The openness fraction, A_o and beam-beam solar transmittance at normal incidence, $\tau_{bb}(\theta = 0)$, really represent a geometric quantity and it has been confirmed that they can be used interchangeably (ASHRAE 1311-RP). Openness is simply the fraction of a material, by area, that is open. In equivalent layer fenestration model, beam-beam transmittance at normal incidence (i.e., openness fraction), beam-diffuse transmittance and reflectance at normal incidence are required to characterize drapery fabric, roller blind and insect screen material. A conventional venetian blind in equivalent layer model can be characterized by specifying the geometry, solar reflectance and transmittance, and emissivity of the slats. The off-normal solar properties of drape, roller blind and insect screen materials were formulated based on measurements (ASHRAE 1311-RP). The long-wave properties of the of the drape fabrics, roller blinds and insect screens can be calculated from the material emissivity and openness of the fabric (ASHRE 1311-RP). The optical model development for venetian blinds is presented by Yahoda and Wright (2004 and 2005), and Kotey et al. (2008).

7.8.16.7 Drapes and Curtains

The off-normal optical properties of drapery fabric is determined from user specified optical properties at normal incidence ($\theta = 0$) using empirical correlations (Kotey et al., 2009a). The input data required to characterize drapery fabric are the beam-beam transmittance of the material at normal incidence $\tau_{bb}(\theta = 0) = A_o$, the beam-diffuse transmittance of the material at normal incidence $\tau_{bd}(\theta = 0)$, and the beam-diffuse (total) reflectance of the material $\rho_{bt}(\theta = 0)$. The off-normal properties are calculated as follows.

Off-normal Transmittance:

$$\tau_{bb}^m(\theta) = \tau_{bb}^m(\theta = 0) \cdot \cos^b(\theta) \quad (7.609)$$

$$\tau_{bt}^m(\theta) = \tau_{bt}^m(\theta = 0) \cdot \cos^b(\theta) \quad (7.610)$$

$$b = [-0.5 \cdot \ln(\tau_{bb}^m(\theta = 0), 0.01)^{\max}, 0.35]^{\max} \quad (7.611)$$

$$b = [-0.5 \cdot \ln(\tau_{bt}^m(\theta = 0), 0.01)^{\max}, 0.35]^{\max} \quad (7.612)$$

$$\tau_{bt}^m(\theta) = \tau_{bd}^m(\theta) + \tau_{bb}^m(\theta) \quad (7.613)$$

The off-normal reflectance:

$$\rho_{bt}^m(\theta) = \rho_{bd}^m(\theta) = \rho_{bt}^m(\theta = 0) + (\rho_{bt}^m(\theta = 90^\circ) - \rho_{bt}^m(\theta = 0)) \cdot (1 - \cos^{0.6}(\theta)) \quad (7.614)$$

$$\rho_{bt}^m(\theta = 90^\circ) = \rho_{bt}^m(\theta = 0) + (1 - \rho_{bt}^m(\theta = 0)) \cdot (0.7(\rho^y)^{0.7}) \quad (7.615)$$

The apparent yarn reflectance is given by:

$$\rho^y = \frac{\rho_{bt}^m(\theta = 0)}{1 - \tau_{bb}^m(\theta = 0)} = \frac{\rho_{bt}^m(\theta = 0)}{1 - A_o} \quad (7.616)$$

The above set of equations for drapery fabrics are used subject to the condition that the solar absorptance of the fabric, at normal incidence, is not less than 1% (ASHRE 1311-RP). The diffuse-diffuse material properties, for Equivalent layer window model, are determined using Rhomberg integration with 32 panels covering the range from $\theta = 0$ to $\theta = 90^\circ$ (ASHRAE 1311-RP). The subscript “X” stands for either front or back side of the layer.

$$\tau_{x,dd}^m = 2 \int_{\theta=0}^{\pi/2} \tau_{x,bt}^m(\theta) \cos \theta \sin \theta d\theta \quad (7.617)$$

$$\rho_{x,dd}^m = 2 \int_{\theta=0}^{\pi/2} \rho_{x,bt}^m(\theta) \cos \theta \sin \theta d\theta \quad (7.618)$$

The above set of equations for drapery fabrics apply to the full range of A_o , fabric transmittance and fabric reflectance including that falls within the bounds of Keyes’ (1967) fabric chart plus sheer fabrics (ASHRAE 1311-RP). The longwave thermal emissivity and thermal transmittances of drapery fabric are calculated using the following correlations and fabric openness fraction (Kotey et al. 2008).

$$\varepsilon^m = 0.87 \cdot (1 - A_o) \quad (7.619)$$

$$\tau^m = 1 - 0.95 \cdot (1 - A_o) \quad (7.620)$$

The optical and thermal properties determined using the above same sets of equations are equally valid for pleated drape shades (Kotey, et. al., 2009a). For pleated drape, the effective beam-beam and beam-diffuse solar properties are determined by tracking both radiation components, for a given incident angle, and interaction with a fabric pleated rectangular geometry shown in Figure 7.64. The solar optical properties of the two different pleat planes are evaluated on the basis of the local solar incidence angle. Therefore, the effective layer properties are influenced not just by horizontal solar profile angle, Ω_H , but also by incidence angle (ASHRAE 1311-RP).

The solar diffuse-diffuse and long-wave effective properties of the pleated drape are evaluated using a much simpler net-radiation analysis using conventional shape factors (Kotey, et. al., 2009a). Users can chose and apply the pleated drape model to any fabric and any degree of fullness (ASHRAE 1311-RP).

Figure 7.64: Geometry used for Pleated Drape Analysis

7.8.16.8 Venetian Blinds

The effective shortwave optical and longwave optical properties of venetian blind layer is estimated using analytical models (Yahoda and Wright 2004, 2005; Kotey et al. 2008). The model requires properties of venetian blind slats and geometry of the slats shown in Figure 7.65.

Figure 7.65: Geometry and properties used for venetian blind analysis. The effective longwave properties are obtained for the layer knowing longwave properties of the slats.

The model assumes that venetian blind slats reflect and transmit solar radiation diffusely (ASHRAE 1311-RP). The same assumption is made regarding thermal radiation. The input data required to characterize a venetian blind are: front and back side reflectance and transmittance of the slat, geometry and infrared emissivity and transmittance of the slate. The effective optical properties of the venetian blind are determined by tracking beam and diffuse solar radiation through various interactions with slats positioned at a given slat angle. The model uses simple four-surface model if the slats are fully sunlit and a six-surface model if the slats are partially sunlit (ASHRAE 1311-RP). Slats are assumed to be thin and flat but a correction is applied to account for slat

curvature effect (Kotey et al. 2008).

7.8.16.9 Roller Blinds

The off-normal properties of roller-blind are determined from solar properties of roller blind fabric measured at normal incidence ($\theta = 0$) using correlations (Kotey, et. al., 2009b). The off-normal properties for roller blind shades are calculated using the set equations given below:

$$\tau_{bb}(\theta) = \begin{cases} \tau_{bb}(\theta = 0) \cdot \cos^b\left(\frac{\theta}{\theta_{\text{cutoff}}} \cdot \frac{\pi}{2}\right) & \theta < \theta_{\text{CutOff}} \\ 0 & \theta \geq \theta_{\text{CutOff}} \end{cases} \quad (7.621)$$

$$b = 0.6 \cdot \cos^{0.3}\left(A_o \cdot \frac{\pi}{2}\right) \quad (7.622)$$

$$\theta_{\text{cutoff}} = 65^\circ + (90^\circ - 65^\circ) \cdot \left(1 - \cos\left(A_o \cdot \frac{\pi}{2}\right)\right) \quad (7.623)$$

$$\tau_{bt}(\theta) = \tau_{bt}(\theta = 0) \cdot \cos^b(\theta) \quad (7.624)$$

$$b = \begin{cases} 0.133 \cdot (\tau^{\text{str}} + 0.003)^{-0.467} & \text{if } (0 \leq \tau^{\text{str}} \leq 0.33) \\ 0.33 \cdot (1 - \tau^{\text{str}}) & \text{if } (0.33 < \tau^{\text{str}} \leq 1) \end{cases} \quad (7.625)$$

$$\tau^{\text{str}} = \frac{\tau_{bt}(\theta = 0) - \tau_{bb}(\theta = 0)}{1 - \tau_{bb}(\theta = 0)} \quad (7.626)$$

$$\tau_{bt}(\theta) = \tau_{bd}(\theta) + \tau_{bb}(\theta) \quad (7.627)$$

The off-normal solar property calculation of roller blind is based on a set of correlations developed from measurement data using samples of commonly used commercially produced roller blind material openness range of 0.0 – 0.14. Thus, these correlations are not applicable for shades with materials openness fraction exceeding 0.20. The mean solar reflectance of a roller blind material was found to be purely diffuse and unaffected by incidence angle and is given by:

$$\rho_{bt}(\theta = 0) = \rho_{bd}(\theta = 0) = \rho_{bt}(\theta) = \rho_{bd}(\theta) \quad (7.628)$$

The diffuse-diffuse transmittance and reflectance are obtained by Rhomberg numerical integration. The longwave properties of roller blind material determined using the material property and the openness fraction (Kotey et al. 2008) as shown below:

$$\varepsilon^{\text{rb}} = 0.91 \cdot (1 - A_o) \quad (7.629)$$

$$\tau^{\text{rb}} = 1 - 0.95 \cdot (1 - A_o) \quad (7.630)$$

Figure 7.66: Geometry used for insect screen analysis

7.8.16.10 Insect Screens

The empirical correlations formulated to obtain the effective off-normal solar and longwave properties of insect screens were based on measurements (Kotey et al. (2009a)). Insect screen geometry is shown in Figure 7.66. The calculation of effective solar properties requires a set of properties measured at normal incidence: $\tau_{bb}(\theta = 0)$, $\tau_{bd}(\theta = 0)$ and $\rho_{bt}(\theta = 0)$.

Openness can be determined by optical measurement at normal incidence, $A_o = \tau_{bb}(\theta = 0)$, but in the case of insect screens A_o can reliably be calculated knowing wire diameter (d), and wire spacing (s) as follows:

$$A_o = (1 - d/s)^2 \quad (7.631)$$

The incidence angle beyond which direct beam transmission is cut off, θ_{CutOff} , can also be estimated purely from geometry and is given by:

$$\theta_{CutOff} = \cos^{-1}(d/S) \quad (7.632)$$

The off-normal properties are calculated as follows.

$$\tau_{bb}(\theta) = \begin{cases} \tau_{bb}(\theta = 0) \cdot \cos^b\left(\frac{\theta}{\theta_{cutoff}} \cdot \frac{\pi}{2}\right) & \theta < \theta_{cutoff} \\ 0 & \theta \geq \theta_{cutoff} \end{cases} \quad (7.633)$$

$$b = -0.45 \ln(\text{MAX}(\tau_{bb}(\theta = 0), 0.01)) + 0.1 \quad (7.634)$$

$$\tau_{bt}(\theta) = \tau_{bt}(\theta = 0) \cdot \cos^b(\theta) \quad (7.635)$$

$$b = -0.65 \ln(\text{MAX}(\tau_{bt}(\theta = 0), 0.01)) + 0.1 \quad (7.636)$$

$$\tau_{bd}(\theta) = \tau_{bt}(\theta) - \tau_{bb}(\theta) \quad (7.637)$$

$$\rho_{bt}(\theta) = \rho_{bt}(\theta = 0) + (\rho_{bt}(\theta = 90^\circ) - \rho_{bt}(\theta = 0)) \cdot (1 - \cos^b(\theta)) \quad (7.638)$$

$$b = -0.45 \ln(\rho^w) \quad (7.639)$$

$$\rho^w = \frac{\rho_{bt}(\theta = 0)}{1 - \tau_{bb}(\theta = 0)} \quad (7.640)$$

$$\rho_{bt}(\theta = 90^\circ) = \rho_{bt}(\theta = 0) + (1 - \rho_{bt}(\theta = 0)) \cdot (0.35\rho^w) \quad (7.641)$$

The diffuse-diffuse material properties are obtained by Rhomberg numerical integration. The longwave properties of insect screen are given by expressions similar those formulated for drapery fabrics, and roller blinds (Kotey et al. 2008) is given by:

$$\varepsilon^{screen} = \varepsilon^w \cdot (1 - A_o) \quad (7.642)$$

$$\tau^{screen} = 1 - \tau^w \cdot (1 - A_o) \quad (7.643)$$

The apparent wire material emissivity can be taken as $\varepsilon^w = 0.93$ for common insect screens - screens with dark, rough, non-metallic wire surfaces. The corresponding infrared wire material transmittance is $\tau^w = 0.98$. A lower infrared emissivity can be used for screens constructed with shiny metallic wire. For example, to model stainless-steel wire mesh use $\varepsilon^w = 0.32$ and $\tau^w = 0.81$.

7.8.16.11 Integration with Heat Balance Method

The solar model calculations are performed surface by surface following the existing structure of EnergyPlus's heat balance algorithm. The optical and thermal calculations are performed for each surface at each time step. The thermal model needs to be updated at each time step during the surface heat balance iteration. Thus, window thermal model is invoked during the surface heat balance but only once. This is consistent with the current EnergyPlus's window model inside surface heat balance iteration scheme. The equivalent layer window thermal model also has internal iteration scheme. The thermal model routine also requires the solar and shortwave radiation flux absorbed by each layer of a fenestration at each time step. The calculation of the absorbed radiation flux is performed using the existing scheme except that the optical properties are calculated by the equivalent layer optical model. The equivalent layer thermal model returns the temperatures and the fluxes at each layer.

7.8.16.12 Equivalent Layer Window Solar Model

The equivalent layer window solar model calculates the transmittance of the window and absorptance of each layer. Separate optical properties calculations are performed for exterior beam and diffuse radiations, and interior diffuse radiation (e.g., lighting and inter-reflected solar gain). The fractions for beam radiations depend on solar incident angle and hence updated for each time step. Diffuse radiation fractions are the same for all time steps unless the shade characteristics are altered; for instance, when the venetian blind slat angle is controlled. Otherwise, the diffuse fractions are constant for a given configuration and time step. The hub of the optical properties calculation routine for Equivalent Layer window model is the routine "ASHWAT_Solar". For beam radiation,

at each time step, first the normal incidence optical properties are modified for current incident angle. Using the off-normal properties, then the ASHWAT_Solar routine sets up the coefficient matrix based on the net radiation concept to determine the effective absorptance of each layer and the window transmittance. The total intensity of shortwave radiation absorbed at each layer is determined by multiplying the incident solar radiation, reflected internal solar radiations, and internal shortwave source components by the appropriate absorbed fractions and summing them.

7.8.16.13 Equivalent Layer Window Thermal Model

The equivalent layer thermal model is calculated only once for each time step. But the thermal model has internal iterative solutions scheme. During each time step, the procedure initially assumes that room air and means radiant temperatures are known. The surface heat balance loops through all zone surfaces while invoking the Equivalent Layer thermal model only once for each window surface at the first iteration. The window surfaces temperatures from the first iteration are used to complete the heat balances for the indoor (and implicitly the outdoor) face of each surface iteratively. Once indoor surface temperatures are calculated using the surface heat balance, the zone air temperature can be updated and the loads are predicted. Shaded fenestration in general do not have single inside temperature by virtue their long-wave radiation transmittance. The equivalent layer window model accounts for this using effective emissivity of the composite layers derived for each fenestration (ASHRAE 1311-RP) as shown below:

$$\varepsilon^{eff} = \sum_{j=0}^{nl} \left[\varepsilon_j \cdot \prod_{k=j+1}^{nl+1} \tau_k \right] \quad (7.644)$$

where

ε^{eff} = composite indoor (room-side) longwave emissivity, (-)

ε_j = effective emissivity of layer j, (-)

τ_k = effective infrared transmittance of layer k ($\{\tau_1 = 1\}$)

nl = number of layers in fenestration system (glazing and shade). Layers are numbered outside to inside (layer 1 is outermost, layer nl is innermost).

Each equivalent layer window surface yields net longwave radiant flux exchanged with the zone surfaces. Net longwave radiation exchange from the window to the zone is recast for a composite surface temperature calculation as follows:

$$T^{eff} = \sqrt[4]{\frac{Q_{lw}}{\sigma \varepsilon^{eff}}} + T_0 \quad (7.645)$$

where

T^{eff} = inside surface temperature of the composite layer, °C (°F)

Q_{lw} = infrared radiant gain from zone, W/m² (Btu/h-ft²)

σ = Stefan-Boltzmann constant, W/m²-K⁴ (Btu/h-ft²-R⁴)

T_0 = Temperature of absolute zero, -273.15°C (-459.67°F)

Recalculating effective inside face window temperature may result in extra convection flux. The “extra” (Other) convective flux is computed; this is the gain in excess of that resulting from the standard surface heat balance model. The net other convection term Q_X calculated below is added to the zone air heat balance (ASHRAE 1311-RP).

$$QX = Q_{conv} - hc \cdot (T^{eff} - T_a) \quad (7.646)$$

Where,

h_c = inside convective coefficient of the fenestration, W/m²-K (Btu/h-ft²-F)
 Q_{conv} = total convective heat flux to zone from equivalent layer window thermal model, W/m² (Btu/h-ft²); includes open-channel gains and impact of inside surface convective coefficient
 T_a = zone air temperature, °C (°F)

Chapter 8

Air Heat Balance Manager / Processes

8.1 Convection from Surfaces

This contribution is expressed using the convective heat transfer coefficient as follows:

$$q_{conv} = \sum_{i=1}^{nsurfaces} h_{c,i} A_i (T_a - T_{s,i}) \quad (8.1)$$

The inside heat transfer coefficient is modeled from a choice of correlations.

8.2 Convection from Internal Sources

This component is the companion part of the radiant contribution from internal gains described previously. It is added directly into the air heat balance. Such a treatment also violates the tenets of the heat balance since the surface temperature of the surfaces producing the internal loads exchange heat with the zone air through normal convective processes. However, once again, the details required to include this component in the heat balance are generally not available, and its direct inclusion into the air heat balance is a reasonable approach.

8.3 Infiltration/Ventilation

8.3.1 Infiltration

Any outdoor air that enters by way of infiltration is assumed to be immediately mixed with the zone air. The determination of the amount of infiltration air is quite complicated and subject to significant uncertainty. In the most common procedure, the infiltration quantity is converted from a number of air changes per hour (ACH) and included in the zone air heat balance using the outside temperature at the current simulation time step.

EnergyPlus contains three models for infiltration. The first is the “Design Flow Rate” model that was inherited from EnergyPlus’ predecessor programs. It is accessed through the ZoneInfiltration:DesignFlowRate object and is based on environmental conditions modifying a design flow rate. The second is the “Effective Leakage Area” model based on Sherman and Grimsrud (1980) and accessed using the ZoneInfiltration:EffectiveLeakageArea input object. The third is

the “Flow Coefficient” model based on Walker and Wilson (1998) and accessed using the ZoneInfiltration:FlowCoefficient input object. The model formulations for the Effective Leakage Area and Flow Coefficient models are from the ASHRAE Handbook of Fundamentals (2001 Chapter 26; 2005 Chapter 27) where they are referred to as “Basic” and “Enhanced”, respectively.

8.3.2 Infiltration Design Flow Rate

Infiltration (Ref Object: ZoneInfiltration:DesignFlowRate) is the unintended flow of air from the outdoor environment directly into a thermal zone. Infiltration is generally caused by the opening and closing of exterior doors, cracks around windows, and even in very small amounts through building elements. In this model, the user defines a design flow rate that can be modified by temperature differences and windspeed. The basic equation (Coblentz and Achenbach 1963) used to calculate infiltration with this model is:

$$Infiltration = (I_{design}) (F_{schedule}) [A + B |(T_{zone} - T_{odb})| + C (WindSpeed) + D (WindSpeed^2)] \quad (8.2)$$

More advanced infiltration calculations are possible using the EnergyPlus AirflowNetwork model for natural infiltration driven by wind when the HVAC system does not operate and/or driven by wind and forced air for times when the HVAC system operates. Exfiltration (the leakage of zone air to the outside) is generally handled better as zone exhaust air in the zone equipment description.

The question of typical values for these coefficients is subject to debate. Ideally, one should do a detailed analysis of the infiltration situation and then determine a custom set of coefficients using methods such as those laid out in Chapter 26 of the ASHRAE Handbook of Fundamentals. The EnergyPlus defaults are 1,0,0,0 which gives a constant volume flow of infiltration under all conditions.

BLAST (one of the EnergyPlus predecessors) used the following values as defaults: 0.606, 0.03636, 0.1177, 0. These coefficients produce a value of 1.0 at 0°C deltaT and 3.35 m/s (7.5 mph) windspeed, which corresponds to a typical summer condition. At a winter condition of 40°C deltaT and 6 m/s (13.4 mph) windspeed, these coefficients would increase the infiltration rate by a factor of 2.75.

In DOE-2 (the other EnergyPlus predecessor), the air change method defaults are (adjusted to SI units) 0, 0, 0.224 (windspeed), 0. With these coefficients, the summer conditions above would give a factor of 0.75, and the winter conditions would give 1.34. A windspeed of 4.47 m/s (10 mph) gives a factor of 1.0.

The source of the BLAST defaults is noted in the BLAST documentation as:

“Empirical equation and the coefficient default were determined from ASHRAE journal articles and other data on the effects of outdoor weather conditions.”

The source of the DOE-2 defaults is based on examining the infiltration relationships described in the ASHRAE Handbook of Fundamentals.

The EnergyPlus example files use all of the above, the BLAST defaults in some (e.g., GeometryTest), the DOE-2 defaults in some (e.g., 5ZoneAirCooled), and the EnergyPlus defaults in some (e.g., LgOffVAVDetCoil).

8.3.3 Infiltration by Effective Leakage Area

The Effective Leakage Area model is based on Sherman and Grimsrud (1980) and accessed using the ZoneInfiltration:EffectiveLeakageArea input object. The model formulation used in EnergyPlus is from the ASHRAE Handbook of Fundamentals (2001 Chapter 26; 2005 Chapter 27) where it is referred to as the “Basic” model.

The Effective Leakage Area, or Sherman-Grimsrud, model is:

$$Infiltration = (F_{Schedule}) \frac{A_L}{1000} \sqrt{C_s \Delta T + C_w (WindSpeed)^2} \quad (8.3)$$

where,

$F_{schedule}$ is a value from a user-defined schedule,

A_L is the effective air leakage area in cm^2 that corresponds to a 4 Pa pressure differential,

C_s is the coefficient for stack-induced infiltration in $(\text{L/s})^2/(\text{cm}^4 \cdot \text{K})$,

ΔT is the absolute temperature difference between zone air and outdoor air,

C_w is the coefficient for wind-induced infiltration in $(\text{L/s})^2/(\text{cm}^4 \cdot (\text{m/s})^2)$, and

$WindSpeed$ is the local wind speed.

8.3.4 Infiltration by Flow Coefficient

The Flow Coefficient model is based on Walker and Wilson (1998) and accessed using the Zone-Infiltration:FlowCoefficient input object. The model formulation used in EnergyPlus is from the ASHRAE Handbook of Fundamentals (2001 Chapter 26; 2005 Chapter 27) where it is referred to as the “Enhanced” or “AIM-2” model.

The Enhanced, or AIM-2, model is:

$$Infiltration = (F_{Schedule}) \sqrt{(c C_s \Delta T^n)^2 + (c C_w (s * WindSpeed)^{2n})^2} \quad (8.4)$$

where,

$F_{schedule}$ is a value from a user-defined schedule,

c is the flow coefficient in $\text{m}^3/(\text{s} \cdot \text{Pa}^n)$,

C_s is the coefficient for stack-induced infiltration in $(\text{Pa}/\text{K})^n$,

n is the pressure exponent,

C_w is the coefficient for wind-induced infiltration in $(\text{Pa} \cdot \text{s}^2/\text{m}^2)^n$, and

s is the shelter factor.

8.3.5 Ventilation

EnergyPlus contains two models for ventilation. The “Design Flow Rate” model, inherited from EnergyPlus’ predecessor programs, is accessed through the ZoneVentilation:DesignFlowRate object and is based on environmental conditions modifying a design flow rate. The “Wind and Stack with Open Area” model, based on equations defined in Chapter 16 of the 2009 ASHRAE Handbook of Fundamentals, is accessed using the ZoneVentilation:WindandStackOpenArea input object. Since the “Wind and Stack with Open Area” object requires the height difference between the midpoint of the lower opening and the neutral pressure level, which is difficult to estimate, this object should be used with care (e.g., research only).

These two ventilation objects can be used alone or in combination to determine ventilation air for a zone. If multiple ZoneVentilation:* objects are specified for a zone, then the total zone ventilation flow rate is the sum of the ventilation air flow rates calculated by each ZoneVentilation object.

8.3.6 Ventilation Design Flow Rate

Ventilation (Ref Object: ZoneVentilation:DesignFlowRate) is the purposeful flow of air from the outdoor environment directly into a thermal zone in order to provide some amount of non-mechanical cooling. Ventilation as specified by this input syntax is intended to model “simple” ventilation as opposed to the more detailed ventilation investigations that can be performed with the AirflowNetwork model. Simple ventilation in EnergyPlus can be controlled by a schedule and through the specification of minimum, maximum and delta temperatures. The temperatures can be either single constant values for the entire simulation or schedules which can vary over time. Specific details are given in the Input/Output reference document. As with infiltration, the actual flow rate of ventilation can be modified by the temperature difference between the inside and outside environment and the wind speed. The basic equation used to calculate ventilation using this model is:

$$Ventilation = (V_{design}) (F_{schedule}) [A + B |T_{zone} - T_{odb}| + C (WindSpeed) + D (WindSpeed^2)] \quad (8.5)$$

More advanced ventilation calculations are possible using the EnergyPlus AirflowNetwork model.

The following description is copied from the Infiltration discussion above. The question of typical values for these coefficients is subject to debate. Ideally, one should do a detailed analysis of the ventilation situation and then determine a custom set of coefficients using methods such as those laid out in Chapter 26 of the ASHRAE Handbook of Fundamentals. The EnergyPlus defaults are 1,0,0,0 which gives a constant volume flow of ventilation under all conditions.

BLAST (one of the EnergyPlus predecessors) used the following values as defaults: 0.606, 0.03636, 0.1177, 0. These coefficients produce a value of 1.0 at 0°C deltaT and 3.35 m/s (7.5 mph) windspeed, which corresponds to a typical summer condition. At a winter condition of 40°C deltaT and 6 m/s (13.4 mph) windspeed, these coefficients would increase the ventilation rate by a factor of 2.75.

In DOE-2 (the other EnergyPlus predecessor), the air change method defaults are (adjusted to SI units) 0, 0, 0.224 (windspeed), 0. With these coefficients, the summer conditions above would give a factor of 0.75, and the winter conditions would give 1.34. A windspeed of 4.47 m/s (10 mph) gives a factor of 1.0.

The source of the BLAST defaults is noted in the BLAST documentation as:

“Empirical equation and the coefficient default were determined from ASHRAE journal articles and other data on the effects of outdoor weather conditions.”

The source of the DOE-2 defaults is based on examining the infiltration relationships described in the ASHRAE Handbook of Fundamentals.

The EnergyPlus example files use all of the above, the BLAST defaults in some (e.g., AirflowNetwork_Simple_house), the DOE-2 defaults in some (e.g., VentilationSimpleTest – has all 3), and the EnergyPlus defaults in some (e.g., 5ZoneNightVent2).

8.3.7 Ventilation by Wind and Stack with Open Area

For this model (Ref Object: ZoneVentilation:WindandStackOpenArea), the ventilation air flow rate is a function of wind speed and thermal stack effect, along with the area of the opening being modeled. This object can be used alone or in combination with ZoneVentilation:DesignFlowRate objects. This model is intended for simplified ventilation calculations as opposed to the more detailed ventilation investigations that can be performed with the AirflowNetwork model. Using the “Wind and Stack with Open Area” model, the natural ventilation flow rate can be controlled by a multiplier fraction schedule applied to the user-defined opening area and through the specification of minimum, maximum and delta temperatures. The temperatures can be either single constant values for the entire simulation or schedules which can vary over time. The equation used to calculate the ventilation rate driven by wind is given by Equation 37 in Chapter 16 of the 2009 ASHRAE Handbook of Fundamentals:

$$Q_w = C_w A_{opening} F_{schedule} V \quad (8.6)$$

where

Q_w = Volumetric air flow rate driven by wind [m^3/s]

C_w = Opening effectiveness [dimensionless]

$A_{opening}$ = Opening area [m^2]

$F_{schedule}$ = Open area fraction [user-defined schedule value, dimensionless]

V = Local wind speed [m/s]

If the user specifies “Autocalculate” for the Opening Effectiveness input field, the opening effectiveness is calculated for each simulation time step based on the angle between the actual wind direction and the Effective Angle (a user-defined input) using the following equation:

$$C_w = 0.55 - \frac{|EffectiveAngle - WindDirection|}{180} * 0.25 \quad (8.7)$$

The difference $|EffectiveAngle - WindDirection|$ should be between 0 and 180 degrees. If the difference $|EffectiveAngle - WindDirection|$ is greater than 180, the difference is reset to be minus 180 degrees. This equation is a linear interpolation using the values recommended by the 2009 ASHRAE Handbook of Fundamentals (page 16.13): 0.5 to 0.6 for perpendicular winds and 0.25 to 0.35 for diagonal winds.

The equation used for calculating the ventilation rate due to stack effect is given by Equation 38 in Chapter 16 of the 2009 ASHRAE Handbook of Fundamentals:

$$Q_s = C_D A_{opening} F_{schedule} \sqrt{2g\Delta H_{NPL}(|T_{zone} - T_{odb}|/T_{zone})} \quad (8.8)$$

where,

Q_s = Volumetric air flow rate due to stack effect [m^3/s]

C_D = Discharge coefficient for opening [dimensionless]

A_{opening} = Opening area [m^2]

F_{schedule} = Open area fraction [user-defined schedule value, dimensionless]

ΔH_{NPL} = Height from midpoint of lower opening to the neutral pressure level [m]. Estimation of this value is difficult; refer to Chapter 16 of the 2009 ASHRAE Handbook of Fundamentals for guidance.

T_{zone} = Zone air dry-bulb temperature [K]

T_{odb} = Local outdoor air dry-bulb temperature [K]

The following equation, given by Equation 39 in Chapter 16 of the 2009 ASHRAE Handbook of Fundamentals, is used to calculate the Discharge Coefficient for Opening when the user sets the value for this input field to “Autocalculate”:

$$C_D = 0.40 + 0.0045 |T_{\text{zone}} - T_{\text{odb}}| \quad (8.9)$$

The total ventilation rate calculated by this model is the quadrature sum of the wind and stack air flow components:

$$Ventilation_{\text{WindAndStack}} = \sqrt{Q_s^2 + Q_w^2} \quad (8.10)$$

If desired, a simple summation, instead of quadrature summation, can be realized by inputting two ZoneVentilation:WindAndStackOpenArea objects. One object can be defined with only a wind-driven component by setting $C_D = 0$, and the other object can have only stack-effect inputs specified and set $C_w = 0$.

8.3.8 Zone Air Balance Outdoor Airflow (ZoneAirBalance:OutdoorAir)

ASHRAE 2009 Handbook of Fundamentals specifies that any unbalanced supply or exhaust ventilation air, $Q_{u,v}$, to a zone causes pressurization/depressurization that influences the flow of infiltration air and thus should be combined with natural infiltration, Q_n , (and, if present, unbalanced duct leakage, $Q_{u,l}$) in superposition. Balanced ventilation airflow, $Q_{b,v}$, to a zone (such as an ERV or HRV with balanced exhaust and intake air flows) does not interact with infiltration air and is added in whole:

$$Q = \sqrt{Q_n^2 + Q_{u,v}^2 + (Q_{u,l})^2} + Q_{b,v} \quad (8.11)$$

where,

Q = Combined outdoor airflow with infiltration, balanced and unbalanced outdoor air flows, and unbalanced duct leakage [m^3/s]

Q_n = Natural infiltration airflow [m^3/s]

$Q_{b,v}$ = Balanced ventilation airflow, excluding infiltration [m^3/s]

$Q_{u,v}$ = Unbalanced ventilation airflow, excluding infiltration [m^3/s]

$Q_{u,l}$ = Unbalanced duct leakage: the difference between supply and return leaks [m^3/s]

The natural infiltration airflow includes all outdoor airflows from all ZoneInfiltration objects for the same zone.

$$Q_n = \sum_i Q_{\text{Infiltration},i} \quad (8.12)$$

where

$Q_{Infiltration,i}$ = Outdoor airflow rate given in the i th ZoneInfiltration objects for the same zone

The balanced ventilation airflow is the sum of outdoor airflows from all ZoneVentilation: DesignFlowRate objects with Ventilation Type = Balanced:

$$Q_{b,v} = \sum_i Q_{v,Balanced,i} \quad (8.13)$$

where

$Q_{v,Balanced,i}$ = Ventilation rate with “Balanced” ventilation type defined in the i th ZoneVentilation:DesignFlowRate object for the same zone

The unbalanced ventilation airflow is given by the following equation:

$$Q_{u,v} = \left[\left(\sum_i Q_{v,Natural,i} + \sum_i Q_{v,Wind,i} \right)^2 + \left(\sum_i Q_{v,Intake,i} \right)^2 + \left(\sum_i Q_{v,Exhaust,i} \right)^2 + \left(\sum_i \text{Max} (0, (Q_{ERV,Exh,i} - Q_{ERV,Sup,i})) \right)^2 \right]^{0.5} \quad (8.14)$$

where

$Q_{v,Exhaust,i}$ = Ventilation rate with “Exhaust” type in the i th ZoneVentilation:DesignFlowRate object for the same zone

$Q_{v,Intake,i}$ = Ventilation rate with “Intake” type in the i th ZoneVentilation:DesignFlowRate object for the same zone

$Q_{v,Natural,i}$ = Ventilation rate with “Natural” type in the i th ZoneVentilation:DesignFlowRate object for the same zone

$Q_{v,Wind,v}$ = Ventilation rate in the i th ZoneVentilation:WindandStackOpenArea object for the same zone

$Q_{ERV,Sup,i}$ = Supply flow rate given in the i th ZoneHVAC:EnergyRecoveryVentilator object

$Q_{ERV,Exh,i}$ = Exhaust flow rate given in the i th ZoneHVAC:EnergyRecoveryVentilator object

For Ventilation Type = Intake in the ZoneVentilation:DesignFlowRate object, an appropriate amount of fan heat will be ignored and the outdoor temperature will be used in the zone air heat balance equation.

This object provides a simple airflow interaction model without having to use the AirflowNetwork capabilities, when the Air Balance Method is specified as Quadrature.

8.4 Air Exchange

Air exchange and interchange between zones is treated as a convective gain. Temperature-difference-controlled or constant air mixing can be specified as a one-way or cross-zone phenomenon modeled using the ZoneMixing or ZoneCrossMixing objects. Air exchange through doorways between refrigerated spaces can be modeled using the ZoneRefrigerationMixing object.

For one-way mixing (using ZoneMixing object(s)), the mixing air flow is only used for the energy and mass balance for the receiving zone. The mass referred to in this section includes air, water vapor and CO₂. The source zone energy and mass balance are not affected, although the user may choose to enter complementary pairs of one-way mixing objects. Multiple mixing flows can be defined for any receiving zone. For cross-zone mixing (using ZoneCrossMixing object(s)), the mixing air flow impacts the mass and energy balances in both the source and receiving zones. A separate ZoneCrossMixing object must be used for each of the two zones exchanging air if the mixing flow is bi-directional and based on a temperature difference greater than zero.

For refrigerated space air exchange (using ZoneRefrigerationDoorMixing object(s)), the mixing air flow impacts the mass and energy balances in both the source and receiving zones. A single object accounts for the two-way air flow with the energy and mass exchanges determined by the air density difference between the two zones.

8.4.1 Temperature Difference Controlled Air Exchange

The volume of air flow into the receiving zone is specified by the user with a number of control parameters and schedules listed in the Input Output Guide. The user can turn this one-way flow on or off based on the temperature difference between the source and receiving zones, or it may be independent of the temperature difference. The density and specific heat of the air flowing into the receiving zone are determined using the average temperature and average humidity ratio in the source and receiving zones. The humidity ratio of the air flowing into the receiving zone is set equal to the humidity ratio of the source zone. The mass, moisture, and energy terms are then used as described in two previous sections, Basis for the Zone and Air System Integration, and Moisture Predictor-Corrector.

$$\rho_{Avg} = f \left(\frac{T_{ReceivingZone} + T_{SourceZone}}{2}, \frac{W_{ReceivingZone} + W_{SourceZone}}{2}, P_{Barometric} \right) \quad (8.15)$$

$$c_{P,Avg} = f \left(\frac{T_{ReceivingZone} + T_{SourceZone}}{2}, \frac{W_{ReceivingZone} + W_{SourceZone}}{2} \right) \quad (8.16)$$

$$\dot{m}_{MixingFlowToReceivingZone} = \sum_{AllSourceZones} \rho_{Avg} \dot{V}_{Air} \quad (8.17)$$

$$\dot{Q}_{MixingFlowToReceivingZone} = \sum_{AllSourceZones} \rho_{Avg} c_{p,Avg} \dot{V}_{Air} (T_{sourceZone} - T_{receivingZone}) \quad (8.18)$$

$$Moisture_{MixingFlowToReceivingZone} = \sum_{AllSourceZones} \rho_{Avg} \dot{V}_{Air} W_{SourceZone} \quad (8.19)$$

where

$c_{P,Avg}$ is the average specific heat of air within the two zones (J/kg.K)

$\dot{m}_{MixingFlowToReceivingZone}$ is the mass of moist air flowing into the receiving zone (kg_{air}/s)

$Moisture_{MixingFlowToReceivingZone}$ is the moisture mass flow rate into the receiving zone (kg_{H2O}/s)

$P_{Barometric}$ is the outside barometric pressure (Pa)

ρ_{Avg} is the average density of air within the two zones (kg/s)

$\dot{Q}_{\text{MixingFlowToReceivingZone}}$ is the energy added to receiving zone air by mixing mass flow (W)

$T_{\text{ReceivingZone}}$ is the temperature in the receiving zone ($^{\circ}\text{C}$)

$T_{\text{SourceZone}}$ is the temperature in the source zone ($^{\circ}\text{C}$)

\dot{V}_{Air} is the volume rate of air flow defined by the user (m^3/s)

$W_{\text{ReceivingZone}}$ is the humidity ratio in the receiving zone ($\text{kg}_{\text{H}_2\text{O}}/\text{kg}_{\text{dryair}}$)

$W_{\text{SourceZone}}$ is the humidity ratio in the source zone ($\text{kg}_{\text{H}_2\text{O}}/\text{kg}_{\text{dryair}}$)

For cross-mixing, the mass of moist air exchanged between the two zones is assumed to be equal. Again, the density and specific heat are based on the average conditions in the two zones. Note that the temperature and humidity ratio differences ensure that when the energy and moisture terms are used in the Moisture Predictor-Corrector, they correctly reflect a loss or gain in each zone.

$$\dot{m}_{\text{MixingFlowToReceivingZone}} = \dot{m}_{\text{MixingFlowToSourceZone}} = \rho_{\text{Avg}} \dot{V}_{\text{Air}} \quad (8.20)$$

$$\dot{Q}_{\text{MixingFlowToSourceZone}} = \rho_{\text{Avg}} C_{p,\text{Avg}} \dot{V}_{\text{Air}} (T_{\text{ReceivingZone}} - T_{\text{SourceZone}}) \quad (8.21)$$

$$\dot{Q}_{\text{MixingFlowToReceivingZone}} = \rho_{\text{Avg}} C_{p,\text{Avg}} \dot{V}_{\text{Air}} (T_{\text{SourceZone}} - T_{\text{ReceivingZone}}) \quad (8.22)$$

$$\text{Moisture}_{\text{MixingFlowToSourceZone}} = \rho_{\text{Avg}} \dot{V}_{\text{Air}} W_{\text{ReceivingZone}} \quad (8.23)$$

$$\text{Moisture}_{\text{MixingFlowToReceivingZone}} = \rho_{\text{Avg}} \dot{V}_{\text{Air}} W_{\text{SourceZone}} \quad (8.24)$$

where

$\dot{m}_{\text{MixingFlowToSourceZone}}$ is the mass of moist air flowing into the source zone ($\text{kg}_{\text{air}}/\text{s}$)

$\text{Moisture}_{\text{MixingFlowToSourceZone}}$ is the moisture mass flow rate into the source zone ($\text{kg}_{\text{H}_2\text{O}}/\text{s}$)

$\dot{Q}_{\text{MixingFlowToSourceZone}}$ is the sensible energy added to source zone air by mixing mass flow (W)

$\dot{Q}_{\text{MixingFlowToReceivingZone}}$ is the sensible energy added to receiving zone air by mixing mass flow,

W

$\text{Moisture}_{\text{MixingFlowToSourceZone}}$ is the latent load added to source zone air by mixing mass flow ($\text{kg}_{\text{H}_2\text{O}}/\text{s}$)

$\text{Moisture}_{\text{MixingFlowToReceivingZone}}$ is the latent load added to receiving zone air by mixing mass flow ($\text{kg}_{\text{H}_2\text{O}}/\text{s}$)

8.4.2 Density Difference Controlled Air Exchange

When closed refrigerated spaces exchange air with other closed spaces, the air flow is determined by the difference in air density between the two spaces. The fundamental assumption for this case is that the mass of dry air exchanged between the two spaces is the same. (Gosney and Olama, 1975] This assumption applies to situations where the colder of the two spaces is essentially sealed to other air flows, that is, there are no open doors or exhaust air flows. Multiple refrigeration door mixing objects can be used for the zone, but if there are multiple doors open at the same time for any significant amount of time, the model will not give results appropriate for that condition.

The sensible and latent energy loads are modeled according to the guidance specified in (ASHRAE 2006d, ASHRAE 2009, and Gosney and Olama, 1975). Equal dry air exchange is assumed, that is, the mass of dry air infiltrating into the receiving zone is assumed to equal the mass of dry air infiltrating out of the source zone.

$$h_{zoneA}, \rho_{zoneA} = f(T_{zoneA}, W_{zoneA}, P_{Barometric}) \quad (8.25)$$

$$h_{zoneB}, \rho_{zoneB} = f(T_{zoneB}, W_{zoneB}, P_{Barometric}) \quad (8.26)$$

$$\rho_{zoneA} > \rho_{zoneB} \quad (8.27)$$

$$\dot{Q}_{Mixing} = \dot{Q}_{FullFlow} \times \text{Schedule}_{DoorOpen} \times F_{Flow} \times (1 - F_{Protection}) \quad (8.28)$$

$$\dot{Q}_{FullFlow} = B(h_{zoneB} - h_{zoneA}) \quad (8.29)$$

$$B = 0.221 A_{door} \rho_{zoneA} F_{Density} \sqrt{\left(1 - \frac{\rho_{zoneB}}{\rho_{zoneA}}\right) g H_{Door}} \quad (8.30)$$

$$F_{Density} = \left[\frac{2}{1 + (\rho_{zoneA}/\rho_{zoneB})^{1/3}} \right]^{1.5} \quad (8.31)$$

$$\dot{m}_{DryAirZonesAB} = \frac{\dot{Q}_{Mixing}}{h_{zoneB} - h_{zoneA}} \quad (8.32)$$

$$\dot{m}_{MixingFlowZoneBtoA} = \sum_{AllZoneBs} \dot{m}_{DryAirZonesAB} (1 + W_{ZoneB}) \quad (8.33)$$

$$\dot{Q}_{MixingFlowZoneBtoA} = \sum_{AllZoneBs} \dot{m}_{ZoneBtoA} C_{p,ZoneB} (T_{zoneB} - T_{zoneA}) \quad (8.34)$$

$$\text{Moisture}_{MixingFlowZoneBtoA} = \sum_{AllZoneBs} \dot{m}_{ZoneBtoA} (W_{zoneB} - W_{zoneA}) \quad (8.35)$$

$$\dot{m}_{MixingFlowZoneAtoB} = \sum_{AllZoneAs} \dot{m}_{DryAirZonesAB} (1 + W_{ZoneA}) \quad (8.36)$$

$$\dot{Q}_{MixingFlowZoneAtoB} = \sum_{AllZoneAs} \dot{m}_{ZoneBtoA} C_{p,ZoneA} (T_{zoneA} - T_{zoneB}) \quad (8.37)$$

$$\text{Moisture}_{MixingFlowZoneAtoB} = \sum_{AllZoneAs} \dot{m}_{ZoneBtoA} (W_{zoneA} - W_{zoneB}) \quad (8.38)$$

where

A_{door} is the area of door between Zones A and B (m²)

F_{Flow} is the doorway flow factor, = 0.8 if $\Delta T > 11^\circ\text{C}$; = 1.1 if $\Delta T \leq 11^\circ\text{C}$

$F_{Protection}$ is the doorway protection factor, = 0 for no protection; = 0.5 for an air curtain; and 0.9 for a strip curtain (dimensionless)

g is the gravitational constant (m/s²)

h_{ZoneA} is the enthalpy of the air within Zone A (J/kg)

h_{ZoneB} is the enthalpy of the air within Zone B (J/kg)

H_{door} is the height of door between source and receiving zones (m)

$\dot{Q}_{FullFlow}$ is the sensible and latent refrigeration load (on Zone A) for fully established flow (W)

Q_{Mixing} is the sensible and latent mixing refrigeration load on Zone A for the time step (W)

$m_{DryAirZoneAB}$ is the mass of dry air exchanged between zones A and B (kg_{air}/s)

$Schedule_{DoorOpen}$ is the value scheduled by user, fraction of time door open during time step (dimensionless)

W_{ZoneA} is the humidity ratio of the air within Zone A ($\text{kg}_{H2O}/\text{kg}_{air}$)

W_{ZoneB} is the humidity ratio of air within Zone B ($\text{kg}_{H2O}/\text{kg}_{air}$)

P_{ZoneA} is the density of air within Zone A (kg/m^3)

ρ_{ZoneB} is the density of air within Zone B (kg/m^3)

8.5 Calculation of Zone Air Temperature

The zone air heat balance is the primary mechanism for linking the loads calculation to the system simulation. As such, the zone air temperature becomes the main interface variable. Its role in the integration process was described previously (“Basis for the Zone and Air System Integration”).

Chapter 9

Building System Simulation System Manager / Processes

EnergyPlus uses a loop based HVAC system formulation. An example of the dual duct VAV system is shown below.

9.1 Air Loops

9.1.1 Definition of Air Loop

In EnergyPlus an air loop is a central forced air HVAC system. The term “loop” is used because in most cases some air is recirculated so that the air system forms a fluid loop. The air loop is just the “air side” of a full HVAC system. The input objects related to these air loops begin “AirLoopHVAC.”

For simulation purposes the air loop is divided into 2 parts: the primary air system (representing the supply side of the loop) and the zone equipment (representing the demand side of the loop). The primary air system includes supply and return fans, central heating and cooling coils, outside air economizer, and any other central conditioning equipment and controls. The zone equipment side of the loop contains the air terminal units as well as fan coils, baseboards, window air conditioners, and so forth. Supply and return plenums are also included on the zone equipment side of the loop.

9.1.2 Simulation Method

Simulating a forced air system and its associated zones can be done in a number of ways. EnergyPlus uses algebraic energy and mass balance equations combined with steady state component models. When the zone air and the air system are modeled with algebraic equations (steady state) then – in cases with recirculated air – there will be one or more algebraic loops. In other words it is not possible to solve the equations directly; instead iterative methods are needed. Typically a humidity ratio and a mass flow rate will be variables involved in the iterative solution.

In EnergyPlus the zone humidity ratios and temperatures are decoupled from the solution of the air system equations. The zone air is assigned heat and moisture storage capacities and the capacity effects are modeled by 1st order ordinary differential equations. During each system simulation time step new zone temperatures and humidities are predicted using past values. The zone temperatures and humidities are then held constant during the simulation of the air system (and the plant). Then

the zone temperatures and humidity ratios are corrected using results from the system simulation. As a result the usual algebraic loops arising in steady state air system simulations are eliminated from the EnergyPlus system simulation. The zone temperatures, humidity ratios, and heating and cooling demands are known inputs to the system simulation.

The need for iteration can be reintroduced by the need for system control. If system setpoints are fixed, externally determined, or lagged and control is local (sensor located at a component outlet, actuator at a component inlet) then iteration can be confined to the components and the overall air system equations can be solved directly. However these requirements are too restrictive to simulate real systems. System setpoints are held fixed during a system time step. But controller sensors are allowed to be remote from the location of the actuator. Consequently EnergyPlus uses iteration over the entire primary air system in order to converge the system controllers.

9.1.3 Component Models

EnergyPlus component models are algorithmic with fixed inputs and outputs. They are embodied as C++ functions within software modules. For each component several choices of inputs and outputs are possible. There is no one choice that will be most usable and efficient for all system configurations and control schemes. For reasons of consistency and comprehensibility the requirement was imposed that all EnergyPlus models be forward models. That is, the component inputs correspond to the inlet conditions and the outputs to the outlet conditions. If another choice of inputs and outputs is needed it is obtained by numerical inversion of the forward model.

9.1.4 Iteration Scheme

The primary air system simulation uses successive substitution starting at the return air inlet node and proceeding in the flow direction to the supply air outlet nodes. The iteration proceeds until an individual actuator-controller has converged (the sensed value matches the setpoint within the specified tolerance). The system controllers are simulated in sequence. During this sequence of iterative solutions the air mass flow rates are held constant. The controllers are converged by the method of interval halving. This method was chosen (rather than for instance Newton-Raphson) for its robustness.

9.1.5 Determination of Air Mass Flow Rates

In most cases the air mass flow rate of the central air system is set by zone equipment downstream of the primary air system. The air terminal unit components with their built in dampers and controllers respond to the zone heating and cooling loads by setting air flow rates at their inlet nodes. These flow rates are passed back upstream to the primary air system, establishing the flow rates in the primary air system branches. These flow rates are held fixed while the primary air system is simulated.

9.2 Air Loop Simulation

A complete simulation of each primary air system – zone equipment air loop is done in the following manner.

- If this is the first simulation this system time-step, just call *ManageAirLoops* (simulates the primary air systems) and *ManageZoneEquipment* (simulates the zone equipment sets) once and quit. This initial pass is simulated with full design air flow rates and allows the zone equipment to set the flow rates for each zone that will meet the zone loads.
- Otherwise loop over primary air systems and zone equipment sets until the temperatures, flow rates, enthalpies, humidity ratios etc. agree to within tolerance at each primary air system – zone equipment gap.

```

while ( ( SimAirLoops || SimZoneEquipment ) && ( IterAir <= MaxAir ) ) {
    ++IterAir; // Increment the iteration counter
    // Call AirflowNetwork simulation to calculate air flows and pressures
    ResimulateAirZone = false;
    if ( SimulateAirflowNetwork > AirflowNetworkControlSimple ) {
        ManageAirflowNetworkBalance( FirstHVACIteration, IterAir, ResimulateAirZone );
    }
    if ( SimAirLoops ) {
        ManageAirLoops( FirstHVACIteration, SimAirLoops, SimZoneEquipment );
        SimElecCircuits = true; //If this was simulated there are possible electric changes that
        need to be simulated
    }

    // make sure flow resolution gets done
    if ( FlowResolutionNeeded ) {
        SimZoneEquipment = true;
    }
    if ( SimZoneEquipment ) {
        if ( ( IterAir == 1 ) && ( ! FlowMaxAvailAlreadyReset ) ) { // don't do reset if already
        done in FirstHVACIteration
            // ResetTerminalUnitFlowLimits(); // don't do reset at all - interferes with
        convergence and terminal unit flow controls
            FlowResolutionNeeded = true;
        } else {
            ResolveAirLoopFlowLimits();
            FlowResolutionNeeded = false;
        }
        ManageZoneEquipment( FirstHVACIteration, SimZoneEquipment, SimAirLoops );
        SimElecCircuits = true; // If this was simulated there are possible electric changes that
        need to be simulated
    }
    FlowMaxAvailAlreadyReset = false;

    //      IterAir = IterAir + 1      ! Increment the iteration counter
    if ( SimulateAirflowNetwork > AirflowNetworkControlSimple ) {
        if ( ResimulateAirZone ) { // Need to make sure that SimAirLoop and SimZoneEquipment are
        simulated
            SimAirLoops = true; // at min three times using ONOFF fan with the AirflowNetwork
        model
            SimZoneEquipment = true;
        }
    }
}

RepIterAir += IterAir;
if ( IterAir > MaxAir ) {
    AirLoopConvergeFail = 1;
} else {
    AirLoopConvergeFail = 0;
}
// Check to see if any components have been locked out. If so, SimAirLoops will be reset to TRUE.
ResolveLockoutFlags( SimAirLoops );

```

The logical flags *SimAirLoops* and *SimZoneEquipment* are used to signal whether the primary air systems or the zone equipment sets need to be resimulated. These flags are set by the subroutine

UpdateHVACInterface which is called from within *ManageAirLoops* and *ManageZoneEquipment* at the end of each half-loop simulation. *UpdateHVACInterface* (when called from *ManageAirLoops*) passes the values at the outlet nodes of a primary air system on to the inlet nodes of the corresponding zone equipment half-loop and similarly (when called from *ManageZoneEquipment*) passes the values of the outlet nodes of a zone equipment half-loop on to the inlet nodes of its corresponding primary air system. Each time *UpdateHVACInterface* is called it also checks whether the values at the half-loop outlet nodes are in agreement with the values at the downstream half-loop inlet nodes. If they are not it sets the simulate flag of the downstream half-loop to *true*. The values checked by *UpdateHVACInterface* and their tolerances are as follows. If the air loop has no return path, then *UpdateHVACInterface* compares and passes only the mass flow rate from the zone equipment inlet node to the primary air system inlet node.

Quantities	Tolerances
specific enthalpy [J/kg]	10.0
mass flow rate [kg/s]	0.01
humidity ratio [kg H O / kg dry air]	0.0001
quality	0.01
air pressure [Pa]	10.0
temperature [C]	0.01
energy [J]	10.0

ResolveAirLoopFlowLimits is invoked to deal with zone equipment – primary air system flow mismatches. For instance the zone air terminal units (ATUs) may be asking for more air than the central fan can supply. In this case *ResolveAirLoopFlowLimits* takes the air flow that the fan can supply and apportions it among the ATUs in proportion to their design maximum air flow rates (*ResolveAirLoopFlowLimits* sets the $\dot{m}_{\max avail,node}$ at the entering node of each ATU in the system).

At the end of the air loop simulation *ResolveLockoutFlags* is called. This subroutine checks if any air system component has requested that the economizer be locked out. If such a request has been made and if the economizer is active, *ResolveLockoutFlags* sets *SimAirLoops* to *true* and the *EconoLockout* flag to *true* to ensure that the air loop will be resimulated with the economizer forced off.

9.3 Primary Air System Simulation

When the EnergyPlus HVAC simulation manager needs to simulate the primary air system side of the air loop it calls *ManageAirLoops*, the primary air system simulation manager subroutine.

Note that “air loop” is used inconsistently in the program: sometimes it means the full loop consisting of both supply & demand sides – primary air system and zone equipment; sometimes it means just the supply side – the primary air system.

Like the other manager routines in EnergyPlus, *ManageAirLoops* has a very simple structure:

```
if ( GetAirLoopInputFlag ) { //First time subroutine has been entered
    GetAirPathData(); // Get air loop descriptions from input file
    GetAirLoopInputFlag = false;
}
```

```
// Initialize air loop related parameters
InitAirLoops( FirstHVACIteration );

// Call the AirLoop Simulation
if ( SysSizingCalc ) {
    SizeAirLoops();
} else if ( !SysSizingCalc ) {
    SimAirLoops( FirstHVACIteration, SimZoneEquipment );
}

// This flag could be used to resimulate only the air loops that needed additional iterations.
// This flag would have to be moved inside SimAirLoops to gain this flexibility.
SimAir = std::any_of( AirLoopControlInfo.begin(), AirLoopControlInfo.end(), []( DataAirLoop::
    AirLoopControlData const & e ){ return e.ResimAirLoopFlag; } );
```

1. If the user input data has not been input, get the data and store it in the air loop data structures.
2. Perform air loop initialization calculations:
 - a. at the beginning of the simulation (one time initializations);
 - b. at the start of each environment (design day or simulation run period);
 - c. before each air loop simulation.
3. If automatic sizing of the loop flow rates is called for, do it.
4. Otherwise perform a simulation of the air loop.

9.3.1 Input data

The input data specifying an air loop consists of:

1. the loop configuration;
 - a. Splitters, Mixers, and Branches;
 - b. Components on the Branches
2. loop control;
 - a. Controllers;
 - b. System Availability Managers;
3. connection to zone equipment;
4. design flow rate.

These objects and their data are described in the EnergyPlus *Input Output Reference* document. The utility routines used to get and check the data are described in the EnergyPlus *Guide for Module Developers*, section Input Services.

9.3.2 Initialization Calculations

9.3.2.1 One Time Calculations

9.3.2.1.1 Zones Served by System

The main one time calculation involves figuring out what zones are served by each air loop. The EnergyPlus input does not explicitly describe which zones receive supply air from a given air loop. Instead that knowledge is embedded implicitly in the overall air loop – zone equipment network description. For sizing calculations it is important to have a data structure that explicitly shows which zones each air loop serves. For instance, the air loop design supply air flow rate is obtained by summing the design heating or cooling air flow rates of the zones connected to the air loop.

For each air loop, the following calculation is performed.

- (1) For each air loop outlet branch, the corresponding zone equipment inlet node is identified.
- (2) This node number is compared to the inlet node of all AirLoopHVAC:SupplyPaths. When a match is found, the AirLoopHVAC:ZoneSplitter for this supply path is identified.
- (3) The outlet nodes of the AirLoopHVAC:ZoneSplitter are compared to the cooling inlet nodes of all the zone ZoneHVAC:AirDistributionUnits. When a match is found this zone is identified as being served by cooling supply air from the air loop.
- (4) Similarly the outlet nodes of the AirLoopHVAC:ZoneSplitter are compared with the heating inlet nodes of all ZoneHVAC:AirDistributionUnits. A match indicates that this zone is served by heating supply air from the air loop.
- (5) The case where there is no AirLoopHVAC:ZoneSplitter for an AirLoopHVAC:SupplyPath must be handled. In this case the program looks for a match between the zone equipment inlet node and a ZoneHVAC:AirDistributionUnit heating or cooling inlet node. When a match is found that zone is identified as being served with heating or cooling supply air from the air loop.
- (6) The list of cooled and heated zones are saved in the air loop data structure AirToZoneNodeInfo.

9.3.2.1.2 Branch Sizing

If this *not* an air loop sizing calculation, but is the first pass through the HVAC code in a normal simulation, loop over all the branches in all air loops and trigger the branch design air flow auto-sizing calculation. The actual calculation is described in the Sizing section of this document.

9.3.2.2 Begin Environment Initializations

For each air loop, loop over all the branches in the loop. Initialize each branch mass flow rate:

$$\dot{m}_{br,max} = \rho_{std} \cdot \dot{V}_{br,max} \quad (9.1)$$

$$\dot{m}_{br,min} = \rho_{std} \cdot \dot{V}_{br,min} \quad (9.2)$$

where ρ_{std} is the density of air at 20 degrees C, humidity ratio = 0, standard pressure.

For each branch, loop over all the nodes on the branch and set the node data to the following values:

$$T_{node} = 20^{\circ}C \quad (9.3)$$

$$W_{node} = W_{oa} \quad (9.4)$$

$$h_{node} = \text{PsyHFnTdbW}(20.0, W_{oa}) \quad (9.5)$$

$$\dot{m}_{node} = \dot{m}_{br, \max} \quad (9.6)$$

$$\dot{m}_{\max, node} = \dot{m}_{br, \max} \quad (9.7)$$

$$\dot{m}_{\max avail, node} = \dot{m}_{br, \max} \quad (9.8)$$

$$\dot{m}_{\min, node} = 0.0 \quad (9.9)$$

$$\dot{m}_{setpt, node} = 0.0 \quad (9.10)$$

$$\dot{m}_{\min avail, node} = 0.0 \quad (9.11)$$

$$p_{node} = p_{std, baro} \quad (9.12)$$

$$Qu_{node} = 0.0 \quad (9.13)$$

where W_{oa} is the humidity ratio of the outside air; PsyHFnTdbW is the EnergyPlus psychrometric function for enthalpy h , given temperature and humidity ratio; and Qu is quality.

9.3.2.3 System Time Step Initializations

For each branch in each air loop, loop over all the nodes on the branch and set $\dot{m}_{setpt, node} = 0.0$; if it is the start of an HVAC solution sequence set $\dot{m}_{\max avail, node} = \dot{m}_{\max, node}$. Then set the mass flow rate setpoints for the air loop nodes.

1) On each air loop, loop over the outlet branches and find the loop outlet nodes. If it is the start of an HVAC solution sequence, set $\dot{m}_{setpt, outletnode} = \dot{m}_{outletbr, \max}$. This will insure that during the first pass through the full loop that the mass flow rate will be at the maximum. Otherwise, set $\dot{m}_{setpt, outletnode} = \dot{m}_{zoneeqinletnode}$. This sets the air loop flow rate to the total zone requirement.

2) Pass the mass flow rate setpoint upstream to the start of the outlet branches; through the splitter, if one exists; and upstream to the beginning node of the splitter inlet branch.

3) Sum the total return air mass flow rate and save it in the AirLoopFlow data structure.

4) For each air loop, loop over the inlet nodes and, at the start of each HVAC solution sequence, set the entering node mass flow rate equal to the primary air system design mass flow rate (subject to it not being larger than the entering node mass flow rate setpoint).

9.3.3 Central air system simulation

The subroutine *SimAirLoops* does the actual simulation the central air system equipment for all the air loops. The simulation of a full air loop (central equipment plus zone terminal units and equipment) requires the interaction of 2 managers: *ManageAirLoops* and *ManageZoneEquipment*. Thus a single call to *SimAirLoops* results in a simulation of all the central air system equipment, but this is one part of a larger iterative simulation of the full air loops involving the zone equipment as well.

SimAirLoops accomplishes its task using a set of nested loops.

- Loop over all of the central air systems (*Air Primary Loops*).
- For each air system, make 1 or 2 simulation passes
- Loop over each controller in the *Air Primary Loop*
- For each controller, repeat the simulation of all the *Air Primary Loop* components until the controller has converged
- Loop over each branch in the *Air Primary Loop*
- On each branch, simulate in sequence each component

During and at the end of each loop some tests are performed.

At the end of the first pass of loop 2, a decision is made on whether a second pass is needed. The first pass has been performed assuming that there is a mass flow balance in the central air system simulation. This is usually the case. A call to *ResolveSysFlow* checks the mass balance and imposes a mass balance if there is not a balance. The lack of a system mass balance requires a resimulation of the central air system: i.e., a second pass in loop 2.

In loop 3, a call to *ManageControllers* simulates controller action and checks for controller convergence. If convergence is achieved loop 3 is exited.

After all the controllers on a loop are converged, steps 5 & 6 are repeated one more time to ensure all the components on the loop have final values.

At the end of the primary air system simulation a call to *UpdateHVACInterface* passes the primary air system outlet node data to the zone equipment inlet nodes. If the data across the supply side – demand side gap doesn't match to within a preset tolerance, the flag *SimZoneEquipment* is set to *true* to ensure that the zone equipment side gets resimulated. Finally a flag indicating whether the economizer is active is set. This flag is used at a higher level to decide whether the primary air system needs to be resimulated if an HVAC component is calling for economizer lockout.

9.4 Outdoor Air System

The *AirLoopHVAC:OutdoorAirSystem* is a subsystem of the primary air system (object *AirLoopHVAC*). To the primary air system it appears to be a single component. Within the subsystem are components and controllers very much like the primary air system. The purpose of the outside air system is to simulate the splitting of the return air into relief and recirculated air; mix the recirculated and outside air to obtain the mixed air (all accomplished by the *OutdoorAir:Mixer*); simulate the components in the outside air stream; control the components and outside air flow

rate (economizer control). The outside air system differs from the primary air system in that it is not described in terms of splitters, mixers, and branches. Instead the components are simply listed in simulation order in an `AirLoopHVAC:OutdoorAirSystem:EquipmentList` input object. The components other than the `OutdoorAir:Mixer` are assumed to be in the outside air stream. The connectivity is defined by upstream component's outlet node = downstream component's inlet node. The `OutdoorAir:Mixer` should be the first component in the `AirLoopHVAC:OutdoorAirSystem:EquipmentList` object.

9.4.1 Simulation

The data for and simulation of the outside air system are contained in the `MixedAir` module. This includes the data and simulation of the `OutdoorAir:Mixer` and the `Controller:OutdoorAir`. The simulation of the outside air system is straightforward.

- All controllers other than `Controller:OutdoorAir` are moved up to the primary air system level, where they are simulated with the primary air system controllers.
- The `Controller:OutdoorAir` is simulated.
- The components contained in the outside air system are simulated in the order of their input in the `AirLoopHVAC:OutdoorAirSystem:EquipmentList`.

9.5 Outdoor Air Mixer

The `OutdoorAir:Mixer` is the fundamental component of the outside air system. There should always be one `OutdoorAir:Mixer` in an `AirLoopHVAC:OutdoorAirSystem`. The outside air mixer splits the primary air system (`AirLoopHVAC`) return air into relief and recirculated air streams. Then it mixes the outside air stream with the recirculated air stream to obtain the mixed air stream. The outdoor air mixer has 2 inlet flow nodes: the return air node and the outside air node. It has 2 outlet flow nodes: the relief air node and the mixed air node.

9.5.1 Simulation

Given the air mass flow rates and conditions (humidity ratio, specific enthalpy) at the return air node, relief air node, and outside air node, the simulation uses mass and energy balance to calculate the air mass flow rate, humidity ratio, and specific enthalpy at the mixed air node. The mixed air temperature is calculated from the mixed air humidity ratio and specific enthalpy using the EnergyPlus psychrometric routine *PsyTdbFnHW*.

9.6 Zone Equipment Simulation

When the EnergyPlus HVAC simulation manager needs to simulate the zone equipment side of the air loop it calls *ManageZoneEquipment*, the zone equipment simulation manager subroutine. Like the other managers, *ManageZoneEquipment* has a very simple structure:

```

IF (GetInputFlag) THEN
  CALL GetZoneEquipment
  GetInputFlag = .FALSE.
END IF

CALL InitZoneEquipment(FirstHVACIteration)

IF (ZoneSizingCalc) THEN
  CALL SizeZoneEquipment
ELSE
  CALL SimZoneEquipment(FirstHVACIteration, SimAir)
END IF

CALL RecordZoneEquipment(SimAir)

CALL ReportZoneEquipment

SimZone = .False.

RETURN

```

1. If the user input data has not been input, get the data and store it in the zone equipment data structures
2. Perform zone equipment initialization calculations.
3. If calculation of the design zone air flow rates and loads needs to be done, do it. The results of this calculation are stored in the zone sizing and air terminal sizing data structures and used by the component automatic sizing algorithms and the central system sizing calculations.
4. Otherwise simulate all of the zone equipment.
5. Transfer the zone equipment outlet node data to the inlet nodes of the primary air systems and check for convergence (done in RecordZoneEquipment by calling UpdateHVACInterface).

9.6.1 Input data

The input specifying a set of zone equipment consists of:

1. the ZoneHVAC:EquipmentConnections object data;
 - a. the zone connection to the air loop – air inlet nodes, exhaust nodes, return nodes, and zone node;
 - b. the components serving each zone – air terminal units, fan coils etc.;
2. zone supply air path data;
 - a. zone splitters and supply plenums;
3. zone return air path data;
 - a. zone mixers and return plenums;

9.6.2 Initialization Calculations

9.6.2.1 One Time Calculations

There are no one time calculations for zone equipment

9.6.2.2 Begin Environment Initializations

For each controlled zone initialize the zone inlet, exhaust and zone nodes to standard conditions. Namely:

$$T_{node} = 20^{\circ}C \quad (9.14)$$

$$W_{node} = W_{oa} \quad (9.15)$$

$$h_{node} = \text{PsyHFnTdbW}(20.0, W_{oa}) \quad (9.16)$$

$$\dot{m}_{node} = 0 \quad (9.17)$$

$$Qu_{node} = 1.0 \quad (9.18)$$

$$p_{node} = p_{oa} \quad (9.19)$$

where W_{oa} is the humidity of the outside air; PsyHFnTdbW is the EnergyPlus psychrometric function for enthalpy h , given temperature and humidity ratio; p_{oa} is the pressure of the outside air; and Qu is quality.

9.6.2.3 System Time Step Initializations

For each controlled zone, set the exhaust nodes conditions equal to the zone node conditions; except set the exhaust nodes mass flow rate and min and max available mass flow rates to zero.

9.6.3 Simulation

The subroutine *SimZoneEquipment* does the actual simulation of all the zone equipment. Note that this includes components that are part of the demand side of an air loop as well as components that are independent of any air loop.

For zone equipment components that are part of the demand side of an air loop the simulation sequence is effectively performed in the direction of the air flow. First the supply air plenums and zone splitters are simulated in their input order. Then the air terminal units are simulated followed by the zone return plenums and zone mixer. Each air terminal unit sets its inlet node to the air mass flow rate required to satisfy its zone load. These mass flow rates are then passed back upstream to the air loop demand-side inlet nodes at the end of each zone equipment simulation sequence. These demand-side inlet mass flow rates are then used as mass flow rate setpoints in the air loop supply-side simulation.

If multiple air-conditioning components are attached to a zone, the components are simulated in the order specified by the user assigned priority given in the `ZoneHVAC:EquipmentList` object, using one of four load distribution schemes. See Zone Equipment Load Distribution described in 9.6.4

For each full air loop there should be 1 supply air path for each primary air system outlet (i.e. 1 for single duct systems, 2 for dual duct systems). For each full air loop there may be one return air path. The supply air paths consist of any combination of zone splitters and zone supply air plenums as long as it forms a tree structure with the supply air path inlet node the root and the air terminal unit inlet nodes as the leaves. The return air paths consist of any combination of zone mixers and zone return air plenums as long as it forms a tree structure with the demand-side outlet node the root and the zone return air nodes as the leaves.

1. Loop over all the supply air paths.
 - a. Loop over each component (supply plenum or zone splitter) on the supply air path and simulate each component. The components are simulated in input order.
2. Loop over all the controlled zones.
 - a. Set the required system output.
 - b. Loop over the components serving the zone in the user prioritized order.
 - i. Simulate each component.
 - ii. Increment the required system output.
3. Loop over all the supply air paths
 - a. Loop over the components on each supply air path in reverse input order. This reverse order simulation passes the air terminal units inlet mass flows back upstream to the return air path inlet node.
 - b. Check to see if the supply air path inlet node mass flow rate has changed. If it has set the *SimAir* flag to *true*. This signals the HVAC manager that the supply-side of the air loop needs to be resimulated.
4. Calculate the zone air flow mass balance – the zone inlet and exhaust mass flow rates are summed and the zone node and return air node mass flow rates are determined by a mass balance for each zone.
5. Calculate the conditions at each zone return air node. Here energy not included in the zone energy balance such as light-heat-to-return-air is added to the return nodes of the controlled zones.
6. Loop over all of the return air paths.
 - a. Loop over each component (return plenum or zone mixer) on the return air path and simulate each component.

This completes a single simulation sequence of all the zone equipment.

9.6.4 Zone Equipment Load Distribution

The function *DistributeSystemOutputRequired* allocates the current zone load among the available pieces of zone equipment for the current load type (cooling, heating, or no-load). Because some air loop components such as AirLoopHVAC:UnitarySystem may be controlled based on a control zone load, the sequenced loads must be known prior to the final iteration of the HVAC simulation so that the air loop equipment will adjust its output accordingly. When the zone equipment list is initially read, the maximum number of equipment across all zones is used to set the number of air loop iterations required after the initial iteration, *MinAirLoopIterationsAfterFirst*. The control sequence is shown below.

1. Initial iteration (*FirstHVACIteration* is true)
 - (a) Set all sequenced loads to the full zone design load for the current load type (cooling or heating).
 - (b) Simulate air loops and zone equipment.
 - (c) Do not adjust any of the sequenced loads - all equipment is called with the design load.
 - (d) Store the sensible output (capacity) for each piece of equipment.
2. Second iteration (*FirstHVACIteration* is false)
 - (a) Set all sequenced loads according to the specified load distribution scheme:
 - SequentialLoad - Initially all sequenced loads are set to the full load required.
 - UniformLoad - The sequenced loads for all active equipment are set to the full load divided by the number of active pieces of equipment. All inactive sequenced loads are set to zero.
 - UniformPLR - Using the current equipment capacities (stored during the initial iteration), distribute the load among the available pieces of equipment, such that each one is operating at the same part load ratio (PLR).
 - SequentialUniformPLR - Using the current equipment capacities (stored during the initial iteration), determine how many of the available pieces of equipment are required to meet the current full load. Then distribute the load among those pieces of equipment, such that each one is operating at the same part load ratio (PLR).
 - (b) Simulate air loops.
 - (c) Simulate zone equipment.
 - If the load distribution type is SequentialLoad, update each successive sequenced load to be the current remaining load.
 - Otherwise, leave the sequenced loads as-is from the initial distribution.
3. Third iteration and beyond (*FirstHVACIteration* is false)
 - (a) Simulate air loops.
 - (b) Simulate zone equipment.
 - If the load distribution type is SequentialLoad, update each successive sequenced load to be the current remaining load.
 - Otherwise, leave the sequenced loads as-is from the initial distribution.

9.7 Air Path Components

9.7.1 Overview

The air path from the outlet of an AirLoopHVAC (the supply side of a full air loop / central air system) to the zone air distribution units (terminal units) is specified in a AirLoopHVAC:SupplyPath. The AirLoopHVAC:SupplyPath consists of AirLoopHVAC:ZoneSplitters and AirLoopHVAC:SupplyPlenums hooked together outlets to inlet.

The air path from the zone return nodes to the AirLoopHVAC inlet node is described in a AirLoopHVAC:ReturnPath object. The AirLoopHVAC:ReturnPath consists of AirLoopHVAC:ZoneMixers and AirLoopHVAC:ReturnPlenums hooked together outlet to inlets.

9.7.2 Zone Supply Air Path

The AirLoopHVAC:SupplyPaths are simulated just before the zone equipment is simulated and just after the zone equipment is simulated (in module ZoneEquipmentManager, subroutine SimZoneEquipment). In both cases the simulation consists of looping over all the AirLoopHVAC:SupplyPaths and simulating each component (AirLoopHVAC:ZoneSplitter or AirLoopHVAC:SupplyPlenum) in the path. For the “just before” simulation a flag *FirstCall* is set to *True* which tells the zone splitter and zone supply plenum models to do a downstream simulation (pass component inlet conditions to component outlets, except for air mass flow rate). For the “just after” simulation, *FirstCall* = *False*, which tells the components to do an upstream simulation (set the component inlet air mass flow rate to the sum of the component outlet air mass flow rates, do nothing with other properties).

9.7.3 Zone Splitter

The AirLoopHVAC:ZoneSplitter divides an inlet air stream into multiple outlet streams. Its data and simulation model are encapsulated in the module *SplitterComponent*. There are two simulation modes. If *SimAirLoopSplitter* is called with input parameter *FirstCall* = *True* then the splitter is simulated in downstream mode. The outlet air streams’ humidity ratio, pressure, enthalpy, and temperature are set to the conditions on the inlet air stream. If *SimAirLoopSplitter* is called with input parameter *FirstCall* = *False*, the splitter is simulated in the upstream mode. In this case the inlet air stream air mass flow rate is set to the sum of the outlet air mass flow rates. The same calculation is done for the maximum available and minimum available air flow rates.

9.7.4 Zone Supply Plenum

The AirLoopHVAC:SupplyPlenum acts analogously to the AirLoopHVAC:ZoneSplitter. The only difference is that the AirLoopHVAC:SupplyPlenum is associated with a Zone for which it sets the supply air flow rate and from which it gets its outlet air conditions. The AirLoopHVAC:SupplyPlenum divides an inlet air stream into multiple outlet streams. Its data and simulation model are encapsulated in the module *ZonePlenum*. There are two simulation modes. If *SimAirZonePlenum* is called with input parameter *FirstCall* = *True* then the plenum is simulated in downstream mode. The outlet air streams’ humidity ratio, pressure, enthalpy, and temperature are set to the zone conditions. If *SimAirZonePlenum* is called with input parameter *FirstCall* = *False*, the plenum is simulated in the upstream mode. In this case the inlet air stream air mass

flow rate is set to the sum of the outlet air mass flow rates. The same calculation is done for the maximum available and minimum available air flow rates.

9.7.5 Zone Return Air Path

The AirLoopHVAC:ReturnPaths are simulated after all the zone equipment is simulated (in module ZoneEquipmentManager, subroutine SimZoneEquipment). The simulation is accomplished by a call to *SimReturnAirPath* (in module *ReturnAirPathManager*). The simulation just consists of looping over all the AirLoopHVAC:ReturnPaths and simulating the components (AirLoopHVAC:ZoneMixer or AirLoopHVAC:ReturnPlenum) in each path.

9.7.6 Zone Mixer

The AirLoopHVAC:ZoneMixer combines multiple inlet air streams into a single outlet air stream. Its data and simulation model are encapsulated in the module *MixerComponent*. The following mass and energy balance equations are used.

$$\dot{m}_{air,out} = \sum_{i=1,n} \dot{m}_{air,in,i} \quad (9.20)$$

$$\dot{m}_{air,out} \cdot W_{air,out} = \sum_{i=1,n} \dot{m}_{air,in,i} \cdot W_{air,in,i} \quad (9.21)$$

$$\dot{m}_{air,out} \cdot h_{air,out} = \sum_{i=1,n} \dot{m}_{air,in,i} \cdot h_{air,in,i} \quad (9.22)$$

$$\dot{m}_{air,out} \cdot P_{air,out} = \sum_{i=1,n} \dot{m}_{air,in,i} \cdot P_{air,in,i} \quad (9.23)$$

$$T_{air,out} = PsyTdbFnHW(h_{air,out}, W_{air,out}) \quad (9.24)$$

Where \dot{m} is air mass flow rate, W is humidity ratio, h is specific enthalpy, P is pressure, and T is temperature. *PsyTdbFnHW* is the EnergyPlus psychrometric function for drybulb temperature as a function of enthalpy and humidity ratio. The air mass flow rate calculation is also done for the maximum and minimum available mass flow rates.

9.7.7 Zone Return Plenum

The AirLoopHVAC:ReturnPlenum acts analogously to the AirLoopHVAC:ZoneMixer. The only difference is that the AirLoopHVAC:ReturnPlenum is associated with a Zone for which it sets the supply air flow rate and from which it gets its outlet air conditions. The AirLoopHVAC:ReturnPlenum combines multiple inlet air streams into a single outlet air stream. Its data and simulation model are encapsulated in the module *ZonePlenum*. The outlet air mass flow rate is obtained from

$$\dot{m}_{air,out} = \sum_{i=1,n} \dot{m}_{air,in,i} \quad (9.25)$$

The outlet air temperature, enthalpy, humidity ratio and pressure are set to the zone conditions.

In addition to its normal function of acting as an air stream mixer, the return plenum can have 2 types of special connection to upstream air terminal units.

- (1) The user can model the effects of duct leakage in VAV single duct systems using the Simplified Duct Leakage Model (see ZoneHVAC:AirDistributionUnit for how to set up this model). After the normal outlet air flow calculation is completed as above, the calculation loops over the air distribution units connected to the zones that feed air to the plenum and adds in to the outlet air mass flow rate the leakage air flow rates from the upstream leaks defined in the ZoneHVAC:AirDistributionUnit inputs. This connection between the leaks and the plenum is not explicit: no extra nodes are defined in the return plenum or in the terminal unit.
- (2) The user can model secondary (recirculated) air drawn from the plenum into a fan powered induction unit (AirTerminal:SingleDuct:SeriesPIU:Reheat or AirTerminal:SingleDuct:ParallelPIU:Reheat). In this case the connection is explicit: extra outlet nodes are defined in the return plenum which act as the secondary air inlet nodes for the terminal units. The recirculated air flow rates are set by the terminal units. The outlet return air is then:

$$\dot{m}_{air,out} = \sum_{i=1,n} \dot{m}_{air,in,i} - \sum_{j=1,m} \dot{m}_{air,recirc,j} \quad (9.26)$$

9.8 Plant Load Profile

The LoadProfile:Plant object is used to simulate a scheduled demand profile. This can be useful when the building loads are already known. Demanded load and flow rate are schedules specified in the object definition. The load profile can specify heating and cooling loads. Cooling loads are entered as negative numbers. The actual load met is dependent on the performance of the supply loop components.

The LoadProfile:Plant object must be connected on the demand side of the plant loop. If desired, multiple LoadProfile:Plant objects can be combined in series and/or parallel.

9.8.1 Calculation Model

The LoadProfile:Plant object calculates the outlet water temperature based on the inlet water temperature from the plant loop and user inputs for the scheduled plant load and the requested flow rate. The calculation can be expressed with the equation:

$$T_{out} = T_{in} - \frac{Q_{load}}{\dot{m}c_p} \quad (9.27)$$

where

T_{out} = the outlet water temperature

T_{in} = the inlet water temperature

Q_{load} = the scheduled plant load

\dot{m} = the water mass flow rate

c_p = the specific heat of water

The user requested flow rate is not always available from the plant loop. The actual flow rate used in the calculation is the lesser of the user requested value and the plant available value.

Note that the LoadProfile:Plant object can still request and receive flow even if the scheduled plant load is zero. In this case the outlet temperature will be the same as the inlet temperature. This allows users to drive the plant loop flow without necessarily affecting the loop temperature.

For reporting purposes the energy consumption of the object is calculated using the equation:

$$E = Q_{load}\Delta t \quad (9.28)$$

where

E = the energy consumption

Q_{load} = the scheduled plant load

Δt = the time step interval

9.9 Plant/Condenser Loops

9.9.1 Integration of System and Plant

In order to integrate the air handling system simulation with the zones simulation, methods were developed to model the system air loop and its interactions with the zones due to temperature controls and the relative difference between the zone and supply air temperatures. A similar situation is encountered when integrating the central plant simulation. Typically, the central plant interacts with the systems via a fluid loop between the plant components and heat exchangers, called either heating or cooling coils. In EnergyPlus the performance of the air systems and plant are interdependent because the simulations are combined. The plant outputs must match the system inputs and vice versa. That is, the temperature of the chilled water leaving the plant must equal the temperature of the water entering the coils, and the chilled water flow rate must satisfy mass continuity. In addition, coil controls are usually necessary to ensure that the values of chilled water flow variables entering and leaving the coil remain in a reasonable range. Plants can also interact with each other so that the operation of a chilled water loop and chiller will affect the operation of a condenser water loop.

9.9.2 Current Primary System Modeling Methodology

There are two main types of loops within the HVAC simulation in EnergyPlus: an air loop and a plant loop. The air loop is assumed to use air as the transport medium as part of an air handling system while the plant loops use a liquid fluid of the user's choosing (typically water). Condenser loops are a special case of plant loop that are for heat rejection and are distinguished by slightly different control options and applicable equipment types. A user may have any number of each type of loop in a particular input file. There are no explicit limits on the number of loops within the program—the user is only limited by computer hardware. Execution speed will naturally vary with the complexity of the input file.

Plant loops are further divided into “half-loops” or “semi-loops” for organizational clarity and simulation logistics (see Figure “Connections between the Main HVAC Simulation Loops and Half-Loops”). These sub-loops, or half-loop sides, are matched pairs that consist of half of a main plant loop. Plant loops are broken into supply and demand sides. The plant demand side half-loop contains equipment that places a load on the primary equipment. This might include coils,

baseboards, radiant systems, etc. The load is met by primary equipment such as chillers or boilers on the supply side half-loop. Each supply side half-loop must be connected to a demand side half-loop and vice versa. A similar breakdown is present on condenser loops where the demand side includes the water side of chiller's condensers while the supply side includes condenser equipment such as cooling towers.

Figure 9.1: Connections between the Main HVAC Simulation Loops and Half-Loops.

The breakdown into two half-loops allows for better handling and control of information and simulation flow throughout the program. Direct connections between the half-loops of the air, plant, and condenser loops are enhanced by components with connections between the various main loop types. For example, coils (heating or cooling) are in reality heat exchangers with an air and a water or refrigerant side. The air side of the coil is handled within the air loop where the control of the device is also maintained. The fluid side of the coil is handled within the plant demand side, which passes the energy requirements of the coil on to the plant supply side. All loops are simulated together by successively modeling each half-loop in a particular calling order. Overall iterations ensure that the results for the current time step are balanced and updated information has been passed to both sides of the sub-loops as well as across to the other side of air loop connections such as coils.

The plant equipment on a half-loop is described by a set of branches for that half-loop. Components can be arranged on a branch in series, and branches can be placed in parallel, with some restrictions. Figure “Branch Layout for Individual Plant Half-Loops” provides an overview of the intended branch layout for each plant half-loop. Branches are individual legs within the loop structure. Thus, the segment between point A and point B is defined as a branch, as is the section between points E and F. There may be multiple sections (C1 to D1 through Cn to Dn) in between the splitter and mixer.

Each half-loop may only have one splitter and one mixer. Thus, equipment may be in parallel between the mixer and splitter, however, within any single branch, there can only be components in series and not in parallel. The topology rules for individual half-loops allow a reasonable amount of flexibility without requiring a complicated solver routine to determine the actual flow and temperature conditions. Note that since plant supply and demand are broken up into two separate half-loops, chillers or boilers may be in parallel to each other in the supply side and coils may be in parallel to each other on the demand side. Thus, the restriction of only a single splitter and mixer on a particular half-loop does not unduly limit the allowable configurations. In some cases a single branch can be used to define an entire half-loop, but in general a half-loop should have a splitter and a mixer even if all equipment on the sub-loop is simply in series.

In addition, to avoid the need for overly complex solver routines, there are some restrictions on the placement of pumps within a particular half-loop. There are two general types of pumps, loop pumps and branch pumps. A pump that is the first component on the first branch (between A and B) is termed a “loop pump” while any pump in the parallel section (between Ci and Di) is termed a “branch pump”. The simplest and most common arrangement is to have one loop pump on the supply side inlet. In plant demand half-loops pumps can be placed only in the inlet branch. This will allow simulation of primary-secondary systems. For more information on pumps and pump placement rules, see the section on PipingSystem:Underground Simulation Pumps in this document.

Essentially, each branch is made up of one or more components linked together in series. The branch has system nodes that store properties at a location on the loop (temperature, enthalpy, flow rate, etc.) at the beginning and end of the branch as well as between components. Components on the branch take the conditions of the node at their inlet and use that information as well as overall control information to simulate the component and write the outlet data to the node following the component. This information is then used either by the next component on the branch or establishes the outlet conditions for the branch.

Although the plant model in EnergyPlus is quite flexible, in most cases the topology of the plant system in the model will be somewhat different from the topology of the actual plant system in a building. EnergyPlus is focused on modeling building energy performance over long periods of time and is not intended as a completely flexible system that can directly model any actual plant system with its full complexity and exact layout. Given the design of an actual complex plant system, the modeler will typically need to develop a simpler system that conforms to EnergyPlus’s capabilities and strives to capture the issues important for energy consumption modeling. Just like complex geometry should be simplified into thermal zones for energy models, complex plants should to be simplified into sets of pairs of closed half-loops with the allowed branch topologies.

9.9.3 Plant Manager

9.9.3.1 Plant Half-Loop Calling Order

Because there can be multiple plant loops in a model that depend on each other, one job of the plant manager is to determine an appropriate calling order for the half-loops. The initial starting calling order (and the order always used prior to EnergyPlus Version 7) is as follows:

1. Call all the demand side half-loops of the plant loops (in input object order)
2. Call all the supply side half-loops of plant loops (in input object order)
3. Call all the demand side half-loops of condenser loops (in input object order)

Figure 9.2: Branch Layout for Individual Plant Half-Loops

4. Call all the supply side half-loops of the condenser loops (in input object order).

This initial calling order is then revised during a setup phase of program execution when the plant component models are iteratively read in, initialized and sized. The algorithm is based on information provided by those component models that connect loops together. The components register that two loop-sides are connected and declare which one places demands on the other. If a half loop is connected and places demands on another loop, then the calling order for the independent demanding loop is placed just ahead of the dependent loaded half-loop. For example a water cooled chiller component model reports that the supply side of the chilled water loop is connected to the demand side of the condenser loop and that the chilled water loop places demands on the condenser loop. The plant manager algorithm is iterative and repeatedly calls all of the half loops a total of four times. After this setup phase, the calling order is fixed for the rest of the simulation.

9.9.4 Plant Flow Resolver

9.9.4.1 Overview of the Plant Flow Resolver Concept

An important aspect of the solution procedure within plant loops is the method used to solve for the fluid flow rates throughout the various half-loops. This involves making the supply side meet a particular load and flow situation based on the simulation of the demand side loops. Load distribution is an issue that must be addressed as well as how flow rates are adjusted and temperatures are updated. These issues are discussed in the next several subsections, and the algorithms described are important to how the plant simulation functions.

In the first step, the plant loop manager calls the appropriate module to simulate (in flow order) all of the components on each branch of the loop except for splitters and mixers. In this step, each component would set the conditions at the outlet node including temperature, flow rate, maximum allowed (design) flow rate, minimum allowed (design) flow rate, maximum available flow rate, and minimum available flow rate. This would be based purely on the component's own control scheme and thus each component would be free to request as much (or as little) flow as desired.

In the second step, the loop manager would resolve the flow at all nodes and through all branches of the local loop. The components are then simulated with the corrected flows. For this iteration, the flow resolver sets the flow rate through each loop component.

9.9.4.2 Overall Loop Flow Rate

The plant models determine an overall fluid flow rate for each loop based on the dynamic requests and needs of the components on the loop. The flow resolver examines the requests and needs of each half-loop and chooses an overall flow rate. As individual plant components are modeled, they register their requests for fluid flow which are stored on the inlet node (variable called MassFlowRateRequest). These requests for flow are used for two purposes, overall loop flows and resolution of parallel flows inside a splitter/mixer. For determining the overall loop flow request, the requests by individual components are further qualified into three categories based on the nature of the device.

1. Need flow and turns loop on
2. Need flow if loop is already on
3. Take what ever flow they get.

The loop will only run at all if there are flow requests of type 1. If there are flow requests of type 2, they will not turn on the loop but may affect the overall flow rate if it is already on because

of some non-zero type 1 requests. Flow requests of type 3 will not affect the overall loop flow rate. These classifications are hard coded and cannot be altered by the user.

9.9.4.3 Pump Control for Plant and Condenser Loops.

The pump is quite simply the component that drives the flow (also see `PipingSystem:Underground Simulation Pumps`). How it reacts depends on several different conditions. In total, there are three different decision variables, two of which are defined by user input. These three deciding factors are whether the pump is constant or variable speed, whether the pump operation is continuous or intermittent, and whether or not there is a request for overall loop flow. After the overall loop flow request has been determined the simulation knows what the loop would like to do. The next thing it does is simulation all the loop pumps to see what the pumps can actually provide. Then the overall loop flow is bounded by the minimum and maximum that the loop pumps can provide at that time. The operation of a constant speed pump is fairly straightforward. If the user designates a constant speed pump that is operating continuously, the pump will run regardless of whether or not there is a load. This may have the net effect of adding heat to the loop if no equipment is turned on. If the pump is constant speed and operates intermittently, the pump will run at its capacity if a load is sensed and will shut off if there is no load on the loop.

A variable speed pump is defined with maximum and minimum flow rates that are the physical limits of the device. If there is no load on the loop and the pump is operating intermittently, then the pump can shutdown. For any other condition such as the loop having a load and the pump is operating intermittently or the pump is continuously operating (regardless of the loading condition), the pump will operate and select a flow somewhere between the minimum and maximum limits. In these cases where the pump is running, it will try to meet the flow request for the overall loop.

In many cases, the first estimate of flow requested by the demand side tends to be fairly accurate and the flow rate does not vary in subsequent iterations. However, because there is the possibility that the coils or some other component might request more flow in future iterations during the same time step, the program must not only set flow rates but also maintain a record of the current maximum and minimum flow rate limits. This information is important not only to the pump itself but also to other pieces of equipment which may control their flow rates and thus require knowledge of the limits within which they may work. In general, the decisions on what to set the maximum and minimum flow rates is directly related to the type of pump (constant or variable speed). For constant speed pumps, the maximum and minimum flow rate values are the same and thus if the flow requested does not match this, the other components must either deal with the flow or a bypass branch must be available to handle the excess flow. For variable speed pumps, the maximum and minimum flow rates are set by the user-defined limits.

9.9.4.4 Plant/Condenser Supply Side

Component models, such as boilers, chillers, condensers and cooling towers are simulated on the supply side of the plant and condenser loops. In order to allow specification of realistic configurations, the plant loop managers were designed to support parallel-serial connection of component models on the loop. In addition, loop managers were designed to support both semi-deterministic models (e.g. the parameter estimation models of the ASHRAE Primary Toolkit [Pedersen 2001]) and “demand based” models (e.g. the performance map models of BLAST and DOE2.1E). As a result, the loop manager must be able to simulate models that require the mass flow rate as an

input and models that calculate the mass flow rate as an output—sometimes in the context of a single loop configuration.

In order to achieve these design criteria without resorting to a pressure based flow network solver in the HVAC portion of the code, a rules-based “flow resolver” was developed for the EnergyPlus plant manager. The flow resolver is based on the following assumptions and limitations:

- Each loop is only allowed to have a single splitter and a single mixer
- Due to the fact that there can only be one splitter and one mixer on a given loop, it follows logically that there can be at most one bypass on each loop side
- No other components may be in series with a bypass, i.e., a branch that contains a bypass may have no other equipment on that branch
- Equipment may be in parallel only between the splitter and mixer components of a loop
- Equipment may be hooked together in series in each branch of the loop
- Flow rates on individual branches will be controlled using maximum and minimum available flow rate limits

The flow resolver employs a simple predictor-corrector algorithm to enforce mass continuity across the plant loop splitter as shown in the following figure.

As previously discussed, the pump establishes the total loop mass flow rate by setting the flow in the first supply side branch. In the second step, a predictor algorithm calls to simulate each piece of equipment on the loop and they update their mass flow rate requests based on the current flow rates, temperatures and load dispatch requests. The loop manager calls the appropriate module to simulate (in flow order) all of the components on each branch of the loop except for splitters and mixers. In this step, each component sets the conditions at its outlet node including temperature and sets component flows on the inlet node. Each component and branch is classified for their type of flow control. Prior to version 7 this was input by the user where branch objects were tagged in the user input file as an ACTIVE, SERIESACTIVE, PASSIVE or BYPASS type of model. As of version 7 this has been hard coded and the input is no longer used. An ACTIVE flow control type describes a demand based plant model that calculates mass flow rate as an output. An ACTIVE component when OFF will shut down the whole branch irrespective of the type of other components on the branch. A SERIESACTIVE branch is like an ACTIVE component except that there are more than one ACTIVE components on the branch so that two components requests may be at odds with each other and so it might not shut down the whole branch when the component is OFF. The flow resolution algorithm is same for both ACTIVE and SERIESACTIVE components and in the rest of the document description of one type will fit the other type too. A PASSIVE type describes a semi-deterministic model that is simulated with the mass flow rate as an input. The BYPASS type designates a loop bypass.

The predictor algorithm first establishes the desired flow rate of each branch by searching for ACTIVE components on the branch. The first ACTIVE component in simulation order sets the desired branch flow. Branches with only PASSIVE components require a flow rate between the minimum and maximum allowable branch flow. Branches with a BYPASS component have a branch flow only when all other branches combined cannot handle the entire loop flow.

Figure 9.3: Plant/Condenser Supply Side Solution Scheme.

The loop flow resolver makes any necessary “corrections” to the requested branch flows in order to enforce overall continuity on the loop. If mass conservation allows all ACTIVE branches to be satisfied, then the remaining flow is divided between the PASSIVE branches and as a last resort, the BYPASS. If there is insufficient flow to meet the branch demand, ACTIVE branch requests are met first in the order that the branches appear in the branch list in the input file.

The flow rate is resolved first for each individual branch. For every branch, the program cycles through each node on the branch and determines what the flow requests and flow limits are. The most restrictive flow constraints are assumed to be valid for the entire branch regardless of component type. Active components are given highest priority for requesting a particular flow rate. If there is more than one active component on a particular branch, then it is assumed that the active component on the branch with the highest flow request dictates the flow request for the entire branch.

Once all of the branches have set their flow rates and constraints, the splitter and mixer must resolve the various flow requests. The mixer and any branch following the mixer is passive. Thus, all of the flow control happens at the splitter. The splitter first attempts to sum the maximum and minimum constraints from all of the active branches coming out of the device and compares those to the constraints that are valid for the branch leading into the splitter. When there is a mismatch between the outlet constraints and the inlet constraints, the simulation will defer to the inlet constraints due to the fact that the pump is in reality controlling flow on the loop. Since the constraints of the pump would be passed across to the demand side from the supply side, an assumption is made that the coils or other demand side components must live within the bounds of the pump.

Once the flow has been resolved at the splitter, the branch flow rates and constraints between the splitter and mixer can be adjusted, if necessary. In some cases, this will be mandatory to maintain a mass balance at the splitter. When the flow rate coming out of the splitter does not match the active branch requests, individual branch flow rates must be adjusted to provide for the extra flow or the “flow deficit”. When there is extra flow, the excess flow is sent through any bypass branch first and then is sent to passive branches in reverse order of their appearance in the splitter outlet list. When all of these branches have been exhausted and there is still excess flow, flow will be increased to the active branches, also in reverse order. The reverse order guarantees that the branch appearing first has the highest priority to receive the flow rate it has requested.

If there is not enough flow to meet all active branch requests (i.e., a “flow deficit”), then the flow rates through the bypass and passive branches are set to zero. The flow rates through the active branches will then be decreased in reverse order until the splitter outlet flow rate matches the available flow at the splitter inlet. For a plant loop flow deficit, the bypass and passive branch flows are also set to zero, and flow rates for each active branch are calculated as follows:

$$\dot{m}_{br} = \frac{\dot{m}_{br_request}}{\dot{m}_{tot_request}} * \dot{m}_{tot_available} \quad (9.29)$$

where:

\dot{m}_{br} = final resolved branch flow rate

$\dot{m}_{br_request}$ = requested branch flow rate

$\dot{m}_{tot_request}$ = total loop mass flow rate request

$\dot{m}_{tot_available}$ = total loop mass flow rate available

It is also necessary to monitor the flow constraints at the branches and components since once the flow rates are changed, the components must be resimulated by the controlling loop (air loop, zone

equipment, or plant supply side). The controllers for these components must know if the constraints have been modified so that the simulation does not toggle between a component requesting a flow that the pump cannot meet and the pump then resetting the flow to what it can provide. Note that once a flow rate for any component has changed that this signals the need to resimulate any sub-loop to which it might have an indirect connection. Currently, this means that if a flow rate on the plant demand side changes, the simulation must recalculate the conditions on both the air loop and zone equipment sub-loops since coils and other equipment could be on either side of the main air loop. Similarly, if the condenser demand side simulation results in a change in flow rate through a chiller condenser, then the plant supply side must be triggered to perform its calculations again. Care has been taken to avoid cases where the various half-loops might simply keep triggering the resimulation of their indirect connections in an infinite loop.

9.9.4.5 Loop Capacitance and Pump Heat

The plant model includes simplified methods of modeling fluid capacitance and the temperature rise because of pumping and friction. The transition from load or energy based plant models to a loop based arrangement makes variables of both the flow rate and the fluid temperature. This means there are more degrees of freedom that must be controlled. The flow resolver concept discussed previously controls the fluid flow rates through the components and maintains an overall mass flow balance through the loop. However, the temperatures still need to be controlled and modeled. A purely iterative procedure can be expected to converge to the appropriate loop temperatures, but the procedure can become slow to converge under conditions where the demand changes rapidly or the supply components may not have enough capacity to meet the system demand. This situation is somewhat analogous to that existing in the link between the zone and the air system. In that case, the convergence and stability of the iterative solution was greatly improved by adding the thermal capacitance of the zone air and other fast responding mass within the zone. Based on that experience, it was decided to add thermal capacitance to the plant loop model to benefit from the added stability. Because the thermal capacitance in the zone/system interaction is relatively small, it was necessary to use a third order numerical solution there. Although the plant loop's fluid thermal capacitance is relatively high, the fluid flows also have high heat capacity and can change temperatures rapidly a simple first order solution was not found to be satisfactory and an exact analytical solution was needed.

In realistic conditions there is often some delay between changes in supply conditions and corresponding changes at demand side components due to the transport of fluid round the loop having a finite velocity.

The act of pumping fluid around a loop adds heat to the fluid through friction. The slight warming occurs at the pump and all around the circuit. The amount of heat is equal to the work done on the fluid by the pump. This so-called pump heat is a complicating factor in plant simulation because the pump heat alters the load on primary equipment. A simple method of accounting for pumping heat is needed that doesn't increase the difficulties of the numerical solution and (as of version 7) in EnergyPlus this accomplished by including the pump heat in the loop capacitance model.

Plant loops include a simple loop capacitance model to simulate these effects based on a well-stirred tank model. Each half-loop has a well-stirred tank located at its inlet as indicated in Figure 9.4. The temperature of the tank is modeled as a function of the tank mass, inlet fluid flow rate and temperature, and pump heat. No energy is lost or gained because of storage in the loop

capacitance.

Figure 9.4: Loop Capacitance Tank Models

The total plant loop volume is separated into two tanks, one on each half-loop inlet. For normal loops (without common pipes) each tank is one half of the plant loop volume. For common pipe plant loops, the tank on the supply side inlet has three fourths of the volume and the tank on the demand side inlet has one fourth. Each plant loop is assigned a total fluid volume as user input or an autocalculate routine based on the design flow rate. The size of the thermal capacitance affects the speed of recovery from situations where the setpoint was not maintained. The user must estimate a fluid volume based on the size of the pipes in the loop. Note that rough estimates seem to be sufficient. Loop capacitance (m^3) could be calculated from pipe size data but this is not usually known. If zero capacitance is specified the above formulation reduces to an instantaneous update in demand update temperature and the demand inlet temperature becomes the supply outlet temperature at the previous time step. If a very large capacitance is specified unrealistic time delay may result and there may be poor response to changes in loop setpoint temperature. The loop capacitance ‘autocalculate’ option sets the loop volume to the product of the maximum loop flow rate and the loop circulation time (a user input which defaults to 2 minutes).

The tank temperature is modeled by drawing a control volume and energy balance around the tank and solving for the temperature. The temperature of each tank is recalculated whenever

the two half-loops are interfaced together. The tank temperature history is stored at the end of the simulation timestep. The model equation for tank (and outlet temperature) is formulated as follows:

$$T_{tank,new} = \frac{\dot{m}c_p T_{inlet} + \frac{M_{tank}c_p T_{tank,old}}{t_{sys}3600} + \dot{Q}_{pumpheat}}{m c_P + \frac{M_{tank}c_p}{t_{sys}3600}} \quad (9.30)$$

The tank temperature at the end of the simulation timestep is solved by the analytical approach and expressed as

$$T_{tank}^t = \left(T_{tank}^{t-\delta t} - \frac{\dot{m}c_p T_{inlet} + \dot{Q}_{pumpheat}}{\dot{m}c_p} \right) \exp \left(-\frac{\dot{m}c_p}{M_{tank}c_p} t \right) + \frac{\dot{m}c_p T_{inlet} + \dot{Q}_{pumpheat}}{\dot{m}c_p} \quad (9.31)$$

where:

$T_{tank}^{t-\delta t}$ is the previous system time-step tank temperature [°C]

T_{tank}^t is the current tank and tank outlet temperature [°C]

\dot{m} is the current fluid mass flow rate through the tank [kg/s]

δt is the duration of system time step [second]

c_p is the heat capacity of fluid [J/kg]

M_{tank} is the mass of the water in the tank [kg]

$\dot{Q}_{pumpheat}$ is the heat generated by a pump in the tank [W]

When modeling plants using one of the common pipe modes for plant loops, the same tank model is used but the tanks are situated differently and account for extra connections. For common pipe situation, the tanks are located on the outlet of a half loop with common pipe interactions downstream of the tank.

The average temperature is reported as the tank temperature. The average temperature is defined as the value of an integral function of tank temperature on an interval $[0, \delta t]$.

$$\begin{aligned} \bar{T} = \frac{1}{\delta t} \int_0^{\delta t} T_{tank}^t dt &= \frac{M_{tank}c_p}{\dot{m}c_p \delta t} \left(T_{tank}^{t-\delta t} - \frac{\dot{m}c_p T_{inlet} + \dot{Q}_{pumpheat}}{\dot{m}c_p} \right) \left(1 - \exp \left(-\frac{\dot{m}c_p}{M_{tank}c_p} \delta t \right) \right) \\ &+ \frac{\dot{m}c_p T_{inlet} + \dot{Q}_{pumpheat}}{\dot{m}c_p} \end{aligned} \quad (9.32)$$

9.9.4.6 Plant Flow Resolver Input

The input specifically related to the flow resolver consists of the plant BranchList and the plant ConnectorList as shown in the Input Output Reference. User defined names link the plant loop to its branches (contained in the BranchList) and define the loop splitters and mixers contained in the ConnectorList. The Connector:Splitter and Connector:Mixer syntax in turn define the relative connection of the branches to each other on the loop.

The Branch definition is input in simulation and connection order for all of the components on the branch. The simulation assumes that the inlet node of the first component listed on the branch is the branch inlet node and the outlet node of the last component listed on the branch is the branch outlet node. Examples of all the input syntax is shown in the Input/Output Reference for the appropriate object.

9.9.5 Summary of Load Distribution Schemes

Five load distribution schemes are employed in EnergyPlus. The figure below illustrates the plant load distribution algorithm. The total loop demand is calculated and used in the **ManagePlant-LoopOperation** routine to determine which equipment is available based on the supervisory control scheme specified by the user. Once all available components have been identified the loop demand is distributed to the available components based on the user specified load distribution scheme.

Figure 9.5: Loop Capacitance Tank Models

- The **OPTIMAL** scheme first loads each component to its optimal part load ratio (specified in input). Any remaining loop demand is distributed evenly to all the components.
- The **UNIFORMLOAD** scheme first divides the load evenly among all available components. If some components do not have the capacity to meet the uniformly distributed load, the remaining load is distributed sequentially to the other available components.
- The **SEQUENTIALLOAD** scheme loads each component one at a time to capacity until the loop demand is met. The components are loaded up in the order that they appear in the equipment list specified in input.
- The **UNIFORMPLR** scheme loads all equipment uniformly by maintaining uniform part load ratios across all equipment on the equipment list. If the load is below the load required by the plant to operate at the largest component minimum part load ratio, the last item is

removed from each equipment list. This process is repeated until the plant can operate above the largest component minimum part load ratio.

- The **SEQUENTIALUNIFORMPLR** scheme loads all equipment in the order specified on the equipment list to capacity while operating all operational equipment at uniform part load ratios.

Note: For all schemes, if the load for any individual component is less than the component load at the minimum PLR, the individual component model will false load or reduce duty cycle while operating at the minimum part load ratio until the load is met.

Examples of application of each Load Distribution schemes can be found in the following tables. Each example assume that we have two pieces of equipment, with Equipment A being first in line in the `PlantEquipmentList`, and having the following characteristics:

Table 9.2: Equipment description

Equipment	A	B
Priority	1	2
Min PLR	0.2	0.15
Max PLR	1	1
Optimum PLR	0.6	0.4
Capacity	40	100

Note: In the examples below:

- "*" Means it will false load or cycle
- "***" Means it is capped by maximum PLR

9.9.5.1 OptimalLoad

The **OptimalLoad** Load Distribution occurs in three steps:

- Step 1: Sequentially load each equipment to the Minimum of Optimal Load (= Load corresponding to optimal Part Load Ratio) and Loop Demand
- Step 2: Evenly distribute the remaining loop demand, without exceeding the maximum Part Load Ratio of each equipment
- Step 3: If there is still some remaining demand, look for any equipment that is not yet at maximum Part Load Ratio and load it (up to its maximum Part Load Ratio)

Table 9.3: Optimal Load Distribution Scheme - Step 1

Plant Load	Initial Loading A	Remaining Load	Initial Loading B	Remaining Load
5	5	0	0	0
25	24	1	1	0
50	24	26	26	0
100	24	76	40	36
150	24	126	40	86
200	24	176	40	136

Table 9.4: Optimal Load Distribution Scheme - Step 2

Plant Load	Interim Loading A	Interim Loading B	Remaining Load
5	5	0	0
25	24	1	0
50	24	26	0
100	40	58	2
150	40	83	27
200	40	100	60

Table 9.5: Optimal Load Distribution Scheme - Step 3

Plant Load	Final Loading A	Final Loading B	Final PLR A	Final PLR B	Load Not Met
5	5	0	0.2 *	-	0
25	24	1	0.6	0.15 *	0
50	24	26	0.6	0.26	0
100	40	60	1 **	0.6	0
150	40	100	1 **	1 **	10
200	40	100	1 **	1 **	60

9.9.5.2 UniformLoad

The **UniformLoad** Load Distribution occurs in two steps:

Step 1: Distribute the load equally to all machines, without exceeding the maximum PLR of the equipment

Step 2: If there is a remaining loop demand, sequentially distribute it to all machines, without exceeding the maximum Part Load Ratio.

Table 9.6: Overview of the UniformLoad Load Distribution Scheme

UniformLoad	Initial Loading		Final Loading		Load Not Met	Final PLR	
Plant Load	A	B	A	B		A	B
10	5	5	5	5	0	0.2 *	0.15 *
25	12.5	12.5	12.5	12.5	0	0.31	0.15 *
50	25	25	25	25	0	0.63	0.25
100	50	50	40	60	0	1 **	0.60
150	75	75	40	100	10	1 **	1 **
200	100	100	40	100	60	1 **	1 **

9.9.5.3 SequentialLoad

The **SequentialLoad** simply loads all machine sequentially up to their maximum Part Load Ratio.

Table 9.7: Overview of the Sequential Load Distribution Scheme

SequentialLoad	Loading		Load Not Met	PLR	
Plant Load	A	B		A	B
5	5	0	0	0.2 *	-
25	25	0	0	0.625	-
50	40	10	0	1 **	0.15 *
100	40	60	0	1 **	0.6
150	40	100	10	1 **	1 **
200	40	100	60	1 **	1 **

9.9.5.4 UniformPLR

The **UniformPLR** Load Distribution occurs in three steps:

- Step 1: Determine PlantCapacity and LargestMinCompPLR for each successive equipment being turned on. PlantCapacity is the capacity of all equipment that is turned on and considered. LargestMinCompPLR is the max of minimum Part Load Ratio for each equipment considered.
- Step 2: While the load to be met is below the LargestMinCompPLR equipment still in consideration, remove the last equipment in the Plant Equipment List. Always keep one equipment.
- Step 3: Divide the Plant Load across the remaining equipment

Table 9.8: UniformPLR Load Distribution Scheme - Step 1

Equipment Considered:	A	A & B
PlantCapacity	40	140
LargestMinCompPLR	0.2	0.2

Table 9.9: UniformPLR Load Distribution Scheme - Step 2 and 3

UniformPLR	A&B in Consideration	A only		Final Loading		Final PLR	
Plant Load	Plant PLR	B	Plant PLR	A	B	A	B
5	0.04	OFF	0.125	5.0	-	0.2 *	-
10	0.07	OFF	0.25	10.0	-	0.25	-
25	0.18	OFF	0.625	25.0	-	0.625	-
50	0.36	ON	N/A	14.29	35.71	0.36	0.36
100	0.71	ON	N/A	28.57	71.43	0.71	0.71
150	1.07	ON	N/A	40.00	100.00	1 **	1 **

9.9.5.5 SequentialUniformPLR

The **SequentialUniformPLR** Load Distribution occurs in two steps:

Step 1: Turn on each equipment sequentially to have enough capacity to meet the loop demand.

Step 2: Operate the resulting equipment at uniform part load ratio

Table 9.10: Overview of the SequentialUniformPLR Load Distribution Scheme

	Sequential Loading				Final Loading		Final	
Plant Load	A	B	PlantCapacity	Plant PLR	A	B	A	B
5	ON	OFF	40	0.13	5.0	-	0.2 *	-
10	ON	OFF	40	0.25	10.0	-	0.25	-
25	ON	OFF	40	0.63	25.0	-	0.63	-
50	ON	ON	140	0.36	14.3	35.71	0.36	0.36
100	ON	ON	140	0.71	28.6	71.43	0.71	0.71
150	ON	ON	140	1.07	40.0	100.00	1 **	1 **

9.9.6 Summary of Plant Loop Demand Calculation Schemes

There are two plant loop demand calculations schemes in EnergyPlus. There is a **SingleSetPoint** and a **DualSetPointDeadband**; the **SingleSetPoint** is the default if that field is left blank in the PlantLoop object. In the SingleSetPoint scheme the Plant Loop requires that a Setpoint Manager set a single setpoint value that sets Node%TempSetPoint. Examples of this Setpoint Manager would be: the objects SetpointManager:Scheduled, SetpointManager:OutdoorAirReset, etc. For the DualSetPointDeadband scheme the Plant Loop requires one or two Setpoint Managers

two setpoint managers are required, one with Control Variable = MaximumTemperature and another with Control Variable = MinimumTemperature. Examples of applicable setpoint managers include: SetpointManager:Scheduled, SetpointManager:OutdoorAirReset, SetpointManager:FollowOutdoorAirTemperature, etc. Look in the Input Output Reference for the correct usage of these SetpointManagers.

The Plant Loop Demand Calculation Scheme determines the amount of heating or cooling necessary to bring the temperature of the Plant Loop to its setpoint(s). When this value is determined then the Load Distribution scheme explained in the previous section takes this value and distributes the load to the appropriate equipment. The demand calculation scheme determines how the load is calculated. In the next section is a summary of the 2 algorithms and how they are used.

9.9.6.1 Loop Demand Calculation Scheme SingleSetPoint

The SingleSetPoint scheme for the PlantLoop takes the value that is placed on the Node%TempSetPoint and calculates the heating or cooling load necessary to obtain that setpoint.

$$\text{DeltaTemp} = \text{LoopSetPoint} - \text{LoopTempIn}$$

$$\text{LoopDemand} = \text{mdot} * \text{Cp} * \text{DeltaTemp}$$

The sign of the Loop Demand determines if the loop has a cooling or heating load. Then the Load Distribution scheme distributes this calculated load to the appropriate equipment.

9.9.6.2 Loop Demand Calculation Scheme DualSetPointDeadband

The DualSetPointDeadband scheme for the PlantLoop takes the value that is placed on the Node%TempSetPointHi and Node%TempSetPointLo calculates the heating or cooling load necessary to obtain that setpoint; if in the DeadBand then no load is calculated. The pseudo code below shows the basis of the algorithm.

```
!Calculate the demand on the loop
IF (mdot > 0.0) THEN
  LoadToHeatingSetPoint = mdot*Cp*(LoopSetPointLo - LoopTempIn)
  LoadToCoolingSetPoint = mdot*Cp*(LoopSetPointHi - LoopTempIn)
  ! Possible combinations:
  ! 1 LoadToHeatingSetPoint > 0 & LoadToCoolingSetPoint > 0 --> Heating required
  ! 2 LoadToHeatingSetPoint < 0 & LoadToCoolingSetPoint < 0 --> Cooling Required
  ! 3 LoadToHeatingSetPoint < 0 & LoadToCoolingSetPoint > 0 --> Dead Band Operation
  ! 4 LoadToHeatingSetPoint > 0 & LoadToCoolingSetPoint < 0 --> Not Feasible
  IF (LoadToHeatingSetPoint .GT. 0.0 .AND. LoadToCoolingSetPoint .GT. 0.0) THEN
    LoopDemand = LoadToHeatingSetPoint
  ELSE IF (LoadToHeatingSetPoint .LT. 0.0 .AND. LoadToCoolingSetPoint .LT. 0.0) THEN
    LoopDemand = LoadToCoolingSetPoint
  ELSE IF (LoadToHeatingSetPoint .LT. 0.0 .AND. LoadToCoolingSetPoint .GT. 0.0) THEN
    LoopDemand = 0.0
  ELSE
    CALL ShowSevereError
  END IF
ELSE
  LoopDemand = 0.0
END IF
```

```
IF (ABS(LoopDemand) < LoopDemandTol) LoopDemand = 0.0
```

The sign of the Loop Demand determines if the loop has a cooling or heating load. Then the Load Distribution scheme distributes this calculated load to the appropriate equipment, if there is any.

9.9.7 Plant and Condenser Equipment Operation Schemes

Plants and condenser loops must have some mechanism for controlling the operation of the loop and which equipment is available under different operating conditions. Once the Loop load is calculated by the return conditions from the demand side and using the loop setpoint, this load needs to be allocated to the supply equipment according to the users input. This is mainly done by the operation schemes.

Each operation scheme must have the type of operation scheme, its identifying name, and the schedule that defines its availability. The first scheme appearing in the list is given the highest priority; the second scheme has second highest priority, etc. In other words, if according to its schedule, the first operation scheme is available, then it is used by the simulation to define how the plant or condenser loop operates. If it is not available, the second operation scheme in the list is checked to see if it is available until the highest priority scheme that is also available is found. See the Input Output Reference for input field details.

9.9.8 Plant Operation Schemes

See the Input Output Reference for input field details. The options for plant control schemes are:

9.9.8.1 Uncontrolled Loop Operation

The PlantEquipmentOperation:Uncontrolled scheme takes the full capacity of the supply equipment and cools or heats the loop accordingly. An example would be a cooling tower where the cooling tower would cool the condenser loop with all of its available capacity and not be limited by a capacity range or setpoint. Uncontrolled loop operation simply specifies a group of equipment that runs ‘uncontrolled’. If the loop runs, this equipment will run also, unless turned off by the loop flow resolver to maintain continuity in the fluid loop.

9.9.8.2 Cooling Load Range Based Operation or Heating Load Range Based Operation

PlantEquipmentOperation:CoolingLoad (or PlantEquipmentOperation:HeatingLoad) defines the different ranges and which equipment list is valid for each range. In each trio, there is a lower limit for the load range, an upper limit for the load range, and a name that links to an equipment availability list (PlantEquipmentList). Load range operation is used when the loop load is calculated and then the equipment is selected in the proper range. This allows for the most efficient operation of the plant equipment or for the user to determine the most efficient plant configuration. When the equipment list has been determined then the load is allocated to the equipment in a manner selected by the user with “Optimal or Sequential” load distribution scheme. The load range based operation scheme has two statements associated with it: a main statement that defines the ranges that individual priority settings are valid and the lists of equipment that may be used for each range.

9.9.9 Condenser Operation Schemes

This is very similar to the plant operation schemes, but there are several more options available with the CondenserLoop. The condenser operation schemes apply to the equipment on the ‘supply side’ of the condenser loop—pumps, cooling towers, ground coupled heat exchangers, etc. The keywords

select the algorithm that will be used to determine which equipment is available for each time step. The ‘*Range Based Operation*’ schemes select a user specified set of equipment for each user specified range of a particular simulation variable. ‘*Load Range Based*’ schemes compare the demand on the condenser supply side with specified load ranges and associated equipment lists. ‘*Outdoor...Range Based*’ schemes compare the current value of an environmental parameter with user specified ranges of that parameter. See the Input Output Reference for input field details.

9.9.9.1 Uncontrolled Loop Operation

The PlantEquipmentOperation:Uncontrolled scheme takes the full capacity of the supply equipment and cools or heats the loop accordingly. An example would be a cooling tower where the cooling tower would cool the condenser loop with all of its available capacity and not be limited by a capacity range or setpoint. Uncontrolled loop operation simply specifies a group of equipment that runs ‘uncontrolled’. If the loop runs, this equipment will run also, unless turned off by the loop flow resolver to maintain continuity in the fluid loop.

9.9.9.2 Cooling Load Range Based Operation or Heating Load Range Based Operation

PlantEquipmentOperation:CoolingLoad (or PlantEquipmentOperation:HeatingLoad) statement defines the different ranges and which equipment list is valid for each range. In each trio, there is a lower limit for the load range, an upper limit for the load range, and a name that links to an equipment availability list (CondenserEquipmentList). Load range operation is used when the loop load is calculated and then the equipment is selected in the proper range. This allows for the most efficient operation of the plant equipment or for the user to determine the most efficient plant configuration. When the equipment list has been determined then the load is allocated to the equipment in a manner selected by the user with “Optimal or Sequential” load distribution scheme. The load range based operation scheme has two statements associated with it: a main statement that defines the ranges that individual priority settings are valid and the lists of equipment that may be used for each range.

9.9.9.3 Outdoor Drybulb Range Based Operation, Outdoor Wetbulb Range Based Operation, Outdoor RHPercent Range Based Operation

The various “PlantEquipmentOperation:Outdoor*” statements define the different ranges of the various environmental parameters and which equipment list is valid for each range. After the keyword and the identifying name, a series of data trios is expected. In each trio, there is a lower limit for the load range, an upper limit for the load range, and a name that links to an equipment availability list (the “CondenserEquipmentList”).

9.9.9.4 Outdoor Drybulb Temperature Difference Based Operation,. Outdoor Wetbulb Temperature Difference Based Operation

The various “PlantEquipmentOperation:Outdoor*Difference” statements control strategies help to control any condenser equipment based on the difference between a reference node temperature and any environmental temperature. For example a cooling tower can be controlled by a strategy, which looks at the difference between the tower inlet temperature and wet-bulb temperature. A difference range is specified for each equipment list.

9.9.10 Primary-Secondary Loop Systems

The method to simulate a primary-secondary system in EnergyPlus is termed Common Pipe.

9.9.10.1 Common Pipe

Common pipe feature eliminates the need of specifying two different EnergyPlus loops each for Primary and Secondary half loops. Instead the user can set up the system as it is used in real life applications. A common pipe simulation requires that pumps be placed on both Demand (Secondary) and Supply (Primary) sides of the loop. A typical Common Pipe layout as used in EnergyPlus is shown in Figure 9.6. The major assumptions in the common pipe implementation are as follows:

- Pumps are placed on both demand and supply side of the loop.
- Secondary pump flow rate can be less than, equal to or greater than the primary pump flow rate.
- The flow at the inlet node of the half loop is equal to the flow at the outlet node of the half loop.
- The pumps can have different schedules and any loop can be shut off when the other loop is still running.

Figure 9.6: Common Pipe Layout Schematic

Common pipe simulation is done during the interface update call at both Supply-to-Demand and Demand-to-Supply. Appropriate checks are used to make sure that the effect of flow reversal

in between iteration is taken care of. Moreover, the common pipe keeps track of the flow rates and temperatures at all the four nodes linked to it; namely, the inlet and outlet nodes of each sub loop. This record will help to decide if loops have converged or not. In situations where the primary component meets the setpoint and the coil controls does not change its flow request, the common pipe converges quickly. The simple description of the control algorithm for common Pipe implementation is as follows:

1. At FirstHVACiteration, the common pipe flow is initialized to zero.
2. Common pipe is simulated at interfaces and thus we will have 2 different flows handle on either side of interface.
3. Loops and corresponding flow rates are assigned inlet or outlet (to common pipe) depending on the interface which calls it. So when common pipe is called from demand to supply interface, the inlet loop is demand side and outlet loop is supply side and vice versa.
4. Inlet flow is compared to outlet flow and the difference is set as the common pipe flow.
5. At each interface the common pipe flow is assigned a direction which can be into the interface (Inlet flow < Outlet flow) or away from interface (Inlet flow > Outlet flow).
6. Outlet temperature is calculated depending on the flow rate and flow direction. When flow is away from interface outlet flow temperature is same as inlet flow temperature. For a common pipe flow into the interface, the outlet flow temperature is calculated as mixed temperature of inlet flow and the common pipe flow.
7. At demand to supply interface, the supply side inlet node temperature and flow rate are updated every iteration. At supply to demand interface, only flow is updated. The temperature is updated only at the end of timestep.
8. Loops iterate till the flow and temperatures at all the 4 concerned nodes do not change.

9.9.10.2 Two-Way Common Pipe

A model referred to as Two-Way Common Pipe is available which provides a way to model Primary-Secondary systems as a single Plant Loop. In a typical EnergyPlus plant loop simulation, the only half loop inlet/outlet node that is controlled is the supply side outlet node. In some cases this requirement becomes a limitation in analyzing different options. A good example is ice thermal storage application, where during charging phase, the coil setpoint can be different from the ice storage equipment setpoint. With this model, the interface between the two half loops includes two additional flow paths that essentially split a single plant loop into both primary and secondary loop sides. Though the Two-Way common pipe is designed to be generic some assumptions apply in modeling the component. The assumptions are as follows

- The secondary flow may be less than, equal to, or greater than the primary flow.
- The mass flow rate at the Primary Side Outlet Node is always equal to the mass flow rate at the Primary Side Inlet Node.

- The mass flow rate at the Secondary Side Outlet Node is always equal to the mass flow rate at the Secondary Side Inlet Node.
- Only one additional node, either primary-side inlet or secondary-side inlet, (along with the primary-side/supply-side outlet node) can be controlled. The system of equations that describe the loop interface will be under specified if both the Primary and Secondary Inlet nodes have to be controlled.

Figure 9.7 shows a schematic of the Two-Way Common Pipe. There are two common pipe legs, shown as broken lines, allow for some recirculation at the half loop level. The model allows for common pipe flow in either or both directions. The model determines flow rates in the common pipes and temperatures at nodes based on the following:

- Which additional node is being controlled to meet a temperature setpoint? If the primary-side inlet node is controlled, then the flows are controlled to deliver the desired temperature at supply side inlet. If the secondary-side inlet node is controlled then the flows are controlled to deliver the desired temperature at the demand side inlet.
- Is the specified setpoint achievable with current secondary and primary outlet conditions? If the setpoint is not achievable, then the flow in each common pipe leg is reduced to its minimum possible value.
- At the controlled node, with known demand outlet temperature, supply outlet temperature, primary flow rate and secondary flow rate, and energy balance is used to calculate recirculation flows in the common pipes for that particular half loop, so that the desired temperature setpoint is achieved.
- With a known flow in one common pipe leg, the flow on Primary to Secondary (or secondary to primary) is easily obtained by mass balance.
- When the Two Way Common Pipe is controlling conditions at the secondary-side, or demand side, inlet node, then the loop capacitance model usually used for the conditions at the demand inlet is not used as it would interfere with control.

9.9.11 Heat Recovery Loop Systems

Heat Recovery is accomplished by specifying another set of supply and demand loops. Each of the heat recovery components, i.e. engine driven and combustion turbine chillers, and internal combustion and combustion turbine generators is designed to use the existing component/loop/solution structure to facilitate the simulation with the existing demand side manager and the supply side manager. Heat recovery normally contains components that produce heat that can be recovered, and the ability to store or use that heat elsewhere in the system. The component that can store the excess heat and allow it to be used elsewhere in the system or for domestic hot water is the Water Heater:Simple and is defined in the Input/Output Reference.

In the example above there is a chilled water Loop with chilled water supplied by a diesel engine driven chiller. There is a hot water Loop that is being supplied by the water heater: simple. There is also scheduled domestic hot water usage on the water heater which excess demand can be met

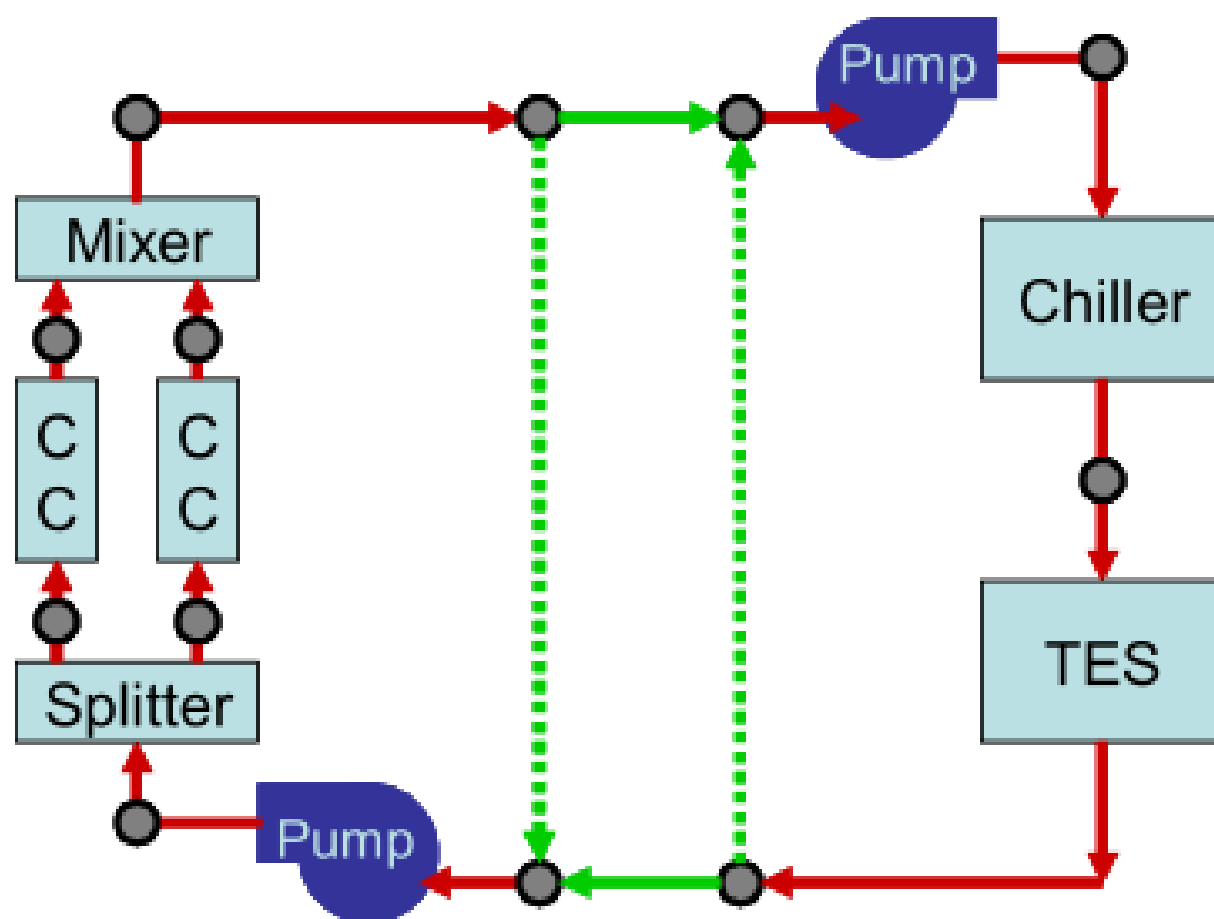

Figure 9.7: Schematic of a Two-Way Common Pipe used in Primary-Secondary System.

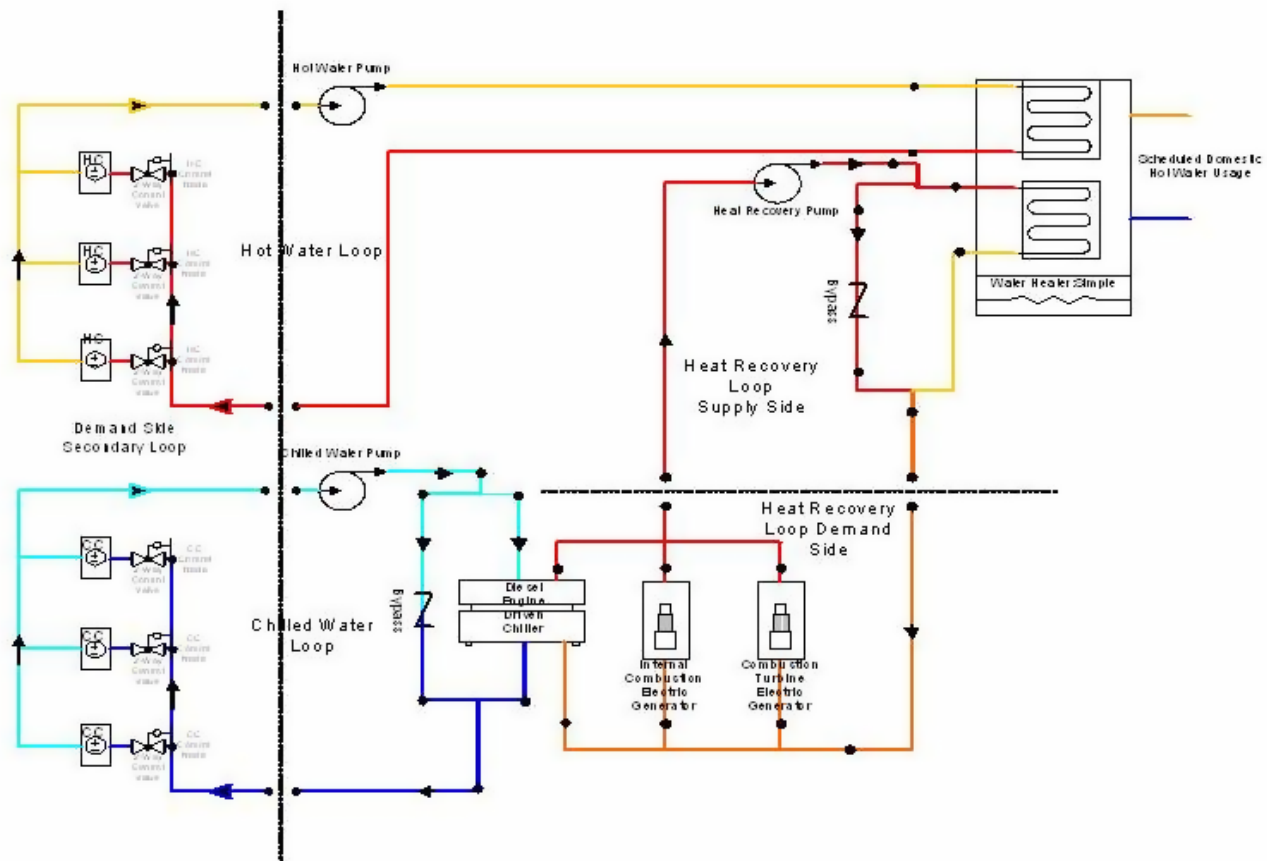

Figure 9.8: Example of a Heat Recovery Loop Simulation.

by a number of user-specified heating sources. Then on the demand side of the heat recovery loop there is the engine driven chiller, internal combustion, and combustion turbine electric generators with specified mass flows to recover the heat. This hot water is pump on the supply side by the heat recovery pump and provides the heat to the water heater to meet the water heater setpoint. This is probably one of the more complex configurations and interactions that would take place in heat recovery, but using the Plant supply and demand side configurations this can be extended to meet most user configurations. The plant water heater can also be used to just meet scheduled domestic hot water use, provide a hot water source for PlantLoop equipment, or provide a hot water storage tank for heat recovery as a single function. Or any combination of the above can be configured. Example files of some of these configurations are provided with the installation.

9.9.12 Plant Pressure Drop Simulation

As of version 4.0, there is an added feature which allows better calculation of pressure in plant and condenser loops. Without any method, the loops essentially ignore the node pressures. This is suitable for many applications, however may cause inaccuracies in the pump power. This is especially prominent in cases where the loop flow may change drastically over a wide range of configurations, as the pump power is based on a rated power value and rated pump head value. As the loop components turn on and off, the pressure drop will change, and so the pump power should be dynamically updated with these changes.

9.9.12.1 Overall model features:

Calculates loop pressure drop based on pressure drop information which is placed on branches. These are entered in terms of generic curves (linear, quadratic) or pressure drop information (minor loss/friction factor).

Loop pressure drop is used as the new pump head. No information is entered about the pump curve, so it is assumed that the pump will always be able to meet this operating point. Future enhancements will allow the pump to ride a curve based on the given pressure head.

Model does not resolve flow rates on parallel branches to match pressure drop, this is explained further below, but basically it takes the maximum pressure drop from parallel pressure components and applies that to all parallel components.

Model works for the following configurations:

1. Pump Location
2. Loop Pump
3. Branch Pumps
4. Loop Types
5. PlantLoop
6. CondenserLoop

The supply side inlet (before the pump) is always set to standard atmospheric pressure. This allows the node pressures around the loop to stay positive. The actual values of pressure are not

all that important, it is the delta pressure that is of interest for our calculations, but this makes the pressure values appear realistic if one plots the pressure around the loop.

The pressure drop is at the branch level, not the component level. If multiple components are found on a single branch, the pressure drop is always applied to the last component on the branch. This is coordinated with the rule that a pump must always be the first component if it is found on a branch.

Calculations use the branch flow rate and the branch entering temperature to calculate properties for the whole branch.

9.9.12.2 Detailed Restrictions:

Pressure drop curves must not be placed on branches which only contain a pump. Pressure curves may be placed on the supply inlet branch with a pump as long as there are other components on that same branch, following the pump.

If using branch pumps, pressure drop curves found on the supply inlet branch will be ignored. Put pressure drop information after pumps.

Currently, pressure drop simulations are not allowed with common pipe (demand pump) simulations. A future version of the pressure drop system will allow this by allowing each pump to handle the pressure drop of the given loop side (demand or supply).

9.9.12.3 Detailed Calculation Steps:

Before the demand side is simulated, the pressure system is initialized. All node pressures are reset, and pressure drop values for branches are re-initialized.

After all components on a branch are simulated, the pressure drop for that branch is calculated. This pressure drop is registered in the pressure drop system to be used in subsequent loop level calculations.

Once the entire loop (demand then supply sides) is simulated, the loop level pressure drop calculations are performed using the following steps:

Beginning at demand side outlet (linked to supply inlet), and working backwards, the node pressure is updated and loop pressure is summed by “adding pressure drops” as they are found around the loop. By working backward, we are able to easily preserve the pump inlet pressure as a realistic value (standard atmospheric pressure).

When a parallel system is encountered, a special operation is performed. Since we are not resolving flows with this version of the pressure simulation, the parallel system is set to use the largest value of pressure drop found on the parallel branches. In this manner, the highest pressure drop component essentially governs the set of parallel branches, and the other components must match the pressure drop in order to achieve their desired flow rate. This is performed by placing “imaginary” valves in the splitter. This allows individual branches to report their own pressure information, while the splitter accounts for the required pressure drop to match the governing branch. This is shown graphically in the figure below.

Because the splitter automatically handles the pressure drop required to match the pressures in the parallel system, the mixer will have uniform flow entering from all branches and exiting.

These calculations are performed around the loop and result in a value of pressure drop for the entire loop.

Pump power requires a value of pressure head before it can add heat to the loop, which is done before any components are calculated, and any pressure system calculations are performed. Because

Splitter contains pressure valves which allow parallel branches to report non-uniform pressure drop, yet overall loop pressure drop is satisfied.

Figure 9.9: Explanation of valves inherently built into Splitter object

of this, the pump power is based on rated head during the first iteration. On subsequent iterations, the pump power is based on the dynamic pressure head calculated by pressure drop information.

If anything drastically changes between one iteration and the next, the loop will be re-simulated, and the latest value of pressure head will be used. By the time the loop is converged, the pressure head between the current and most previous iterations will agree to within simulation tolerance. Thus the pump is using a lagged value of pressure head, but once the loop is converged, the lagged and current values will agree.

9.9.12.4 Pressure Drop Calculations:

There are two types of pressure drop curves that can be entered, each with its own calculation engine:

Generic: A curve of any form (single independent variable) such as linear or quadratic may represent the pressure drop in Pascals as a function of current mass flow rate in kg/s. This is common for regressing component pressure drop such as heat pumps into a quadratic best fit form. The branch pressure drop is then calculated by evaluating this curve with the given branch flow rate.

Pressure Information: This calculation involves two types of pressure drop: frictional effects and minor losses. The governing equation is:

$$\Delta P = \left(f \frac{L}{D} + K \right) \frac{\rho V^2}{2} \quad (9.33)$$

The user enters value for the minor loss coefficient K to represent all the minor losses on that branch. If the user is entering friction information, the minor loss coefficient may be zero or blank.

The user enters roughness, e , or a fixed value of friction factor to account for frictional losses on the branch, as well as an equivalent length L . If the user enters roughness then the friction factor is calculated from a Moody chart approximation (Haaland, 1983):

$$f = \left\{ -1.8 \log \left[\left(\frac{e/D}{3.7} \right)^{1.11} + \frac{6.9}{\text{Re}} \right] \right\}^{-2} \quad (9.34)$$

If the user enters minor loss information, then the friction factor information can be left out.

The diameter is an equivalent value and is used to calculate relative roughness for friction calculations as well as velocity for any pressure drop calculation.

9.9.12.5 Riding Pump Curves to Determine Loop Operating Point

In addition to being able to provide a means of calculating loop pressure drop, EnergyPlus can also perform a “loop-level” pump-system flow resolution. The pressure drop components that were described in the previous sections are combined with the input of a dimensionless pump pressure-flow curve and at each iteration, these are utilized in determining a proper operating point for the loop.

Some restrictions do apply to this simulation. As with the basic pressure drop simulation, common pipes are not valid in the current release. For this pump curve phase, the simulation is also restricted to “loop pumps” such that pumps should not be used on the parallel branches between a mixer and splitter.

The idea of riding a pump curve, as it is currently implemented, is based on a constant speed pump. A variable speed pump in EnergyPlus can already effectively vary its flow/pressure characteristics to meet the demand. Thus, this phase is only implemented for the Pump:ConstantSpeed model.

The model works by approximating the loop with a quadratic pressure drop form, then iterating to find an operating point. The entire plant loop then iterates to find the operating point that attempts to match the requested flows. Note that when doing a pressure based pump simulation, the loop will likely not hit setpoint every timestep, while doing the simpler approach (non-pressure) may result in a tighter-controlled simulation. In deciding this, you must consider the realism of the pressure approach vs. the non-pressure approach which may be more tightly controlled and will have less input requirements.

In the first iteration of the plant, there is not yet enough information to determine a pressure-flow simulation, so flow through the loop is set to the rated flow rate of the pump (irrespective of pump performance curve). For this rated flow rate pressure drop in each branch will be calculated by plant pressure system. So after this first pass through the loop, the pressure system now has a valid system flow-pressure point. From this point (pressure drop in the branch and rated mass flow rate) a pressure constant for each branch is calculated assuming quadratic relationship between pressure drop and mass flow rate.

$$K_{\text{Branch}(i)} = \Delta P_{\text{Branch}(i)} / m_{\text{Rated}}^2 \quad (9.35)$$

If there are parallel branches then equivalent K is calculated from following formula.

$$\frac{1}{\sqrt{K_{\text{ParallelEquivalent}}}} = \sum_{j=1}^m \frac{1}{\sqrt{K_{\text{Branch}(j)}}} \quad (9.36)$$

From all these ‘K’ values of the branches a corresponding K value for complete loop is calculated. This representative K value for the loop will lock down a system curve for a single iteration. This K value will change throughout the higher-level plant iterations and simulation time steps.

The Non-dimensional pump curve is entered in following way,

$$\psi = C_4 \times \varphi^4 + C_3 \times \varphi^3 + C_2 \times \varphi^2 + C_1 \times \varphi + C_0. \quad (9.37)$$

C_{1-4} are curve coefficients with last mandatory non-zero constant term C_0 (as pump curve will not pass through origin).

The nondimensional variables in the previous equation are defined in terms of the following expressions:

ψ - Non-dimensional pressure rise: $\psi = \frac{\Delta P}{\rho N^2 D^2}$

φ - Non-dimensional flow: $\varphi = \frac{\dot{m}}{\rho N D^3}$

The user preprocesses mass flow and pressure values into these nondimensional forms in order to generate the curve fit. The program then resolves the nondimensional forms into actual values based on the pump speed, diameter, and fluid density. This gives the proper pressure-flow relationship for the simulation.

9.9.12.6 Pump-System Operating Point Flow Resolver:

The pressure drop components and the pump curve are described in the prior sections. The routine which actually uses these curves to resolve to an operating point is described here. This routine is called by the pump model as it is determining what flow it should be using. The flow resolver reads the non-dimensional pump curve, loop pressure constant (K value) and rated mass flow rate (or mass flow rate from last iteration). The resolver finds the intersection of the two curves by successive substitution with 0.9 as a damping factor. If the flow rate is outside (or if in any iteration move out of) the range for which pump curve-fit is suggested, the resolver will bring the value within range, thus it is important to specify the curve-fit range (in terms of non-dimensional flow rate) for pump curve by the user. It was observed that simple successive substitution (sometimes) diverges depending on shape of curves and/or location of operating point. Damping factor provides stability to successive substitution and it was observed that it converges for less number of iteration, speeding up the function. The damping factor was set as 0.9 as it showed full stability during testing, although a more optimum value may be available for a particular set of curves. A future version may have an improved selection algorithm for the damping factor itself.

9.10 Steam Systems and Component Models

A steam system uses the vapor phase of water to supply enthalpy or kinetic energy through the piping network. In case of EnergyPlus, the steam system is designed to provide energy solely for the building heating requirements. Hot steam from the boiler or steam generator in buildings can be used to heat a conditioned space with suitable heat transfer equipment such as fan-coils units, unit-heaters, radiators and convectors or steam can also heat water through shell and tube heat exchangers, and hot water can be supplied to the terminal units to provide the zone heating requirements.

The advantages that steam system offer over hot water or other heating systems are:

1. Steam flows through the system unaided by external energy source such as pumps; pressure difference moves steam across the system.
2. Steam, because of its low-density, can be used in high-rise buildings where water systems create excessive pressure.
3. Terminal units such as heating coils can be added or removed without making any changes to the system.
4. Steam components can be repaired or replaced by closing the steam supply without the difficulties associated with draining and refilling like in the water systems.
5. Steam is pressure-temperature dependent, therefore the system temperature can be controlled by varying either steam pressure or temperature.
6. Steam can be distributed through out the system without any change in temperature.

In view of the advantages mentioned, the steam systems are suitable for applications where heat is required for process and comfort heating such as in industrial plants, hospitals, restaurants, dry cleaning plants laundries and commercial buildings. They are also suitable in places where the heating medium has to travel great distances such as in facilities with scattered building locations or where the building height would result in excessive pressure in a water system, or locations where the load changes occur intermittently. Thus steam system is an essential and necessary development step for EnergyPlus.

From EnergyPlus simulation point of view, the advantage associated with a steam system is that steam can be distributed through out the system without change in temperature. This means that the boiler outlet temperature can simply be set equal to the heating coil inlet temperature for a steam system.

Another simulation-based advantage associated with the steam system is Steam Quality, which does not change from boiler outlet to coil inlet. Actual building steam systems are equipped with condensate drains through out the system, these drains remove, almost immediately any condensate that is formed during steam transportation, thereby maintaining the steam quality at constant value of 1.0 through out the high-pressure steam side.

The HVAC steam system implementation includes simulation models for two phase steam equipment like steam boiler, steam to air heating coils, steam pipes and condensate pumps, which can be connected to the generic loop framework.

9.10.1 Steam Loop Assumptions

To replicate the working of an actual building steam system in a satisfactory manner with simulation, it was necessary to make certain assumptions. These assumptions help simplify the loop complexity and increase usability. The effects of the assumptions made are described in detail below.

The following figure describes the Temperature Entropy Ts diagram based on which the steam system operates in EnergyPlus. The steam side of the loop operates on constant saturation pressure of steam: PSteam, the waterside of the loop operates at atmospheric pressure Patm.

It should be noted that the figure is simply a schematic and not a scaled representation of the process on a Mollier Chart. For the following descriptions, please refer to the schematic figure above.

Figure 9.10: Schematic of Temperature – Entropy Diagram for Steam loop

- Process 1–2 on the Ts diagram, represents condensation of steam in the coil at constant pressure; this is where the steam gives up latent heat to the zone.
- Process 2–3 represents the subcooling of condensed steam at higher pressure, this subcooling takes place inside the steam coil, just before the steam trap. The delta temperature represented by 2–3 is the degree of subcooling in the steam coil, and is a user input to the steam coil. This subcool generally accounts for 1 to 2% of the total heat transfer in the steam coil.
- Process 3–4' represents the isenthalpic expansion of water from high-pressure steam side to atmospheric pressure across the steam trap. As steam gives up its latent heat at the steam coil the condensate that forms in the steam coil still exists at higher pressure. This condensate is discharged to a lower pressure across the steam trap, this condensate contains more heat than necessary to maintain the liquid phase at the lower pressure, this excess heat causes some of the condensate to vaporize or flash to steam at lower pressure at some quality. The amount of water that flashes to steam can be calculated by the following equation

$$\%Flash\ Steam = \frac{h_{4'} - h_4}{h_{fg}} \times 100 \quad (9.38)$$

Where $h_{4'}$ is Enthalpy of liquid at steam pressure just before condensate is supposed to leave the coil. Enthalpy at Point 3 is equal to enthalpy at point 4', since it is an isenthalpic process, and h_{fg} is the latent enthalpy of the fluid at atmospheric pressure.

For example, water at 102°C and 120 Kpa flashes to steam at 100°C and atmospheric pressure, with quality equal to 0.003. This results in loss of some latent capacity of steam and is one of the terms contributing to loop loss in steam system.

- Process 4'- 4 represents the condensation of the flashed steam, which has exited from steam trap into the condensate drain. Condensation occurs at atmospheric pressure P_{atm} , there is loss in latent capacity due to this unavoidable process, only condensate can be returned back to the boiler in a steam system.
- Process 4-5 represents the loop sub cooling at atmospheric pressure; this is the sub cooling of the condensate that takes place during condensate return to the boiler because the return loop is not insulated, loop sub cooling is of the order of 20°C to 30°C. This is a user-defined input in every steam coil, because the variability in location of steam coils in a building will result in different condensate return temperatures for each of the coils.
- Process 5-6 represents the temperature and pressure rise in condensate due to pump heat addition. The pumping process generates heat, which is added to the condensate. The condensate is pumped back to the boiler at higher pressure.
- Process 6-2 represents the sensible heat addition by the boiler to the return condensate.
- Process 2-1 represents the latent enthalpy of steam, added by the boiler to the water to convert it to steam at saturation pressure.
- Point 3, which is outlet of the coil and Point 5, which is inlet of the pump are specified directly by the user, subsequently the loop losses in EnergyPlus are directly summed up as

the enthalpy difference between point 3 and 5, which is calculated by fluid property routines in EnergyPlus. This helps to maintain flexibility and at the same time helps negate the intermediate points calculation in the system.

Aspects of the steam loop such as quality of steam, steam pressure, and steam generation which play an important role in EnergyPlus simulation are described in following sections.

9.10.1.1 Constant Pressure Steam loop

The steam loop in EnergyPlus is pressure driven and it is assumed to operate at constant pressure on the gaseous-steam part, while the condensate return loop is assumed to operate at atmospheric pressure. The steam loop essentially operates at saturation pressure corresponding to the steam temperature; the steam boiler serves to maintain the loop temperature. The boiler model determines the amount of energy required to generate the required amount of steam.

Factors such as friction in pipes, which tend to cause small amount of pressure drop in steam loop are neglected in the model. It is assumed that the steam pipes are fairly well insulated to prevent heat loss and subsequent condensation of steam in the pipes. In actual systems small quantities of steam, which condenses due to heat loss during transportation is removed immediately from the system by steam drains. This helps eliminate water hammer, degradation of steam quality and heat transfer capability.

9.10.1.2 Steam Generation at Saturated Conditions:

Building steam heating systems avoid supplying superheated steam because superheat damages the building HVAC equipment. Superheated steam is generated only if there is a cogeneration power system in building such as steam turbine, which requires superheated steam. The purpose of having superheated steam is redundant for building steam heating systems because the amount of energy carried by the same is negligible compared to the latent heat. A simple enthalpy calculation, based on each unit of steam mass flow rate (1 kg/s), has been provided in this section to describe the negligible effect of superheat..

Case 1: Loop Operating at Saturation Conditions (no superheat), calculating enthalpy of saturated steam at boiler outlet temperature.

Boiler Outlet Temperature = 105°C,

$$h_{Case1:NoSuperheat} = [h_{f_{105^{\circ}C}}] \quad (9.39)$$

$$h_{Case1:NoSuperheat} = 2684000 \quad J \quad (9.40)$$

Case 2: Loop operating with Superheated steam, calculating enthalpy of superheated steam for 5°C superheat.

Degree of Superheat = 5°C

Boiler Outlet Temperature = 110°C,

$$h_{Case2:Superheat} = [h_{f_{110^{\circ}C}}] \quad (9.41)$$

$$h_{Case2:Superheat} = 2691000 \quad J \quad (9.42)$$

The energy difference between the superheated state and the saturated state as calculated in the following equation. A 5°C superheat provides only a 0.2608% increase in heat transfer. The advantage of this additional increase in heat transfer is negligible, especially when considering the economic aspect of sizing a bigger heat exchanger to accommodate additional superheat transfer. The detrimental effects of superheated steam on the building HVAC system also come into effect once superheat is used.

$$\Delta Q_{2-1} = \frac{2691000 - 2684000}{2684000} \times 100 = 0.2608 \text{ percent} \quad (9.43)$$

Based on the reasoning above the steam loop in EnergyPlus is designed and implemented to operate at saturated conditions.

9.10.1.3 Steam Quality

The boiler operation is assumed capable to generate steam at quality equal to 1.0 every time. This is a reasonable assumption, since in practice the variability in generated steam quality would only occur if the boiler operation were not properly controlled.

The steam loop is assumed to have perfect transport mechanism. There is no transportation losses due to friction and heat transfer with surroundings. This assumption helps maintain the quality of steam through out the system constant value of either 0 or 1.

Steam enters the coils at boiler outlet conditions. Steam coils are designed with steam traps, which only allow condensed steam to leave the coil; hence the steam always condenses and leaves the coil at quality of 0.0.

With the above simplifying assumption enables the EnergyPlus steam loop to be solved without problems.

9.10.1.4 Steam Traps

Steam traps are essential part of the steam system; they are indirect flow controllers of the loop. Purpose of steam trap is to allow only condensate out of the coil from higher-pressure steam to lower atmospheric pressure condensate return line. Points 3-4', in schematic Figure 9.10, represent this process across the steam trap on the Ts diagram. The expansion process across the steam trap is assumed to be isenthalpic. There is possibility of flashing of high-pressure condensate across the trap because of pressure drop, resulting in generation of steam at lower pressure, this steam generated at lower pressure subsequently condenses in the return piping, and heat is lost to the atmosphere. This heat lost is a part of the steam loop losses.

Steam traps are modeled in the EnergyPlus steam coil by assigning the condensate outlet from the coil a quality of 0.0 and sub cooling the condensate at lower pressure.

Although condensate from the steam coil contains valuable heat, attempting to utilize this heat by holding the condensate in the coil reduces the heat transfer area. It causes operational problems because it retains air, which further reduces heat transfer and non-condensable gases such as carbon dioxide, which cause slow corrosion of the steam coil. Steam moves rapidly in mains and supply piping so when condensate accumulates to the point where the steam can push a slug of it, serious damage can occur from the resulting water hammer, hence the condensate should be immediately removed from the steam coil. This is achieved with steam traps.

Hence an ideal steam trap should remove all condensate, air, and non-condensable gases that might be in the system, with little or no loss of steam.

9.10.1.5 Loop Losses

Subcooling of condensate in condensate return piping and flash steam condensing across the steam trap constitute the unavoidable loop losses in the EnergyPlus simulation steam system. These losses can be inferred from Figure 9.10 and are summed up by calculating enthalpy difference between points 3 and 5 on the schematic Ts diagram.

Unavoidable losses in the EnergyPlus steam loop occur due to pressure drop across the steam trap, which causes flashing of steam and loss in some percentage of latent heat of steam, process 3-4' and 4'-4 on the Ts diagram in Figure 9.10. The condensate is pumped backed to the boiler through return pipe network, which is not insulated. Sub cooling of the condensate occurs in the return network, represented by process 4-5 on the Ts diagram in Figure 9.10. This loop sub cool contributes to significant percentage of loop losses.

In practical systems the return pipeline to the boiler is not insulated despite the condensate containing some valuable heat, however due to low mass flow rate of steam, this amount is negligible and only recovered if separate heat recovery systems are used by coupling them to the loop. The condensate is occasionally collected in a receiver and then pumped back to the boiler. EnergyPlus simulation mimics practical systems by assumed that the return pipeline is not insulated and accounts for this by calculating loop losses.

The loop losses are calculated in the steam coil simulation model rather than the steam pipe simulation, because the condensate sub cool in the return loop is a direct function of the location of the steam coil in the building. In building energy software like EnergyPlus the user would have a fair idea about location of steam coils rather than the location of condensate return piping.

9.10.2 Steam To Air Heat Exchanger

9.10.2.1 Description of Model:

The steam to air heat exchanger (Coil:Heating:Steam input object) is the terminal equipment in the steam loop on the demand side that satisfies the heating requirements of the various zones. The steam-to-air heat exchanger simulation model in EnergyPlus calculates the mass flow rate of steam desired to meet the heating demand.

A heating coil can be used either as a zone coil or a coil in the air loop depending on the user and application. The steam coil simulation model is designed to take these two locations into consideration. An air-loop steam heating coil is temperature controlled and the zone coil is zone load controlled. This relatively simple and straightforward concept of coil control is preferred over the iterative method to determine mass flow rates using various numeric techniques. The assumptions made in the coil model are described in the section below.

This model accounts for the latent heat transfer and sensible cooling of water; the question of superheat is eliminated because steam is assumed to be saturation conditions. Steam enters the coil at quality equal to 1.0, at saturation temperature and leaves the coil with desired degree of subcooling. The user inputs the desired degree of subcooling, which determines the condensate outlet condition from the coil.

EnergyPlus heat balance methods determine the amount of heating required in the zone to maintain the zone at the desired conditions. Based on this value of heating load, the zone coil determines the mass flow rate of steam required since the heating coil load is the control variable in a zone coil. The following equation describes this calculation to determine steam mass flow rate required for the desired heating capacity. The steam latent heat of vaporization, h_{fg} and the

condensate heat capacity, $C_{p,w}$ are evaluated at the steam coil inlet node temperature and standard barometric pressure of 101325.0 Pa.

$$\dot{m}_{zc} = \frac{Q_{zc}}{h_{fg} + c_{p,w} \times \Delta T_{sc}} \quad (9.44)$$

In case of the air loop-heating coil, the load on the coil is calculated within the coil simulation routine. The air loop coil is setpoint controlled and heats the air to maintain the air stream at the desired setpoint, the setpoint is a user input, generally in the range of 12°C to 16°C. The following equation describes the air loop coil load.

$$Q_{al} = \dot{m}_a \times c_{p,a} \times [T_{sp} - T_a] \quad (9.45)$$

The following equation is used to determine the steam mass flow rate required by the air loop coil to meet the heating requirements.

$$\dot{m}_{al} = \frac{Q_{al}}{h_{fg} + c_{p,w} \times \Delta T_{sc}} \quad (9.46)$$

Each of the zone coils and air loop coils are simulated independently and the steam mass flow rates for each is added over every time step of simulation. This value of total mass flow rate is reported to the boiler, which in turns supplies this required amount of steam.

The control of the steam to air coil is a complex issue. The loop splitter-splits total steam flow from the boiler and delivers the required amount of steam to each of the coils connected to the loop through the steam pipe network. In cases where the system is undersized, the coils demand more mass flow rate of steam than the boiler can generate. The splitter in this case cannot provide all the coils with requested steam mass flow. Subsequently the coils are starved of steam and the zone temperatures fall. In some cases the user might schedule off the coil, they should then not operate. These issues need to be taken care of in the implementation of the steam coil simulation model. The control algorithm for the steam coil operation under various situations is best explained with the help of pseudo-code using standard IF THEN ELSE blocks.

*****PSEUDO CODE SECTION STARTS*****

9.10.2.2 Steam coil is zone load controlled.

$$IF \ (Coil = LoadControlled) \ THEN \quad (9.47)$$

Check for operational conditions only then continue simulation further. The operational conditions are the inlet mass flow rates of steam and air to the coil, the user schedule to the coil and heating load on the coil. The coil is simulated only if these conditions are met.

$$IF \ [(\dot{m}_s > 0) .and. (\dot{m}_a > 0) .and. (Schedule = ON) .and. (Q_{ZC} > 0.0)] \ THEN \quad (9.48)$$

If the heating demand from the zone-heating coil is greater than coil capacity, then the heating coil is undersized, and the coil can only deliver its maximum heating capacity to the zone. In this case the heating demand on the coil is set equal to this lower value of maximum heating capacity. If the above is not true then the simulation ignores this statement and proceeds to the next one.

$$IF \ [(Q_{ZC} > Q_{ZC_{Max}})] \ THEN \ [Q_{ZC} = Q_{ZC_{Max}}] \quad (9.49)$$

The following equation calculates the steam mass flow rate required by the coil. This flow rate is required to meet the heating requirements for the zone. This value of mass flow is requested from the splitter outlet.

$$\dot{m}_{zc} = \frac{Q_{zc}}{h_{fg} + c_{p,w} \times \Delta T_{sc}} \quad (9.50)$$

If the calculated value of steam mass flow with the previous equation is greater than the maximum inlet steam flow that the splitter can provide to the coil at that time step. Then the requested coil flow rate is set equal to the inlet steam flow rate. This is the maximum amount of steam that can be supplied to the coil at this moment. The coil can provide heating capacity equal to this limited amount of steam. If the requested flow rate is less than what the splitter can provide then the program ignores the logic of the IF Loop Below

$$IF (\dot{m}_{zc} > \dot{m}_{in}) THEN (\dot{m}_{zc} = \dot{m}_{in}) \quad (9.51)$$

Re-Calculating the coil heating capacity with the lower value of steam mass flow rate.

$$Q_{ZC} = \dot{m}_{zc} \times (h_{fg} + c_{p,w} \times \Delta T_{sc}) \quad (9.52)$$

$$END IF \quad (9.53)$$

The following equations calculate the outlet condensate-water and outlet air temperatures to the zone based on the amount of heating capacity provided by the coil.

$$Tw_{out} = Ts_{in} - \Delta T_{sc} \quad (9.54)$$

$$Ta_{out} = Ta_{in} + \frac{Q_{zc}}{\dot{m}_a \times c_{p,a}} \quad (9.55)$$

ELSE Else the coil is not running and in this case set outlets to inlets.

$$\dot{m}_s = 0, \quad \dot{m}_a = 0, \quad Q_{zc} = 0, \quad Tw_{out} = Ts_{in}, \quad Ta_{out} = Ta_{in} \quad (9.56)$$

$$END IF \quad (9.57)$$

END IF End IF for the zone load controlled coil.

9.10.2.3 Steam coil is temperature controlled.

$$IF (Coil = TemperatureControlled) THEN \quad (9.58)$$

Check for operational conditions and continue simulation further. The operational conditions are the inlet mass flow rates of steam and air to the coil, the user schedule to the coil and delta temp exists between the setpoint and air inlet temperature. The coil is simulated only if these conditions are met.

$$IF \left[\begin{array}{l} (\dot{m}_s > 0) .and. (\dot{m}_a > 0) .and. (Schedule = ON) .and. \\ (T_{SP} - Ta_{in}) > 0.0001 \end{array} \right] THEN \quad (9.59)$$

Calculate the heating load on the coil using setpoint and inlet air temperatures.

$$Q_{al} = \dot{m}_a \times C p_a \times [T_{sp} - T_a] \quad (9.60)$$

The logic loop for temperature-controlled coil begins here. In case the heating load on the coil is negative, which might occur if the setpoint is below the air inlet temperature, the coil operation needs to be shut off.

$$IF (Q_{al} < 0.0) THEN \quad (9.61)$$

Assigning the inlet to outlet and mass flows to zero shuts off the coil operation.

$$\dot{m}_s = 0, \quad \dot{m}_a = 0, \quad Q_{al} = 0, \quad Tw_{out} = Ts_{in}, \quad Ta_{out} = Ta_{in} \quad (9.62)$$

If air loop coil load is greater than maximum coil load calculated at maximum steam mass flow rate, in such case the coil is undersized, the coil can only deliver to the air loop its maximum heating capacity. Setting the air loop coil load equal to maximum load on coil. If this is not the case then the program ignores this ELSE IF block and proceeds to the next one.

$$ELSE IF [(Q_{al} > Q_{al_{Max}})] THEN [Q_{al} = Q_{al_{Max}}] \quad (9.63)$$

If the heating coil is under sized then it can only provide its maximum heating capacity, in this case the air temperature will be below the setpoint, and is calculated based on this maximum allowed value of heat transfer. Calculating the air and water outlet temperatures.

$$Ta_{out} = Ta_{in} + \frac{Q_{al}}{\dot{m}_a \times c_{p,a}} \quad (9.64)$$

$$Tw_{out} = Ts_{in} - \Delta T_{sc} \quad (9.65)$$

Determining the mass flow rate of steam required by the undersized coil. This value of mass flow is requested from the splitter outlet.

$$\dot{m}_{al} = \frac{Q_{al}}{h_{fg} + c_{p,w} \times \Delta T_{sc}} \quad (9.66)$$

A check is introduced to determine if this requested mass flow rate is greater than what the splitter outlet can provide to the coil at that particular time step of simulation. In this case the requested value of steam mass flow is greater than what the splitter can provide to that coil, subsequently set the requested coil flow rate equal to the inlet steam flow rate, delivered to the coil by the splitter. This is the maximum amount of steam that can be supplied to the coil at this moment. If the requested flow rate is less than what the splitter can provide then the program ignores the logic of the IF Loop.

$$IF (\dot{m}_{al} > \dot{m}_{in}) THEN (\dot{m}_{al} = \dot{m}_{in}) \quad (9.67)$$

Re-Calculating the coil heating capacity and air outlet temperature with the lower value of steam mass flow rate provided by the splitter.

$$Q_{al} = \dot{m}_{al}(h_{fg} + c_{p,w} \times \Delta T_{sc}) \quad (9.68)$$

$$Ta_{out} = Ta_{in} + \frac{Q_{al}}{\dot{m}_a \times c_{p,a}} \quad (9.69)$$

$$End\ IF \quad (9.70)$$

If the above two IF ELSE block are not true, then the coil is perfectly sized, the splitter can provide the required mass flow rate to the coil, and the setpoint temperature can be maintained as desired.

$$ELSE \quad (9.71)$$

The ideal case where the coils can meet the required setpoint temperature. Setting the outlet air temperature to the setpoint, calculating the water outlet temperature and the required steam mass flow rate.

$$Ta_{out} = T_{SP} \quad (9.72)$$

$$Tw_{out} = Ts_{in} - \Delta T_{sc} \quad (9.73)$$

$$Q_{al} = \dot{m}_a \times c_{p,a} \times [T_{sp} - T_a] \quad (9.74)$$

END IF End IF statement, for the air coil heating loop.

END IF End IF statement for the operating condition loop

END IF End IF statement for the Temperature Setpoint Controlled Coil

The steam coil model encapsulates the above described control logic along with the other necessary simulation code for reading the user inputs and the code for reporting the simulation results.

*****PSEUDO CODE SECTION ENDS*****

The two main types of coil control discussed above are followed by common simulation code in the coil model. This code calculates the loop losses occurring due to flashing of steam across the steam trap, isenthalpic expansion occurring across the steam trap due to pressure difference, and loss occurring due to condensate sub cooling returning back to the boiler. The above-mentioned two processes are explained in Figure 9.10 as process 3-4' and 4-5.

The loop loss calculation is included in the steam coil simulation model, because the degree of subcooling in the return piping for the condensate is solely a function of the coil location. In practical applications a coil, which is further away from boiler would return back condensate at much lower temperatures compared to coil, which is closer to boiler. Hence for user ease it makes perfect sense to include this input into the coil and calculate the pump inlet conditions in the steam coil simulation model itself.

The loop losses in the EnergyPlus steam system is calculated by determining the enthalpy difference between point 3 and 5. The simulation code that determines the loop loss is common to both the coil models, this helps determine the condensate pump inlet conditions.

The following equation is used to calculate condensate enthalpy at coil outlet, point 3 in Figure 9.10. Point 2 represents condensed steam; enthalpy at this point is calculated directly by EnergyPlus property routines.

$$h_{f3} = h_{f2} - c_{p,w} \times \Delta T_{SC} \quad (9.75)$$

Point 4 is at atmospheric pressure, enthalpy at this is calculated directly by EnergyPlus property routines. It is saturation enthalpy of steam at quality equal to 0.0 and saturation temperature at atmospheric pressure.

Point 5 is inlet to the pump; enthalpy at this point is calculated with the following equation. The delta temperature represents the degree of loop subcooling occurring during condensate return back to the pump.

$$h_{f5} = h_{f4} - c_{p,w} \times \Delta T_{LSC} \quad (9.76)$$

Subsequently loop loss for each coil would be enthalpy difference between 3 and 5 and is calculated using the following equation

$$\Delta Q_{loss} = \dot{m}_s \times (h_{f3} - h_{f5}) \quad (9.77)$$

The total loop loss would be a summation of the individual losses occurring for each of the steam coils, this is the unavoidable loss in current steam system.

A simple schematic describing the coil framework, inlet and outlet conditions to the coil and the flow rate resolution is shown in Figure 9.11. Five zone coils and one air loop coil are described in the picture, Qzone is calculated by EnergyPlus heat balance and it is the input to the zone coils, while in air loop coil the Qal is calculated within the simulation model

Figure 9.11: Schematic of Steam Coil Connection to the Steam Loop

As depicted in the figure above the steam condenses on entering the coils, sub cools by the specified amount and leaves the heat exchanger as water. The steam in the heat exchanger at any moment has to condense eventually since steam trap at the outlet to coil permits only water to leave the coil. Steam traps being an essential part of the loop are modeled by controlling the coil outlet condition at quality equal to 0.0. Subsequently the amount of heat transferred to air is a direct function of latent heat and the degree of sub cooling desired by the user.

9.10.2.4 Model Assumptions

The steam coils works on two basic assumptions, firstly, it's assumed that perfect latent heat transfer takes place over every time step, secondly, the user specified degree of subcooling occurs in the coil. Steam coils always use steam traps- purpose of which is to only let water out of the coil, hence the modeler knows with certainty the outlet dryness fraction of steam coil is at quality equal to 0.0, because water leaves coil. Hence the heat transfer is equal to latent heat of steam, which is independent of UA value of coil when averaged over time step of EnergyPlus simulation.

In practice there is 1% to 2% sub cooling of the outlet water stream, the user with desired degree of subcool input accounts for this, subsequently UA calculation for the coil model become superfluous and is neglected in the EnergyPlus model.

Ideally for sub-cooling UA would play an important role, however sub cooling in steam coil constitutes negligible amount of heat transfer, hence this model avoids the UA calculation. This is a very reasonable assumption since sensible heat transfer is barely 1% to 2% of the total heat transfer in steam coils, simply due to large latent heat capacity of coil. NOTE in his thesis he gives a little example here which is probably not necessary for the Docs.

9.10.3 Condensate Pump

The steam loop operates at a pressure differential over the gaseous and liquid part of the loop; subsequently a condensate pump is required to pump the condensed steam back to the boiler at the required pressure. Two main reasons for condensed steam to be returned to the boiler is energy savings in reheating water since the water is at high temperature, secondly the water is treated by chemicals to prevent corrosion in the pipes and equipment. This is an expensive process and therefore it's economical to reuse the chemically treated water.

9.10.3.1 Description of Pump Model

The pump model designed in EnergyPlus is a variable speed condensate pump. Condensation of steam produces water, this takes place at variable rate hence the return water flow rate would be variable but constant when averaged over a time step. Condensate pumps operate intermittently; the pump will run at its capacity if a load/flow rate is sensed and will shut off if there is no load on the loop.

The condensate pump essentially operates between maximum and minimum flow rates, which are the physical limits of the device. The pump is designed to meet the flow request made by demand side components, which are the coils in case of steam system.

The main difference between the variable volume pump and the constant volume pump is the Part Load Performance Curve. The fraction of full load power is determined by the third order equation, which follows:

$$P_{Frac} = C_1 + C_2 \times PLR + C_3 \times PLR^2 + C_4 \times PLR^3 \quad (9.78)$$

In preceding equation, PLR stands for part load ratio while C1 to C4 are pump- part load coefficients. The following five equations describe the pump operation and calculation of pump output variables such as total power, shaft power and pump heat to fluid etc.

$$\dot{V} = \frac{\dot{m}}{\rho_w} \quad (9.79)$$

Using the previous equation the pump volume flow rate is determined; the user enters the value of the maximum and minimum volume flow rate.

The pump part load ratio is a function of the pump volume flow rate at any instance determined by the loop and the pump nominal volume flow rate, which is a user input. The following equation calculates the Part Load Ratio (PLR).

$$PLR = \frac{\dot{V}}{\dot{V}_{nom}} \quad (9.80)$$

The pump power is calculated as described in following equation. Pump power is a product of fractional full load power and pump nominal power use. Fractional full load power is calculated in a preceding equation while pump nominal power is a user input to the model.

$$P = P_{Frac} \times P_{Nom} \quad (9.81)$$

The shaft power is simply the product of the pump power and motor efficiency, this is required to calculate the heat generated and delivered to the fluid being pumped. The following equation is used to calculate pump shaft power.

$$P_S = P \times \eta_m \quad (9.82)$$

The model assumes that all heat generated and lost ends up in the fluid to the loop, this assumption is necessary since EnergyPlus operates on a closed loop. The following equation is used to calculate the pump heat to the fluid, which raises the condensate temperature. The pump motor efficiency is defined by the user input and the fractional motor loss to fluid is the amount of heat generated by the pump motor that is added to the fluid loop (as opposed to being lost to the environment where the pump is located). *FracMotorLossToFluid* is also a user input

$$P_H = P_S + (P - P_S) \times F_{mf} \quad (9.83)$$

The shaft power relates to the increase in head through the pump to the loop operating pressure. The head lost through the piping network due to frictional heat, represents the heat gain by the fluid throughout the network. For model simplicity, this heat is added along with the heat resulting from the pump motor. The difference between the pump power and the shaft power is the inefficiency of the pump, or the amount of energy input into the pump that the motor converts to heat rather than mechanical energy. Some of this heat is added to the fluid being pumped. These two above-mentioned terms are used in the *PumpHeatToFluid* equation for calculating P_H shown above.

A simple energy balance over the pump based on the pump inlet conditions and flow rate is used to calculate the pump outlet temperature. The condensate outlet temperature from the pump is slightly higher than inlet due to the heat dissipation to the fluid steam during pumping action. This is calculated in the following equation. The pump water outlet temperature is the boiler inlet temperature.

$$T_{w_{out}} = T_{w_{in}} + \frac{P_H}{\dot{m} \times c_{p,w}} \quad (9.84)$$

Pump control is an important part of the steam loop. Existing control structure from EnergyPlus has been utilized to operate the condensate pump. The pump is simulated first on the supply side of the loop after the demand side loop has determined what the demand on the loop will be.

A simple schematic describing the flow across the pump is shown in the following figure

Figure 9.12: Schematic of Condensate Pump in Steam Loop

9.10.3.2 Model Assumptions

Due to the fact that a pump is a mechanical device that acts on the fluid it is circulating, it causes the fluid temperature rise. The EnergyPlus model assumes that all pressure increase caused by the pump will eventually be lost due to friction, and that friction will be added as heat to the fluid. Although the plant and condenser loops in steam systems are simple pressure-based models, a simplifying assumption has been made in EnergyPlus to assume the heat resulting from the pump itself and from friction throughout the loop is added at the fluid being pumped. In case of steam, this assumption is easily justified because the volume flow rate of water is very small in the loop.

9.10.4 Steam Pipe

9.10.4.1 Description of Model

The steam pipe essentially serves as “energy carrier” and transfers the node conditions from one point of the pipe to another. It’s simply a node inlet to node outlet connection, transferring values from inlet to outlet. The pipe forms an important part of the framework connecting various equipments from the supply to demand side and inlet and outlets of the equipments.

The steam pipe supports two additional properties, which are pressure and quality, unlike its water counterpart. Pipe simulation model in EnergyPlus is hardwired to water as a fluid type; this necessitated the development of similar model supporting pressure and quality for the steam system.

9.10.4.2 Model Assumptions

The piping network in the developed steam system is assumed to perfectly distribute steam, return the condensate, and remove air and non-condensable gases. It is also assumed that the pipes are sized to distribute steam not only at full load but also at partial loads and excess loads that can occur during system warm up.

The steam pipe is perfect and there is no losses occurring in transportation. This assumption was necessitated since if pipe losses were accounted for, the loss would have to be distributed into the zone, which would be a very complex issue in itself, since in EnergyPlus the pipes are unaware of their locations and simply serve as connectors.

Chapter 10

Loop, Equipment Sizing and other Design Data

The importance of correct equipment sizing is often ignored in discussions of building simulation methods. The lack of reliable, efficient and flexible sizing calculations can present a serious barrier to the adoption and acceptance of building simulation programs. This section describes the sizing methodology implemented in EnergyPlus. This method includes:

1. A zone by zone heat balance load and air-flow calculation for multiple design days;
2. Significant user control with modest input requirements;
3. Zone, system and plant level calculations of design heating and cooling capacities and fluid flow rates;
4. Modular, component-specific sizing algorithms for each HVAC component.
5. Options for monitoring how the initial sizes operate over multiple design days and then making adjustments and repeating plant level calculations

10.1 Sizing Manager

The sizing calculations in EnergyPlus are managed by a sizing manager contained in the software module *SizingManager*. The main sizing manager routine *ManageSizing* is called from *ManageSimulation* before the annual simulation sequence is invoked. *ManageSizing* performs the following tasks.

- By calling *GetSizingParams*, *GetZoneSizingInput*, *GetSystemSizingInput* and *GetPlantSizingInput* reads in all the user sizing input contained in objects *Sizing:Parameters*, *Sizing:Zone*, *Sizing:System* and *Sizing:Plant*. These objects and their data are described in the EnergyPlus Input Output Reference, Group Design Objects.
- Set the *ZoneSizingCalc* flag equal to *true*.
- Loop over all the sizing periods by each day. **This starts the zone design calculations.**

- Call *UpdateZoneSizing(BeginDay)* to initialize zone design load and flow rate sequences.
- Loop over hours in the day
 - * Loop over zone time steps in each hour
 - Call *ManageWeather* to obtain outside conditions for this time-step.
 - Call *ManageHeatBalance* to do a full heat balance calculation for each zone. The call to *ManageHeatBalance* also brings about an HVAC simulation. *ZoneSizingCalc = true* signals the *HVACManager* to ignore the real HVAC system and instead run the ideal zonal system (described below) used to calculate design loads and flow rates. *HVACManager* also calls *UpdateZoneSizing(DuringDay)* to save the results of the ideal zonal system calculation in the design load and flow rate sequences.
- Call *UpdateZoneSizing(EndDay)* to calculate peaks and moving averages from the zone design sequences for each design day.
- Call *UpdateZoneSizing(EndZoneSizingCalc)* to calculate for each zone the peak heating & cooling loads and flow rates over all the sizing periods (design days and sizing periods from the weather file, if specified). The corresponding design load and flow rate sequences are saved for use in the system design calculations. **This ends the zone design calculations.**
- Set the *SysSizingCalc* flag equal to *true*.
- Call *ManageZoneEquipment* and *ManageAirLoops* to read in the zone and central system inputs needed for the system design calculations. The program needs enough information to be able to figure out the overall air loop connectivity.
- Loop over all the sizing periods by each day. **This starts the system design calculations.**
 - Call *UpdateSysSizing(BeginDay)* to initialize system design load and flow rate sequences.
 - Loop over hours in the day
 - * Loop over zone time steps in each hour
 - Call *ManageWeather* to obtain outside conditions for this time-step.
 - Call *UpdateSysSizing(DuringDay)* to save the results of the system design calculations in the system design load and flow rate sequences.
 - Call *UpdateSysSizing(EndDay)* to calculate peaks and moving averages from the system design sequences for each sizing period.
- Call *UpdateSysSizing(EndSysSizingCalc)* to calculate for each system the peak heating & cooling loads and flow rates over all the sizing periods (design days and sizing periods from the weather file, if specified). The corresponding design load and flow rate sequences are saved for use in the component sizing calculations. **This ends the system design calculations.**
- And this ends the tasks of the Sizing Manager.

10.2 HVAC Sizing Simulation Manager

After the Sizing Manager has completed its initial pass, all the data needed to complete a running model should be available and the program is ready to run the main simulation(s). However, as of Version 8.3 there is now an option of applying some advanced sizing calculations using what are called HVAC Sizing Simulations.

With this new sizing method we distinguish between different kinds of simulations and introduce some new terminology. The Primary Simulations are the main simulations that are the final version of the model to be run. Prior to Version 8.3, these are just the usual simulations with the final results. When the program is running the zone heat balance model over the sizing periods for zone sizing (for step 3 in the Sizing Manager description above), we call those Ideal Loads Sizing Simulations. When the program is running the zone heat balance model over the sizing periods for component loads calculations we call those Ideal Component Loads Simulations. HVAC Sizing Simulations are a kind of simulation, where the program creates copies of sizing periods and runs them as complete EnergyPlus simulations with the most current equipment sizes and full HVAC systems. The advanced sizing algorithms monitor what occurred during those sizing periods and determines if new size results are needed and signals systems and components to repeat their sizing calculations. The process can repeat in an iterative manner and a Sizing Pass refers to a set of the HVAC Sizing Simulations for each of the sizing periods (e.g. two design days).

If the user has selected a sizing option that requires HVAC Sizing Simulations the main `ManageSimulation` will call `ManageHVACSizingSimulation` before going on to the main simulations.

- Instantiate a new `HVACSizingSimulationManager` object.
- Call `DetermineSizingAnalysesNeeded()`. This checks what user input and decides what, if anything, needs to be done for advanced sizing algorithms. This involves, for example, checking the input in `Sizing:Plant` object to see if coincident sizing option has been selected.
- Call `SetupSizingAnalyses()`. This method creates the data logging apparatus needed to monitor operation during HVAC Sizing Simulations. Individual sizing algorithms include selecting specific variables, such as system node states or load output variables, that will be recorded.
- Loop over some number of Sizing Passes. The set of sizing periods, run as HVAC Sizing Simulations, can iterate up to a maximum limit on the number of passes
 - Loop over all the sizing periods by each day. This runs the HVAC Sizing Simulations which have basically the same set of calls as are used for marching through time and calling of EnergyPlus modeling for the Primary Simulations (in `ManageSimulation`).
 - Call `PostProcessLogs()`. This method applies running averages (if desired) and averages system timestep data to fill zone timestep data in the records.
 - Call `ProcessCoincidentPlantSizeAdjustments()`. This method retrieves data from the logs and calls for the coincident plant sizing algorithm to execute. Set flag if the sizing analyses request another Sizing Pass. (See the section below on Coincident Plant Sizing.)
 - Call `RedoKickOffAndResize()`. The methods calls `SetupSimulation()` and sets flag to signal that system and component level sizing methods need to be called again. These are fake timesteps used to initialize and are not part of a Simulation.

- Break out of Sizing Pass loop if size results did not change or the limit on Sizing Passes has been reached.
- Empty HVACSizingSimulationManager object to free memory

Currently the only application for HVAC Sizing Simulations is to improve the sizing of plant loops using the Coincident sizing option. However this approach may be expanded in the future to extend advanced sizing methods to air-side equipment.

10.3 Zone Design Loads and Air Flow Rates

10.3.1 Overview

There is no single best way to establish design HVAC flow rates and size HVAC equipment. Different building designs, climates, and HVAC systems will impose varying constraints on the designer. The method used to size an HVAC system in a hot, moist climate such as Miami will be different than the method used for a building in Albuquerque. The type of building is also relevant - a simple watts per square foot loads estimate could be adequate for a building containing a network server farm while a detailed, dynamic loads simulation would be necessary for a passive solar building. In the end the designer's experience and engineering judgement will play an important role in any sizing calculation.

HVAC equipment sizing begins with the calculation of space heating and cooling loads. A space cooling (heating) load is defined as the rate at which heat must be removed (added) to a space to maintain a constant temperature. The current industry standard method for calculating space loads is the *heat balance method* [ASHRAE Fundamentals (2001), page 29.1; Pedersen et al., (1997); Pedersen (2001)]. Since EnergyPlus is a heat balance based simulation program it is straightforward for the program to use this method for calculating zone loads.

10.3.2 Zone Design Data Arrays

The zone design data arrays are:

ZoneSizingInput(i) stores the input data from the Sizing:Zone objects.

CalcZoneSizing(i,j) stores the results of the zone design calculations for all zones and all design days. The index i is for the controlled zones, j for design days.

CalcFinalZoneSizing(i) stores the results of the zone design calculations for the peak heating and cooling cases for each zone. The index i is for the controlled zones.

ZoneSizing(i,j) corresponds to *CalcZoneSizing* but includes the effect of the user specified sizing factor or user specified zone design flow rate.

FinalZoneSizing(i) corresponds to *CalcFinalZoneSizing* but includes the effect of the user specified sizing factor or user specified zone design flow rate.

TermUnitFinalZoneSizing(k) corresponds to *FinalZoneSizing* but includes the effect of any air system terminal unit sizing factors input with DesignSpecification:AirTerminal:Sizing objects. The index k is for each air terminal unit. There may be more or less terminal units than there are controlled zones.

The data stored in *CalcZoneSizing*, *CalcFinalZoneSizing*, *ZoneSizing*, *FinalZoneSizing* and *TermUnitFinalZoneSizing* includes the following data items.

Table 10.1: Zone Sizing Data

Name	Description
Select data from Zone-SizingInput	
DesHeatMassFlow	the zone design heating air mass flow rate in [kg/s]
DesCoolMassFlow	the zone design cooling air mass flow rate in [kg/s]
DesHeatLoad	the zone design heating load in [W]
DesCoolLoad	the zone design cooling load in [W]
DesHeatDens	the zone design heating air density [kg/m ³]
DesCoolDens	the zone design cooling air density [kg/m ³]
DesHeatVolFlow	the zone design heating air volume flow rate [m ³ /s]
DesCoolVolFlow	the zone design cooling air volume flow rate [m ³ /s]
DesHeatCoilInTemp	zone heating coil design air inlet temperature [C]
DesCoolCoilInTemp	zone cooling coil design air inlet temperature [C]
DesHeatCoilInHumRat	the zone heating coil design air inlet humidity ratio [kg/kg]
DesCoolCoilInHumRat	the zone cooling coil design air inlet humidity ratio [kg/kg]
HeatMassFlow	current zone heating air mass flow rate at the HVAC time step [kg/s]
CoolMassFlow	current zone cooling air mass flow rate at the HVAC time step [kg/s]
HeatLoad	Current zone heating load [W]
CoolLoad	Current zone cooling load [W]
HeatZoneTemp	Current zone temperature during heating [C]
HeatZoneRetTemp	current zone return temperature during heating [C]
CoolZoneTemp	Current zone temperature during cooling [C]
CoolZoneRetTemp	current zone return temperature during cooling [C]
HeatZoneHumRat	Current zone humidity ratio during heating [C]
CoolZoneHumRat	Current zone humidity ratio during cooling [C]
ZoneTempAtHeatPeak	zone temperature at maximum heating [C]
ZoneRetTempAtHeatPeak	zone return temperature at maximum heating [C]
ZoneTempAtCoolPeak	zone temperature at maximum cooling [C]
ZoneRetTempAtCoolPeak	zone return temperature at maximum cooling [C]
ZoneHumRatAtHeatPeak	zone humidity ratio at maximum heating [kg/kg]
ZoneHumRatAtCoolPeak	zone humidity ratio at maximum cooling [kg/kg]
TimeStepNumAtHeatMax	zone time step number (in the day) at the heating peak
TimeStepNumAtCoolMax	zone time step number (in the day) at the cooling peak
HeatDDNum	design day index of design day causing heating peak

Table 10.1: Zone Sizing Data

Name	Description
CoolDDNum	design day index of design day causing cooling peak
MinOA	design minimum outside air [m ³ /s]
HeatFlowSeq(i)	daily sequence of zone heating air mass flow rates (zone time step) [kg/s]
CoolFlowSeq(i)	daily sequence of zone cooling air mass flow rates (zone time step) [kg/s]
HeatLoadSeq(i)	daily sequence of zone heating loads (zone time step) [W]
CoolLoadSeq(i)	daily sequence of zone cooling loads (zone time step) [W]
HeatZoneTempSeq(i)	daily sequence of zone temperatures (heating, zone time step) [C]
HeatZoneRetTempSeq(i)	daily sequence of zone return temperatures (heating, zone time step) [C]
CooltZoneTempSeq(i)	daily sequence of zone temperatures (cooling, zone time step) [C]
CoolZoneRetTempSeq(i)	daily sequence of zone return temperatures (cooling, zone time step) [C]
HeatZoneHumRatSeq(i)	daily sequence of zone humidity ratios (heating, zone time step) [kg/kg]
CoolZoneHumRatSeq(i)	daily sequence of zone humidity ratios (cooling, zone time step) [kg/kg]

10.3.3 Zone Design Load Calculation

As described in the preceding section, the Sizing Manager initiates the zone design calculation by looping over all of the design days and calling the Heat Balance Manager for each zone time-step in each design day. The Heat Balance manager then causes the HVAC Manager to be called in a manner identical to a normal simulation. The *ZoneSizingCalc* set to *true* signals the HVAC Manager to ignore the actual HVAC system and instead calculate the design zone loads and air flow rates using an ideal zonal system.

In module *HVACManager*, subroutine *ManageHVAC* calls *SimHVAC*. *SimHVAC* checks *ZoneSizingCalc*. If it is *true*, *SimHVAC* calls *ManageZoneEquipment* and returns, rather than simulating the actual system. In turn *ManageZoneEquipment* checks if *ZoneSizingCalc* is *true*; if it is it calls *SizeZoneEquipment* rather than *SimZoneEquipment*.

SizeZoneEquipment assumes that each controlled zone is served by an ideal air conditioning unit. This unit supplies heating or cooling air at a fixed, user input temperature and humidity (specified in the Sizing:Zone objects). The units have infinite capacity: the flow rate can be any amount.

Before the ideal zone load is calculated, the function checks whether the user wants to account for the heat gain or loss caused by the ventilation air from a Dedicated Outdoor Air System (DOAS).

If the user has selected *Account For Dedicated Outdoor Air = Yes* the function performs an ideal DOAS calculation. The DOAS supply temperature is set according to the user's choice of 1 of 3 possible control strategies: *NeutralSupplyAir*, *NeutralDehumidifiedSupplyAir*, or *ColdSupplyAir*. The different strategies are:

- *DOAS Control Strategy = NeutralSupplyAir*. The purpose of this strategy is to cool or heat the outdoor air (OA) to keep it between the T_l and T_h setpoints.
- *DOAS Control Strategy = Neutral Dehumidified Supply Air*. The purpose of this strategy is to cool and dehumidify the outdoor air, then reheat it to a “neutral” temperature so that no sensible load is imposed on the space or AHU unit. The DOAS will with this strategy handle some or all of the latent load. If the outdoor air temperature is greater than T_l the outdoor air is cooled to T_l and reheated to T_h . If the outdoor air temperature is below T_l it is heated to T_h .
- *DOAS Control Strategy = ColdSupplyAir*. The purpose of this strategy is to provide cool, dehumidified ventilation air to the zone. In this case the DOAS can handle part of the sensible zone cooling load as well as meet part or all of the latent load. If the outdoor air temperature is below T_l it is heated to T_h . If it is above T_l , it is cooled to T_l .

With the DOAS supply temperature set and the air mass flow rate set to the minimum design ventilation flow rate the heat addition rate is just

$$\dot{Q}_{doa} = c_{p,air} \dot{m}_{vent,min} (T_{sup} - T_z) \quad (10.1)$$

UpdateSystemOutputRequired is then invoked to adjust the load to be met by the ideal zone system.

The ideal loads calculation steps are as follows.

- 1) Loop over all the controlled zones.
- 2) If the system is active (zone temperature not in the deadband and zone load greater than 1 watt) the sign of the zone load is used to determine whether heating or cooling is required and T_{in} and W_{in} are set to the appropriate values from the Sizing:Zone input. When the SupplyTemperature method is specified in the Sizing:Zone object, T_{in} is fixed at the cooling or heating supply temperature. When the TemperatureDifference method is selected, T_{in} is calculated at each time step using the current zone air temperature. The system output Q_{sys} is simply set equal to the zone demand - it is assumed that the ideal system can always meet the zone load. The air flow rate corresponding to the load is just

$$\dot{m}_{sys} = Q_{sys} / (C_{p,air} \cdot (T_{in} - T_z)) \quad (10.2)$$

If the system is not active, the mass flow rate is set to zero and the system output is left at zero.

- 3) The results for each zone are stored in the zone sizing data arrays.

10.3.4 Updating and Adjusting the Zone Results

The results from *SizeZoneEquipment* are at the system time-step and are for all design days. These results then need to be summed or averaged over the zone time-step, peak values calculated for each design day, a heating & a cooling load sequence chosen for each zone from all the design day results, possible further smoothing of results done, zone coil loads calculated, and user sizing multipliers or user specified design flows taken into account. These tasks are accomplished by the subroutine *UpdateZoneSizing*. It is called at the start of each design day (*CallIndicator* = *BeginDay*), at the zone time-step (*CallIndicator* = *DuringDay*), at the end of the design day (*CallIndicator* = *EndDay*) and at the end of the zone design calculation (*CallIndicator* = *EndZoneSizingCalc*).

10.3.4.1 BeginDay

The environment (in this case, a design day) name and number are stored in the zone sizing data structures

10.3.4.2 DuringDay

The calculated and stored sequences are summed or averaged over the zone time-step.

10.3.4.3 EndDay

- (1) Smooth the design sequences by applying a moving, fixed-width averaging window to the sequences. The width of the window is user specified in the *Sizing:Parameters* input object. The sequences that are smoothed are:
 - (a) *CoolFlowSeq*
 - (b) *CoolLoadSeq*
 - (c) *HeatFlowSeq*
 - (d) *HeatLoadSeq*
 - (e) *CoolZoneRetTempSeq*
 - (f) *HeatZoneRetTempSeq*
- (2) The peak heating and cooling loads and mass & volume flow rates are extracted from each set of design sequences.
- (3) Using the time of the peak and the design outside air fraction the design zone heating and cooling coil inlet temperatures and humidity ratios are calculated.
- (4) For each zone, looking at the results for all of the design days, the design days that cause the peak heating and peak cooling for that zone are chosen and the corresponding design sequences and peak loads and flow rates are saved in the *CalcFinalZoneSizing* array. This finishes the calculated - unmodified by the user - portion of the zone design calculation.

10.3.4.4 EndZoneSizingCalc

- (1) Write out onto a comma-separated file the calculated design sequences for each zone: *HeatLoadSeq*, *CoolLoadSeq*, *HeatFlowSeq*, *CoolFlowSeq* and the corresponding peaks and volumetric flow peaks.
- (2) The data in *CalcZoneSizing* and *CalcFinalZoneSizing* is moved to *ZoneSizing* and *FinalZoneSizing*. The user modifications to the calculated sizing will be applied to and stored in *ZoneSizing* and *FinalZoneSizing*.
- (3) The user can modify the calculated zone design results by specifying heating and cooling sizing factors at the global or zone level or by specifying and actual design heating or cooling zone design volumetric flow rate. All of this input is treated as a sizing factor. If the user inputs a cooling design volumetric flow rate for a zone it is divided by the calculated cooling design volumetric flow rate for the zone to give a zone cooling sizing factor. Note that the user can input a zone sizing factor or a zone design flow rate - not both - so there is never a conflict.
- (4) Once the zone heating and cooling sizing factors are established, the design flow and load sequences as well as peak loads and flows are multiplied by the appropriate sizing factor and stored in *ZoneSizing* and *FinalZoneSizing*. This is the data that will be used for sizing zone HVAC equipment and in the system sizing calculation.
- (5) The outside air fractions are recalculated using the new user-modified design flow rates and new design zone coil inlet conditions calculated and stored. At this point the condition that the design flow rates are never allowed to be less than the minimum outside air flow rate is imposed.

If *outside air method* is *flow/zone*, the input *outside air flow per zone* value will be used, even if it is zero or blank. If *outside air method* is *sum*, the sum of the *outside air flow per person* * *DesignNumberOfPeople* + *outside air flow per area* * *ZoneArea* will be used. If *outside air method* is *maximum*, the maximum of the *outside air flow per person* * *DesignNumberOfPeople* and *outside air flow per area* * *ZoneArea* will be used. If *outside air method* is *flow/person*, *outside air flow per person* will be used to calculate the design minimum outside airflow rate.

If *cooling design air flow method* is *flow/zone*, then *cooling design air flow rate* will be used for the design max cooling air flow rate. If *cooling design air flow method* is *design day*, then the design day calculation will set the design max cooling air flow rate. If *cooling design air flow method* is *design day with limit*, then the maximum from *cooling min flow per area* and *cooling min flow* will set a lower limit on the design max cooling air flow rate. In all cases, the maximum from *cooling min flow per area*, *cooling min flow*, and *cooling min flow fraction* will set a minimum zone cooling air flow rate. In all cases the maximum design cooling air flow rate must be \geq to the ventilation requirement.

If *heating design air flow method* is *flow/zone*, then *heating design air flow rate* will be used for the design max heating air flow rate. If *heating design air flow method* is *design day*, then the design day calculation will set the design max heating air flow rate. If *heating design air flow method* is *design day with limit*, then the maximum from *heating max flow per area*, *heating max flow* and *heating max flow fraction* will set an upper limit on the design max heating air flow rate. The design max heating air flow rate must always be \geq the ventilation requirement. In each case, the

outside airflow will be modified based on zone ventilation effectiveness specified in the zone sizing object.

This concludes the calculation of the zone design flow rates and loads.

10.3.5 Air Terminal Unit Sizing

Each controlled zone may have one or more air terminal units (AirTerminal:*) served by one or more central air handlers (AirLoopHVAC). Each air terminal unit may reference a DesignSpecification:AirTerminal:Sizing object which is used to adjust the *FinalZoneSizing* data for each terminal unit with these user inputs:

<i>DesSensCoolingFrac</i>	= Fraction of Design Sensible Cooling Load
<i>DesCoolSATRatio</i>	= Cooling Design Supply Air Temperature Difference Ratio
<i>DesSensHeatingFrac</i>	= Fraction of Design Sensible Heating Load
<i>DesHeatSATRatio</i>	= Heating Design Supply Air Temperature Difference Ratio
<i>MinOAFrac</i>	= Fraction of Minimum Outdoor Air Flow

All of these factors default to 1.0. Function *UpdateTermUnitFinalZoneSizing* first fills each instance of *TermUnitFinalZoneSizing* with a copy of *FinalZoneSizing* for the controlled zone served by the terminal unit. Then, if there is an applicable DesignSpecification:AirTerminal:Sizing input, the following adjustments are made:

$$CoolLoad_{TU} = CoolLoad_{FZ} \cdot DesSensCoolingFrac \quad (10.3)$$

$$minOAFlow_{TU} = minOAFlow_{FZ} \cdot MinOAFrac \quad (10.4)$$

$$CoolFlowRatio = DesSensCoolingFrac / DesCoolSATRatio \quad (10.5)$$

$$CoolFlow_{TU} = CoolFlowNoOA_{FZ} \cdot CoolFlowRatio + MinOAFrac \cdot (CoolFlowWithOA_{FZ} - CoolFlowNoOA_{FZ}) \quad (10.6)$$

$$CoolFlow_{TU} = \max(CoolFlow_{TU}, minOAFlow_{TU}) \quad (10.7)$$

Where:

<i>CoolLoad</i>	= Cooling load variables: <i>DesCoolLoad</i> , <i>CoolLoadSeq</i> , <i>NonAirSysDesCoolLoad</i>
<i>CoolFlow</i>	= Cooling flow variables: <i>DesCoolVolFlow</i> , <i>CoolFlowSeq</i>
<i>CoolFlowNoOA</i>	= Cooling flow variables not adjusted for minimum outdoor air: <i>DesCoolVolFlowNoOA</i> , <i>CoolFlowSeqNoOA</i>
<i>minOAFlow</i>	= minimum outdoor air flow rate
Subscript <i>FZ</i>	= Value from <i>FinalZoneSizing</i>
Subscript <i>TU</i>	= Value for <i>TermUnitFinalZoneSizing</i>

Likewise for heating.

10.3.6 Zone HVAC Scalable Sizing

For zone HVAC equipment, scalable sizing applies to supply air flow rate and capacity for both cooling and heating. The scalable sizing method allowed for supply air flow rates include: *FractionOfAutosizedCoolingAirflow*, sizing method allowed for supply air flow rates include: *FractionOfAutosizedCoolingAirflow*, *FractionOfAutosizedHeatingAirflow*, *FlowPerFloorArea*, *FlowPerCoolingCapacity*, and *FlowPerHeatingCapacity*. The supply air flow rate scalable sizing methods are defined as follows:

FlowPerFloorArea: the simulation engine determine the supply air flow rates from the user specified *supply air flow rates per unit floor area* and the zone floor area of the zone served by the zone HVAC equipment.

FractionOfAutosizedCoolingAirflow: the simulation engine determines the supply air flow rates from the user specified *flow fraction* and *autosized cooling design supply air flow rate*.

FractionOfAutosizedHeatingAirflow: the simulation engine determines the supply air flow rates from the user specified *flow fraction* and *autosized heating design supply air flow rate*.

FlowPerCoolingCapacity: the simulation engine determines the supply air flow rates from the user specified *supply air flow per cooling capacity value* and *autosized cooling design capacity*.

FlowPerHeatingCapacity: the simulation engine determines the supply air flow rates from the user specified *supply air flow per heating capacity value* and *autosized heating design capacity*.

The scalable capacity sizing may be indirectly impacted by the scalable supply air flow rates sizing values. Moreover, the autosized cold water, hot water and steam flow rates in the parent zone HVAC objects and capacity in child components are determined using the scalable sizing method. Scalable capacity sizing methods allowed for cooling and heating include: *CapacityPerFloorArea*, *FractionOfAutosizedCoolingCapacity*, *FractionOfAutosizedHeatingCapacity*. The scalable sizing capacity methods are defined as follows:

CapacityPerFloorArea: the simulation engine determines the cooling or heating capacity from user specified capacity per floor area value and the floor area of the zone served by the zone HVAC equipment.

FractionOfAutosizedCoolingCapacity: the simulation engine sizes the cooling capacity from the user specified *capacity fraction* and *autosized cooling design capacity* value.

FractionOfAutosizedHeatingCapacity: the simulation engine sizes the heating capacity from the user specified *capacity fraction* and *autosized heating design capacity* value.

10.4 System Design Loads and Air Flow Rates

10.4.1 Overview

The purpose of the system design calculation is to estimate design heating and cooling loads and air flow rates for each air loop in the simulation problem. The calculation sequence for system level design loads and air flow rates resembles the calculation sequence for zone loads and air flow rates. There is an update subroutine *UpdateSysSizing* called at the beginning, during, and end of a loop in the Sizing Manager over all the design days. The major difference is that this calculation is done at the zone time-step only. There is no idealized component calculation triggered at the system time-step as in the zone calculation. The system design calculation operates at the zone

time step using the design environment weather data and the data stored in the zone sizing arrays. The results of the system design calculation are stored in the system sizing arrays described below.

10.4.2 System Design Data Arrays

The system design data arrays are:

SysSizInput(i) stores the input data from the Sizing:System objects.

SysSizing(i,j) stores the results of the system design calculations for all systems and all design days. The index *i* is for air loops, *j* for design days.

CalcSysSizing(i) stores the results of the system design calculations for the peak heating and cooling cases for each air loop. The index *i* is for the air loops.

FinalSysSizing(i) corresponds to *CalcSysSizing* but includes the effect of the user specified sizing factor or user specified system design flow rate.

The data stored in *SysSizing*, *CalcSysSizing* and *FinalSysSizing* includes the following data items.

Table 10.2: System Sizing Data

Name	Description
All the data from SysSizInput	
CoinCoolMassFlow	coincident peak cooling mass flow rate [kg/s]
CoinHeatMassFlow	coincident peak heating mass flow rate [kg/s]
NonCoinCoolMassFlow	noncoincident peak cooling mass flow rate [kg/s]
NonCoinHeatMassFlow	noncoincident peak heating mass flow rate [kg/s]
DesMainVolFlow	design main supply duct volume flow [m ³ /s]
DesHeatVolFlow	design heat supply duct volume flow [m ³ /s]
DesCoolVolFlow	design cool supply duct volume flow [m ³ /s]
SensCoolCap	design sensible cooling capacity [W]
TotCoolCap	design total cooling capacity [W]
HeatCap	design heating capacity [W]
PreheatCap	design preheat capacity [W]
MixTempAtCoolPeak	mixed air temperature at the time of the cooling peak [C]
MixHumRatAtCoolPeak	mixed air humidity ratio at the time of the cooling peak [kg water/kg dry air]
RetTempAtCoolPeak	return air temperature at the time of the cooling peak [C]
RetHumRatAtCoolPeak	return air humidity ratio at the time of the cooling peak [kg water/kg dry air]
OutTempAtCoolPeak	outside air temperature at the time of the cooling peak [C]

Table 10.2: System Sizing Data

Name	Description
OutHumRatAtCoolPeak	outside air humidity ratio at the time of the cooling peak [kg water/kg dry air]
HeatMixTemp	design mixed air temperature for heating [C]
HeatMixHumRat	design mixed air humidity ratio for heating [kg water/kg dry air]
HeatRetTemp	design return air temperature for heating [C]
HeatRetHumRat	design return air humidity ratio for heating [kg water/kg dry air]
HeatOutTemp	design outside air temperature for heating [C]
HeatOutHumRat	design outside air humidity ratio for heating [kg water/kg dry air]
HeatFlowSeq(i)	daily sequence of system heating air mass flow rate (zone time step) [kg/s]
CoolFlowSeq(i)	daily sequence of system cooling air mass flow rate (zone time step) [kg/s]
SumZoneCoolLoadSeq(I)	daily sequence of zones' summed cooling load (zone time step) [W]
CoolZoneAvgTempSeq(I)	daily sequence of zones flow weighted average temperature (zone time step) [W]
SensCoolCapSeq(I)	daily sequence of system sensible cooling capacity (zone time step) [W]
TotCoolCapSeq(I)	daily sequence of system total cooling capacity (zone time step) [W]
HeatCapSeq(i)	daily sequence of system heating capacity (zone time step) [W]
PreHeatCapSeq(i)	daily sequence of system preheat capacity (zone time step) [W]
SysCoolRetTempSeq(i)	daily sequence of system cooling return temperatures (zone time step) [C]
SysCoolRetHumRatSeq(I)	daily sequence of system cooling return humidity ratios (zone time step) [kg water/kg dry air]
SysHeatRetTempSeq(i)	daily sequence of system heating return temperatures (zone time step) [C]
SysHeatRetHumRatSeq(I)	daily sequence of system heating return humidity ratios (zone time step) [kg water/kg dry air]
SysCoolOutTempSeq	daily sequence of system cooling outside temperatures (zone time step) [C]

Table 10.2: System Sizing Data

Name	Description
SysCoolOutHumRatSeq	daily sequence of system cooling outside humidity ratios (zone time step) [kg water/kg dry air]
SysHeatOutTempSeq	daily sequence of system heating outside temperatures (zone time step) [C]
SysHeatOutHumRatSeq	daily sequence of system heating outside humidity ratios (zone time step) [kg water/kg dry air]

10.4.3 System Design Flow Rate and Load Summation and Adjustment

There is no system level subroutine corresponding to *SizeZoneEquipment*. Instead the system design loads and flow rates are calculated using the zone level results. The zone design flow rates for the zones served by an air loop are summed to obtain the system level design flow rates. These air flows are mixed with the system level design minimum outside air flow rate to obtain system design coil loads. These activities are all performed within the *UpdateSysSizing* subroutine in the *SimAirServingZones* module. It is called at the start of each design day (*CallIndicator* = *BeginDay*), at the zone time-step (*CallIndicator* = *DuringDay*), at the end of the design day (*CallIndicator* = *EndDay*) and at the end of the zone design calculation (*CallIndicator* = *EndSysSizingCalc*).

There is a logical flag *SysSizingCalc* corresponding to *ZoneSizingCalc*. It is used to allow the component routines to distinguish a normal simulation call from a being called during a system sizing calculation.

Note that throughout this section, any reference to a “zone” is equivalent to “air terminal unit”.

10.4.3.1 BeginDay

- (1) The environment (in this case, a design day) name is stored in the system sizing data structures.
- (2) Loop over the zones cooled by this air loop:

$$\text{NonCoinCoolMassFlow}_{sys} = \Sigma \text{DesCoolMassFlow}_{zone}$$

- (3) Loop over the zones heated by this air loop:

$$\text{NonCoinCoolMassFlow}_{sys} = \Sigma \text{DesHeatMassFlow}_{zone}$$

10.4.3.2 DuringDay

- (1) Loop over the zones cooled by this air loop:

$$\begin{aligned} \text{CoolFlowSeq}_{sys}(i) &= \Sigma \text{CoolFlowSeq}_{zone}(i) \\ \text{SysCoolRetTemp}(i) &= \Sigma (\text{CoolZoneRetTempSeq}(i) * \text{CoolFlowSeq}_{zone}(i)) / \text{CoolFlowSeq}_{sys}(i) \\ \text{SysCoolRetHumRat}(i) &= \Sigma (\text{CoolZoneHumRatSeq}(i) * \text{CoolFlowSeq}_{zone}(i)) / \text{CoolFlowSeq}_{sys}(i) \\ \text{FracOA} &= \rho_{air} * \text{DesOutAirVolFlow}_{sys} / \text{CoolFlowSeq}_{sys}(i) \end{aligned}$$

$$T_{mix} = T_{outside} * FracOA + SysCoolRetTemp(i)(1 - FracOA)$$

$$W_{mix} = W_{outside} * FracOA + SysCoolRetHumRat(i)(1 - FracOA)$$

$$SysCoolOutTempSeq(i) = T_{outside}$$

$$SysCoolOutHumRatSeq(i) = W_{outside}$$

Get the current (zone time-step) system cooling capacity:

$$SysSensCoolCap_{cur} = C_{p,air} * CoolFlowSeq_{sys}(i) * (T_{mix} - T_{sup})$$

$$SensCoolCapSeq(I) = SysSensCoolCap_{cur}$$

If $SysSensCoolCap_{cur}$ is the maximum for the day so far then save $SysSensCoolCap_{cur}$ as the design value:

$$SensCoolCap(i)_{sys} = SysSensCoolCap_{cur}$$

And save the corresponding mixed, return and outside conditions:

$$CoolMixTemp_{sys} = T_{mix}$$

$$CoolMixHumRat_{sys} = W_{mix}$$

$$CoolRetTemp_{sys} = SysCoolRetTemp(i)$$

$$CoolRetHumRat_{sys} = SysCoolRetHumRat(I)$$

$$CoolOutTemp_{sys} = T_{outside}$$

$$CoolOutHumRat_{sys} = W_{outside}$$

Here ρ_{air} is the density of dry air at 20°C and standard elevation corrected pressure, [kg/m³];

FracOA is the outside air fraction; $C_{p,air}$ is the specific heat of dry air at 20°C, [J/kg-K];

T_{sup} is the user specified design cooling supply temperature [C]; T_{mix} is the current mixed air temperature [C]; W_{mix} is the current mixed air humidity ratio [kg water / kg dry air]; $T_{outside}$ is the current outside air temperature [C]; $W_{outside}$ is the current outside air humidity ratio [kg water / kg dry air].

(2) Loop over the zones heated by this air loop.

$$HeatFlowSeq_{sys}(i) = \Sigma HeatFlowSeq_{zone}(i)$$

$$SysHeatRetTemp(i) = \Sigma (HeatZoneRetTempSeq(i) * HeatFlowSeq_{zone}(i)) / HeatFlowSeq_{sys}(i)$$

$$SysHeatRetHumRat(i) = \Sigma (HeatZoneHumRatSeq(i) * HeatFlowSeq_{zone}(i)) / HeatFlowSeq_{sys}(i)$$

$$FracOA = r_{air} * DesOutAirVolFlow_{sys} / HeatFlowSeq_{sys}(i)$$

$$T_{mix} = T_{outside} * FracOA + SysHeatRetTemp(i)(1 - FracOA)$$

$$W_{mix} = W_{outside} * FracOA + SysHeatRetHumRat(i)(1 - FracOA)$$

$$SysHeatOutTempSeq(i) = T_{outside}$$

$$SysHeatOutHumRatSeq(i) = W_{outside}$$

Get the current (zone time-step) system heating capacity:

$$SysHeatCap_{cur} = C_{p,air} * MinFlowRat_{sys} * HeatFlowSeq_{sys}(i) * (T_{sup} - T_{mix})$$

$$HeatCapSeq(I) = SysHeatCap_{cur}$$

If $SysHeatCap_{cur}$ is the maximum for the day so far then save $SysHeatCap_{cur}$ as the design value:

$$HeatCap(i)_{sys} = SysHeatCap_{cur}$$

And save the corresponding mixed, return and outside conditions:

$$HeatMixTemp_{sys} = T_{mix}$$

$$HeatMixHumRat_{sys} = W_{mix}$$

$$HeatRetTemp_{sys} = SysHeatRetTemp(i)$$

$$HeatRetHumRat_{sys} = SysHeatRetHumRat(I)$$

$$HeatOutTemp_{sys} = T_{outside}$$

$$HeatOutHumRat_{sys} = W_{outside}$$

Here $MinFlowRat_{sys}$ is the user specified minimum supply flow ratio.

10.4.3.3 EndDay

If the user has specified *coincident* system sizing then:

$$DesCoolVolFlow_{sys} = \rho_{air} * CoinCoolMassFlow_{sys}$$

$$DesHeatVolFlow_{sys} = \rho_{air} * CoinHeatMassFlow_{sys}$$

$$DesMainVolFlow_{sys} = \mathbf{Max}(DesCoolVolFlow_{sys}, DesHeatVolFlow_{sys})$$

If the user has specified *noncoincident* system sizing then:

$$DesCoolVolFlow_{sys} = \rho_{air} * NonCoinCoolMassFlow_{sys}$$

$$DesHeatVolFlow_{sys} = \rho_{air} * NonCoinHeatMassFlow_{sys}$$

$$DesMainVolFlow_{sys} = \mathbf{Max}(DesCoolVolFlow_{sys}, DesHeatVolFlow_{sys})$$

Based on the outdoor air method selected, the $DesCoolVolFlow_{sys}$ and $DesHeatVolFlow_{sys}$ are modified based on the system ventilation efficiency calculated based on the maximum outdoor air fraction.

10.4.3.4 EndSysSizingCalc

At this point all the calculations have been done in $SysSizing(i,j)$: we have results for each design day. Now these results need to be processed to find the heating and cooling design quantities for each system over all the design days.

For coincident sizing the task is quite easy.

- (1) Loop over all of the air loops.
 - (a) Loop over all of the design days.
 - (i) If the value of $DesCoolVolFlow$ in $SysSizing$ for the current design day is greater than the value stored in $CalcSysSizing$, then move $DesCoolVolFlow$ from $SysSizing$ into $CalcSysSizing$ along with $CoolDesDay$, $CoinCoolMassFlow$, $SensCoolCap$, $CoolFlowSeq(i)$, $SensCoolCapSeq(i)$, $CoolMixTemp$, $CoolRetTemp$, $CoolMixHumRat$, $CoolRetHumRat$, $CoolOutTemp$, $CoolOutHumRat$, $SysCoolRetTempSeq(i)$, $SysCoolRetHumRatSeq(i)$, $SysCoolOutTempSeq(i)$ and $SysCoolOutHumRatSeq(i)$.
 - (ii) If the value of $DesHeatVolFlow$ in $SysSizing$ for the current design day is greater than the value stored in $CalcSysSizing$, then move $DesHeatVolFlow$ from $SysSizing$ into $CalcSysSizing$ along with $HeatDesDay$, $CoinHeatMassFlow$, $HeatCap$, $PreHeatCap$, $HeatFlowSeq(i)$, $HeatCapSeq(i)$, $PreHeatCapSeq(i)$, $HeatMixTemp$, $HeatRetTemp$, $HeatMixHumRat$, $HeatRetHumRat$, $HeatOutTemp$, $HeatOutHumRat$, $SysHeatRetTempSeq(i)$, $SysHeatRetHumRatSeq(i)$, $SysHeatOutTempSeq(i)$ and $SysHeatOutHumRatSeq(i)$.

At the end of each design day loop the peak cooling and the peak heating data will be stored in $CalcSysSizing$. At this point we set $DesMainVolFlow$ in $CalcSysSizing$ equal to the maximum of $DesCoolVolFlow$ and $DesHeatVolFlow$.

For noncoincident sizing the task is harder since we don't have a single time-step during which all the zone peaks occur. So there is no obvious value for outside air temperature at the peak, return

air temperature at the peak and so forth. We must return to the zone sizing data and calculate average values for return and outside conditions.

(b) Loop over all of the zones cooled by this air loop.

In *FinalZoneSizing* replace the value in *DesCoolCoilInTemp* with the user specified *CoolSupTemp_{sys}*. Do the same for *DesCoolCoilInHumRat* and *CoolSupHumRat*. This ensures that zone equipment connected to an air loop will use the system design supply air conditions as coil entering conditions.

$$NonCoinCoolMassFlow_{sys} = \Sigma DesCoolMassFlow_{zone}$$

$$SysCoolRetTemp = (ZoneRetTempAtCoolPeak * DesCoolMassFlow_{zone}) / NonCoinCoolMassFlow_{sys}$$

$$SysCoolRetHumRat = (ZoneHumRatAtCoolPeak * DesCoolMassFlow_{zone}) / NonCoinCoolMassFlow_{sys}$$

$$SysCoolOutTemp = (T_{OA,zonepeak} * DesCoolMassFlow_{zone}) / NonCoinCoolMassFlow_{sys}$$

$$SysCoolOutHumRat = (W_{OA,zonepeak} * DesCoolMassFlow_{zone}) / NonCoinCoolMassFlow_{sys}$$

At the end of the zone loop calculate mixed air conditions and the system sensible cooling capacity.

$$FracOA = \rho_{air} * DesOutAirVolFlow_{sys} / NonCoinCoolMassFlow_{sys}$$

$$T_{mix} = SysCoolOutTemp * FracOA + SysCoolRetTemp * (1 - FracOA)$$

$$W_{mix} = SysCoolOutHumRat * FracOA + SysCoolRetHumRat * (1 - FracOA)$$

$$SysSensCoolCap = C_{p,air} * NonCoinCoolMassFlow * (T_{mix} - T_{sup})$$

Then (for noncoincident sizing) the variables calculated in section (ii) are moved into the *CalcSysSizing* Array.

(c) Loop over all of the zones heated by this air loop.

In *FinalZoneSizing* replace the value in *DesHeatCoilInTemp* with the user specified *HeatSupTemp_{sys}*. Do the same for *DesHeatCoilInHumRat* and *HeatSupHumRat*. This ensures that zone equipment connected to an air loop will use the system design supply air conditions as coil entering conditions.

$$NonCoinHeatMassFlow_{sys} = \Sigma DesHeatMassFlow_{zone}$$

$$SysHeatRetTemp = (ZoneRetTempAtHeatPeak * DesHeatMassFlow_{zone}) / NonCoinHeatMassFlow_{sys}$$

$$SysHeatRetHumRat = (ZoneHumRatAtHeatPeak * DesHeatMassFlow_{zone}) / NonCoinHeatMassFlow_{sys}$$

$$SysHeatOutTemp = (T_{OA,zonepeak} * DesHeatMassFlow_{zone}) / NonCoinHeatMassFlow_{sys}$$

$$SysHeatOutHumRat = (W_{OA,zonepeak} * DesHeatMassFlow_{zone}) / NonCoinHeatMassFlow_{sys}$$

At the end of the zone loop calculate mixed air conditions and the system sensible cooling capacity.

$$FracOA = \rho_{air} * DesOutAirVolFlow_{sys} / NonCoinHeatMassFlow_{sys}$$

$$T_{mix} = SysHeatOutTemp * FracOA + SysHeatRetTemp * (1 - FracOA)$$

$$W_{mix} = SysHeatOutHumRat * FracOA + SysHeatRetHumRat * (1 - FracOA)$$

$$SysHeatlCap = C_{p,air} * NonCoinHeatlMassFlow * (T_{sup} - T_{mix})$$

Then (for noncoincident sizing) the variables calculated in section (ii) are moved into the *CalcSysSizing* Array.

- (2) We now have the calculated system sizing data. This data needs to be altered to take into account the user input system design flow rates (if any), or the fact that the user may have requested that the system flow rate be sized on the ventilation requirement. Note that user specified sizing ratios have already been applied to the zone sizing data which have been used in our preceding system sizing calculation. Thus the user specified sizing ratios do not have to be explicitly taken into account at the system level.

First we move the calculated system sizing data from *CalcSysSizing* array into the *FinalSysSizing* array. *FinalSysSizing* will contain the user modified system design data when we are all done.

Loop over the air loops.

- (i) As in the zone case, the user specified system design flow rates are turned into sizing ratios by dividing the user input value by the calculated value. The same strategy is employed for sizing on the ventilation requirement: the design ventilation flow rate is divided by the calculated design flow rate value. For each air loop this gives us a $SizRat_{cool}$ and $SizRat_{heat}$.

$$\begin{aligned} CoinCoolMassFlow &= SizRat_{cool} * CoinCoolMassFlow_{calc} \\ NonCoinCoolMassFlow &= SizRat_{cool} * NonCoinCoolMassFlow_{calc} \\ DesCoolVolFlow &= SizRat_{cool} * DesCoolVolFlow_{calc} \end{aligned}$$

Since the flow rates have been altered the outside air fraction will change. This will alter the design mixed air conditions and lead to an altered value for the cooling capacity. This must be done for the time-step sequence and for the peak value.

- (ii) Loop over the zone timesteps (index = i).

$$\begin{aligned} CoolFlowSeq_{sys}(i) &= SizRat_{cool} * CoolFlowSeq_{sys,calc}(i) \\ FracOA &= \rho_{air} * DesOutAirVolFlow_{sys} / CoolFlowSeq_{sys}(i) \\ T_{mix} &= SysCoolOutTempSeq(i) * FracOA + SysCoolRetTempSeq(i) * (1 - FracOA) \\ SensCoolCapSeq(i) &= C_{p,air} * CoolFlowSeq_{sys}(i) * (T_{mix} - T_{sup}) \end{aligned}$$

- (iii) Do the same calculation for peak cooling.

$$\begin{aligned} FracOA &= \rho_{air} * DesOutAirVolFlow_{sys} / DesCoolVolFlow \\ T_{mix} &= CoolOutTemp_{sys} * FracOA + CoolRetTemp_{sys} * (1 - FracOA) \\ W_{mix} &= CoolOutHumRat_{sys} * FracOA + CoolRetHumRat_{sys} * (1 - FracOA) \\ SensCoolCap_{sys} &= C_{p,air} * DesCoolVolFlow_{sys} * (T_{mix} - T_{sup}) \\ T_{mix} \text{ and } W_{mix} &\text{ are saved in } FinalSysSizing. \end{aligned}$$

- (iv) Do the same calculation for the heating case.

$$\begin{aligned} CoinHeatMassFlow &= SizRat_{heat} * CoinHeatMassFlow_{calc} \\ NonCoinHeatMassFlow &= SizRat_{heat} * NonCoinHeatMassFlow_{calc} \\ DesHeatVolFlow &= SizRat_{heat} * DesHeatVolFlow_{calc} \end{aligned}$$

- (v) Loop over the zone timesteps (index = i).

$$\begin{aligned}
HeatFlowSeq_{sys}(i) &= SizRat_{Heat} * HeatFlowSeq_{sys,calc}(i) \\
FracOA &= \rho_{air} * DesOutAirVolFlow_{sys} / HeatFlowSeq_{sys}(i) \\
T_{mix} &= SysHeatOutTempSeq(i) * FracOA + SysHeatRetTempSeq(i) * (1-FracOA) \\
HeatCapSeq(i) &= C_{p,air} * HeatFlowSeq_{sys}(i) * (T_{sup} - T_{mix})
\end{aligned}$$

(vi) Do the same calculation for peak heating.

$$\begin{aligned}
FracOA &= \rho_{air} * DesOutAirVolFlow_{sys} / DesHeatVolFlow \\
T_{mix} &= HeatOutTemp_{sys} * FracOA + HeatRetTemp_{sys} * (1-FracOA) \\
W_{mix} &= HeatOutHumRat_{sys} * FracOA + HeatRetHumRat_{sys} * (1-FracOA) \\
HeatCap_{sys} &= C_{p,air} * DesHeatVolFlow_{sys} * (T_{sup} - T_{mix}) \\
T_{mix} \text{ and } W_{mix} &\text{ are saved in } FinalSysSizing .
\end{aligned}$$

$$(vii) DesMainVolFlow_{sys} = \mathbf{MAX}(DesCoolVolFlow_{sys}, DesHeatVolFlow_{sys})$$

At this point, the design main flow is the larger of the cooling design flow or the heating design flow. The program stores the information for which was dominant for each airloop in the boolean data structure variables sysSizeCoolingDominant and sysSizeHeatingDominant.

10.4.4 System Sizing Adjustments for Air Terminal Operation

Additional adjustments are made to system air flow sizes based on details of the how the zone air terminals connected to the system will eventually operate. These system sizing adjustments were added as of version 8.9 of EnergyPlus. The basic idea is to account for operating details of the air terminal units attached to the system by making adjustments to the system sizing results after the zone equipment has been setup and sized. The routine ManageSystemSizingAdjustments has been added that first sets up the zone equipment and then makes adjustments to the system sizing by mining information from the air terminal models for minimum flow fractions, operating modes during heating, and any user-defined hard sizes to improve accuracy and robustness. Once the air terminals are setup, the actual operating flow rates during heating are often quite different from the design heating flow rate derived from the zone loads. The adjustment method scans all the air terminals and develops accurate values for the minimum and maximum flow rates that will occur during heating operation. Then the system design heating flow rate is adjusted to reflect this new result. For example in a VAV system with Normal action dampers that is cooling dominated, the heating design flow rate is no longer really related to the zone loads, but is the cooling design flow rate times the minimum flow fraction at the dampers. Similarly when heating loads dominate, the cooling design flow rate needs to be adjusted to account for how the terminals will really operate during cooling rather than the cooling-load-based sizing result.

The routine ManageSystemSizingAdjustments adjusts system sizing outcomes based on how the zone air terminals finish out their sizing. The zone models are executed to trigger their sizing routines, by calling ManageZoneEquipment(). Then for each airloop, the routine loops over all the zones attached to that air loop. The air terminal units are scanned to sum design flow rates. Every air terminal connected to a particular air loop is summed for: (1) minimum flow rate during heating operation (airLoopHeatingMinimumFlowRateSum), (2) maximum flow rate during heating operation (airLoopHeatingMaximumFlowRateSum), and (3) maximum flow rate (airLoopMaxFlowRateSum). The routine also stores zone level flow information for Standard 62.1 calculations, V_{pz} , V_{pzmin} , V_{dz} , and V_{dzmin} for both cooling and heating.

The three summed values for terminal air flows for each airloop are reported to the EIO and table summary report using the outputs "Sum of Air Terminal Maximum Heating Flow Rates [m3/s]," "Sum of Air Terminal Minimum Heating Flow Rates [m3/s]," and "Sum of Air Terminal Maximum Flow Rates [m3/s]."

The summed values are used to "Adjust" the system sizing results in the following ways. The setting for the type of zone sum to use can be either *noncoincident* or *coincident* (determined in the input field called Type of Zone Sum to Use in the Sizing:System input object). For *noncoincident* the design system heating flow rate is set to be the larger of the airloop heating maximum flow rate sum (from the air terminals) and the design flow rate from the load based calculations (described above). The design system main flow rate is set to be the larger of the airloop maximum flow rate sum (from the air terminals) and the design flow rate from the larger of the cooling and heating calculations. The cooling design flow rate is set differently depending on if the air loop was cooling dominant or heating dominant. For *noncoincident* and **cooling dominant**, the cooling design air flow rate is set to the design main air flow (typically the airLoopMaxFlowRateSum). For *coincident* and **heating dominant**, the cooling design air flow rate is set to the larger of the original cooling-load-based value for flow and the lowest value the air handler will really operate at (from the airLoopHeatingMinimumFlowRateSum).

For *coincident* type sums, the air terminal summation is not as useful because we generally expect that the straight sum of air terminal sizes will be larger than the coincident sum because by its very nature the straight sum is only expected to match noncoincident approach. Therefore the adjustments are more to keep design flows within bounds set by minimum and maximum sums so that the coincident sum is within physical bounds set by how the air terminals can operate. For *coincident* and **cooling dominant** airloops, (a) the heating design flow rate is the larger of the heating minimum flow rate (from the airLoopHeatingMinimumFlowRateSum) and the design heat flow from the coincident design calculation, (b) the main design flow is not typically altered but it will be checked to be at least as large as the heating minimum flow rate (from the airLoopHeatingMinimumFlowRateSum), and (c) the cooling design flow rate is set to the main design flow which we expect to be the result of the coincident design calculation. For *coincident* and **heating dominant** airloops, (a) the heating design flow rate is the larger of the heating maximum flow rate (from the airLoopHeatingMaximumFlowRateSum) and the design heat flow rate from the coincident design calculation, (b) the main design flow rate is set to be the larger of the heating maximum flow rate (from the airLoopHeatingMaximumFlowRateSum) and main design flow rate from the coincident sizing calculations, and (c) the cooling design flow rate is set to be the larger of the heating minimum flow rate (from the airLoopHeatingMinimumFlowRateSum) and the cooling design flow rate from the coincident calculation.

The resulting adjusted system sizes for each airloop are reported to the EIO and table summary report using the outputs "Adjusted Heating Design Air Flow Rate [m3/s]," "Adjusted Cooling Design Air Flow Rate [m3/s]," and "Adjusted Main Design Air Flow Rate [m3/s]."

10.4.5 Central Heating Maximum System Air Flow Ratio Sizing

The routine ManageSystemSizingAdjustments also includes calculating the ratio for the central heating maximum system air flow rate to the maximum flow rate for the airloop. This ratio is the input field called Central Heating Maximum System Air Flow Ratio in the Sizing:System object and, as of version 8.9, can be autosized. The value is calculated even if the input was not autosized so that inputs can be checked. The corrected values are used to autosize the central heating flow

ratio, if set to autosize by the user. The ratio is calculated by dividing the adjusted design heating flow by the adjusted design main flow.

10.4.6 System Design Outdoor Air Flow Rate

The design outdoor air flow rate input in the Sizing:System object can be set to autosize. The sizing calculations for determining the system-level design outdoor air flow rate, *Vot*, depend on the method chosen in the field called System Output Air Method in Sizing:System, either *ZoneSum*, *Standard62.1VentilationRateProcedure*, or *Standard62.1SimplifiedProcedure*, and the design results at the zone level, see Zone Outdoor Air Design Data discussion below. The calculations generally follow the Standard 62.1 approach and are discussed separately in the Demand Controlled Ventilation section elsewhere in the Engineering Reference. The sizing calculations apply the Standard 62.1 calculations separately for both peak cooling design conditions and peak heating design conditions and take the larger to be the single design outdoor air volume flow rate. The predefined table summary report "Standard 62.1 Summary" provides comprehensive summary of the calculations for outdoor air rate. As of version 8.9, the system level summations and flow rate results are based on the adjusted system sizes and zone level summations that mine the individual air terminals attached to the air handlers.

This concludes the system design calculation.

10.4.7 Scalable System HVAC Sizing

The scalable system sizing applies to system supply air flow rates and system capacity in cooling and heating modes.

Scalable System Air Flow Sizing

The scalable sizing methods for supply air flow rate allowed are either, *FlowPerFloorArea*, *FractionOfAutosizedCoolingAirflow*, or *FlowPerCoolingCapacity*. The scalable system air flow sizing methods are defined as follows:

FlowPerFloorArea means the program calculates the cooling supply air volume flow rate from zone floor area served by the airloop and user specified *Flow Per Floor Area* value.

FractionOfAutosizedCoolingAirflow means the program calculates the cooling supply air volume flow rate from user specified fraction and the autosized design cooling supply air volume flow rate value determined by the simulation.

FractionOfAutosizedHeatingAirflow means the program calculates the heating supply air volume flow rate from user specified fraction and the autosized design heating supply air volume flow rate value determined by the simulation.

FlowPerCoolingCapacity means the supply air volume is calculated from user specified flow per cooling capacity and design cooling capacity determined by the simulation.

FlowPerHeatingCapacity means the supply air volume is calculated from user specified flow per heating capacity and design heating capacity determined by the simulation.

Scalable System Capacity Sizing

The scalable sizing methods for system capacity available are: *CapacityPerFloorArea*, *FractionOfAutosizedCoolingCapacity* and *FractionOfAutosizedHeatingCapacity*. The scalable system capacity sizing methods are defined as follows:

CapacityPerFloorArea means the program calculates the design capacity from user specified capacity per floor area and floor area of the zones served by the airloop.

FractionOfAutosizedCoolingCapacity means the program calculates the design cooling capacity from user specified fraction and the auto-sized design cooling capacity.

FractionOfAutosizedHeatingCapacity means the program calculates the design heating capacity from user specified fraction and the auto-sized design heating capacity.

10.5 Plant and Condenser Loop Sizing

The program needs to be able to autosize the fluid flow rate in each plant fluid loop. The design plant loop flow rates are set by the sum of the needs of the demanding components on each loop. For chilled water loops these components will be cooling coils. For hot water loops - hot water coils. And for condenser loops - various types of chiller that use condenser water for cooling. Each component that uses water for heating or cooling stores its design water flow rate (in its sizing routine) in the array *CompDesWaterFlow*, labeled by its inlet water supply node number. These individual component design water flow rates are then accessed, summed for each plant loop, and stored in the *PlantSizingData* array. This array also contains the user specified design values for each plant loop.

10.5.1 Maximum Loop Flow Rate

The loop maximum volume flow rate m^3/s is just set equal to the value stored in the *PlantSizingData* array for this loop.

10.5.2 Loop Volume

The loop volume m^3 is calculated as the product of the maximum loop volume flow rate and the user input for loop circulation time which defaults to 2 minutes.

$$V_{loop} = \dot{V}_{loop,max} \cdot t_{loop} \cdot 60 \quad (10.8)$$

Where:

$\dot{V}_{loop,max}$ = maximum loop volume flow rate (m^3/s), and
 t_{loop} = loop circulation time (minutes).

10.6 Coincident Plant Sizing using HVAC Sizing Simulation

Coincident plant sizing is an advanced sizing method that uses HVAC Sizing Simulations to determine coincident flows. This section describes the algorithm used for sizing plant loop flow rate based on the coincidence of flow requests that actually occur when operating the system. The purpose is to provide a more accurate value for the plant loop design flow rate. This value is held in *PlantSizData(PltSizIndex).DesVolFlowRate*. For plant, this flow rate is the main independent variable used by component models in their sizing routines (along with the design temperature difference in *Sizing:Plant*). The code is contained in a *PlantCoincidentAnalysis* object, one for each plant loop that is to be sized using the coincident method using HVAC Sizing Simulation.

The analysis will proceed as follows:

1. Find the maximum mass flow rate over all Sizing Periods, along with the coinciding return temperature and load. Record which sizing period and timestep. This system node used for logging here is the plant loop supply side inlet node.
2. Find the maximum load, and the coinciding mass flow and return temperature. Record which sizing period and timestep. For a heating or steam plant loop, the load that is logged is associated with the output variable called Plant Supply Side Heating Demand Rate. For a cooling or condenser plant loop, the load log is as for the output variable called Plant Supply Side Cooling Demand Rate.
3. Calculate a maximum design flow rate from the maximum load, from step 2, and the temperature difference entered in the Plant:Sizing object and the specific heat (at 5 degC) of the plant fluid.
4. Compare the flow rate from step 1 to the flow rate from step 3 and take the higher.
5. Apply a sizing factor to the flow rate from Step 4, if desired. The user can select among different options for which sizing factor use.
6. Compare the flow rate from step 5 to the current value for plant loop flow rate and calculate a normalized change using

$$\text{Normalized_Change} = \frac{|\text{NewFlowRate} - \text{PreviousFlowRate}|}{\text{PreviousFlowRate}} \quad (10.9)$$

- Compare magnitude of Normalized_Change to a threshold, currently set at 0.005, to determine if it was significant or not.
- If change is significant, then alter the size result for that plant loop. Set flags that sizes have changed and sizing calculations need to be called again. Trigger special setup timesteps with flags set so that all plant system and component level sizes will be recomputed. Not this will call and resize all of plant so that if one loop has coincident sizing and it places a load on a loop that has noncoincident sizing, the noncoincident loop might still change size because the loop it depends on changed. Call for another Sizing Pass.
- If change is not significant, then leave the sizes alone and do not trigger resizing. Do not call for another Sizing Pass.

See OutputDetailsAndExamples documentation for a description of a fairly comprehensive report sent the EIO file called “Plant Coincident Sizing Algorithm” which provides the user details for each execution of the algorithm. There is also a predefined summary table

The algorithm described above can have powerful impacts on the sizes of plant loops. It is not uncommon for a hot water plant to size out at around half of what would be determined from the noncoincident sum of the sizes of all the components connected to the loop. The maximum load aspect of the algorithm is able to increase plant flow rates above the size of the pumps, whereas the flow rate aspect of the algorithm is only able to reduce the flow rates. It can happen that load spikes cause sizes to increase after the first Sizing Pass, and then the coincident flow rate bring the sizes back down some during subsequent Sizing Passes. It is worthwhile to explore multiple

Sizing Passes, or iterations, because sometimes the algorithm will switch between coincident flow and coincident demand from one Sizing Pass and gradually find a size that just meets conditions. Be aware that all the controls and EMS are also

10.7 Component Sizing

10.7.1 Introduction

In EnergyPlus each HVAC component sizes itself. Each component module contains a sizing subroutine. When a component is called for the first time in a simulation, it reads in its user specified input data and then calls the sizing subroutine. This routine checks the autosizable input fields for missing data and calculates the data when needed.

A number of high-level variables are used in the sizing subroutines.

CurDuctType (in *DataSizing*) contains the information about the current duct type. The types can be *main*, *cooling*, *heating* or *other*.

CurZoneEqNum (in *DataSizing*) is the current zone equipment set index and indicates that the component is a piece of zone equipment and should size itself using the zone sizing data arrays.

CurSysNum (in *DataSizing*) is the current air loop index and indicates that the component is part of the primary air system and should size itself using the system sizing data arrays.

10.7.2 Fan Sizing

Fan sizing is done in subroutine *SizeFan*.

10.7.2.1 Max Flow Rate

If the fan is part of the central air system then check the duct type.

For duct type = *main*, *other* or default, $\dot{V}_{fan,max} = \text{DesMainVolFlow}_{sys}$.

For duct type = *cooling*, $\dot{V}_{fan,max} = \text{DesCoolVolFlow}_{sys}$.

For duct type = *heating*, $\dot{V}_{fan,max} = \text{DesHeatVolFlow}_{sys}$.

If the fan is zone equipment then check whether it is part of a component that only does heating.

For heating only $\dot{V}_{fan,max} = \text{DesHeatVolFlow}_{zone}$.

Otherwise $\dot{V}_{fan,max} = \max(\text{DesHeatVolFlow}_{zone}, \text{DesCoolVolFlow}_{zone})$.

If the max fan flow rate is less than *SmallAirVolFlow* the max flow rate is set to zero.

10.7.3 Design Fan Heat

The design fan heat added to the air stream is calculated using fan model inputs of maximum volume flow rate, pressure rise, fan total efficiency and motor efficiency. For multi-speed fans, the highest air volume flow rate is used in the calculation. Fan heat is accounted for when sizing cooling coils.

Where:

$$P_{fan,des} = (\dot{V}_{fan,des} * \Delta P) / e_{tot,des} \quad (10.10)$$

$$\dot{Q}_{fan,heat,des} = e_{motor,des} * P_{fan,des} + (P_{fan,des} - (e_{motor,des} * P_{fan,des})) * f_{motor \text{ in air}} \quad (10.11)$$

and:

- $P_{fan,des}$: fan design total power (W)
- $\dot{V}_{fan,des}$: fan design volume flow rate (m³/s)
- ΔP : fan pressure rise (Pa)
- $e_{tot,des}$: fan total efficiency
- $\dot{Q}_{fan,heat,des}$: design fan heat to air stream (W)
- $e_{motor,des}$: fan motor efficiency
- $f_{motor \text{ in air}}$: motor in air stream fraction

The design fan temperature rise (C) due to fan heat is added to the cooling coil inlet air temperature or subtracted from the cooling coil outlet air temperature during sizing calculations as appropriate for blow-through or draw-through fan configurations, respectively. The calculation uses a straight-forward inversion of the classic $Q = \dot{m} * Cp * \Delta T$ equation as:

$$T_{fan,heat,des} = \dot{Q}_{fan,heat,des} / (C_{p,air} * \rho_{air} * \dot{V}_{fan,des}) \quad (10.12)$$

10.7.4 Coil:Cooling:Water

The sizing is done in function *SizeWaterCoil* of module *WaterCoils*.

10.7.4.1 Initial Calculations

For central cooling coils, the first step is to determine the design air flow rate, load, and design air entering and exit conditions. The coil design air flow rate is not generally the same as the maximum system air flow rate (used to size the central fans). The cooling coil peak load (either sensible or total) can occur at a different time than the system peak flow rate. Hence the coil air entering conditions can be different than those at the peak system flow rate. Also, the method of controlling the coil's cooling output may also affect coil design flow rate as well as the coil design exit temperature and humidity.

By choosing Type of Load to Size On = *Sensible* or *Total* in Sizing:System the user indicates to the program to save the cooling coil air flow rate and system air conditions (mixed, return, outside) at the time of either the system cooling sensible or total load peak. Note that the choice *VentilationRequirement* uses the time of the sensible peak.

Choosing Central Cooling Capacity Control Method = *VAV*, *Bypass*, *VT*, or *OnOff* indicates which type of cooling output control the program should assume when calculating the design air flow rate. The function *GetCoilDesFlowT* in module *ReportSizingManager* calculates the air flow rate and exit air temperature for each capacity control method.

Table 10.3: Cooling coil calculations for different capacity control methods

Control Method	Calculations
VAV	$T_{cc,exit} = T_{cool,supply}$ $\dot{V}_{cc,air} = \frac{\dot{m}_{cc,air,peak}}{\rho_{air}}$
Bypass	$T_{cc,exit} = T_{cool,supply}$ $\dot{V}_{cc,air} = \dot{V}_{cc,air,max} \cdot \max\left(0, \min\left(1, \frac{T_{mix,at-peak} - T_{sup,avg}}{T_{mix,at-peak} - T_{cc,exit}}\right)\right)$
VT	$T_{cc,exit} = \max(T_{cool,supply}, T_{sup,avg})$ $\dot{V}_{cc,air} = \dot{V}_{cc,air,max}$
OnOff	$T_{cc,exit} = T_{cool,supply}$ $\dot{V}_{cc,air} = \dot{V}_{sys,air,max}$

Where:

$$T_{sup,avg} = T_{zones,avg} - \sum_{zones} \frac{\dot{Q}_{sens,at-peak}}{\rho_{air} c_{p,air} \dot{V}_{cool,air,max}} \quad (10.13)$$

and:

- $C_{p,air}$: the specific heat of air (J/kgC)
- $\dot{m}_{cc,air,peak}$: the air mass flow rate through the cooling coil at the sensible or total system peak cooling load (m³/s)
- $\sum_{zones} \dot{Q}_{sens,at-peak}$: sum of the zone sensible cooling loads at the time of the peak system cooling load
- ρ_{air} : the density of air (kg/m³)
- $T_{cc,exit}$: the design cooling coil exit temperature (c)
- $T_{cool,supply}$: the supply air temperature for cooling specified in Sizing:System (C)
- $T_{mix,at-peak}$: the mixed air temperature at the time of the system peak cooling load (C)
- $T_{zones,avg}$: the average zone temperature at the time of the system peak cooling load (C)
- $\dot{V}_{cc,air}$: the design volumetric air flow rate through the cooling coil (m³/s). This is the flow rate at either the sensible or total cooling load peak from the design period calculations.
- $\dot{V}_{cool,air,max}$: the maximum cooling volumetric air flow rate from the design calculations (m³/s). This flow rate occurs at the maximum zone cooling demand.
- $\dot{V}_{sys,air,max}$: the maximum volumetric air flow rate from the design calculations (m³/s). This flow rate occurs at either the maximum zone cooling or heating demand.

10.7.4.2 Design Coil Load - System Coils

Design coil load (cooling capacity) is not an input for Coil:Cooling:Water. It is used for calculating the design water flow rate.

The design load is calculated as:

$$\dot{Q}_{coil,des} = \dot{m}_{a,coil,des} (h_{a,coil,des,in} - h_{a,coil,des,out}) + \dot{Q}_{fan,heat,des} \quad (10.14)$$

Where:

- $h_{a,coil,des,in}$: is the coil design inlet air enthalpy (J/kg)
- $h_{a,coil,des,out}$: is the coil design outlet air enthalpy (J/kg)
- $\dot{m}_{a,coil,des}$: is the coil design air mass flow rate (kg/s)
- $\dot{Q}_{fan,heat,des}$: is the design fan heat (W) - see Section 10.7.3

The design air mass flow rate depends on the location of the coil. If the coil is in the outside air stream, the flow rate is set to:

$$\rho_{air} \dot{V}_{a,coil,oa,des} \quad (10.15)$$

where $\dot{V}_{a,coil,oa,des}$ is the design outside air volumetric flow rate for the system. Otherwise, it is set to:

$$\rho_{air} \dot{V}_{cc,air} \quad (10.16)$$

where $\dot{V}_{cc,air}$ is calculated above in the Initial Calculations section.

To obtain the inlet and outlet enthalpies, we need the inlet and outlet temperatures and humidity ratios. The inlet and outlet conditions depend on whether the coil is in the outside air stream and if it is not, whether or not there is outside air preconditioning.

10.7.4.2.1 Coil in outside air stream:

- $T_{air,in,des} = T_{out,cool,at-peak}$ (the outside air temperature at the design cooling peak)
- $T_{air,out,des} = T_{sys,precool}$ (the specified Precool Design Temperature from the System:Sizing object)
- $W_{air,in,des} = W_{out,cool,at-peak}$ (the outside humidity ratio at the design cooling peak)
- $W_{air,out,des} = W_{sys,precool}$ (the specified Precool Design Humidity Ratio from the System:Sizing object)

10.7.4.2.2 Coil in main air stream, no preconditioning of outside air

- $T_{air,in,des} = T_{mix,cool,at-peak}$ (the mixed air temperature at the design cooling peak. Plus the design fan temperature rise due to fan heat, $+ T_{fan,heat,des}$, for blow through configuration - see Section 10.7.3)
- $W_{air,in,des} = W_{mix,cool,at-peak}$ (the mixed humidity ratio at the design cooling peak)
- $T_{air,out,des} = T_{cc,exit}$ (calculated above in the Initial Calculation section. Minus the design fan temperature rise due to fan heat, $- T_{fan,heat,des}$, for draw through configuration - see Section 10.7.3)
- $W_{air,out,des} = W_{sup,cool}$ (the specified Central Cooling Design Supply Air Humidity Ratio from the Sizing:System object)

10.7.4.2.3 Coil in main air stream, outside air preconditioned

The outside air fraction is calculated as (where $V_{cc,air}$ is calculated as above):

- $f_{oa} = \frac{\dot{V}_{air,out,des}}{\dot{V}_{cc,air}}$
- $T_{air,in,des} = f_{oa}T_{precool} + (1 - f_{oa})T_{ret,cool,at-peak}$ (Precool temperature is the specified Precool Design Temperature from System:Sizing Manager; $T_{ret_cool_at-peak}$ is the return temperature at the system cooling peak load. Plus the design fan temperature rise due to fan heat, $+ T_{fan,heat,des}$, for blow through configuration - see Section 10.7.3)
- $W_{air,in,des} = f_{oa}W_{precool} + (1 - f_{oa})W_{ret,cool,at-peak}$ (Precool humidity ratio is the specified Precool Design Humidity Ratio from System:Sizing Manager; $W_{ret_cool_at-peak}$ is the return humidity ratio at the system cooling peak load)
- $T_{air,out,des} = T_{cc,exit}$ (calculated above in the Initial Calculation section. Minus the design fan temperature rise due to fan heat, $- T_{fan,heat,des}$, for draw through configuration - see Section 10.7.3))
- $W_{air,out,des} = W_{sup,cool}$ (the specified Central Cooling Design Supply Air Humidity Ratio from the Sizing:System object)

With the inlet and outlet conditions established, we can obtain the inlet and outlet enthalpies:

$$\begin{aligned} h_{air,coil,des,in} &= \text{PsyHFnTdbW}(T_{air,in,des}, W_{air,in,des}) \\ h_{air,coil,des,out} &= \text{PsyHFnTdbW}(T_{air,out,des}, W_{air,out,des}) \end{aligned} \quad (10.17)$$

Where PsyHFnTdbW is the EnergyPlus function for calculation air specific enthalpy given the air temperature and humidity ratio. We now have all we need to calculate the design coil capacity, $\dot{Q}_{coil,des}$.

10.7.4.3 Design Coil Load - Zone Coils

If the coil is part of an AirTerminal:SingleDuct:ConstantVolume:FourPipeInduction unit or an Zone-HVAC:FourPipeFanCoil, the cooling load (cooling capacity) is passed down from the terminal unit or fan coil sizing calculations. Otherwise the load is defined as:

$$\dot{Q}_{coil,des} = \dot{m}_{a,coil,des} (h_{a,coil,des,in} - h_{a,coil,des,out}) + \dot{Q}_{fan,heat,des} \quad (10.18)$$

Where:

- $h_{a,coil,des,in}$: is the coil design inlet air enthalpy (J/kg)
- $h_{a,coil,des,out}$: is the coil design outlet air enthalpy (J/kg)
- $\dot{m}_{a,coil,des}$: is the coil design air mass flow rate (kg/s)
- $\dot{Q}_{fan,heat,des}$: is the design fan heat (W) - see Section 10.7.3

The enthalpies are given by:

$$\begin{aligned} h_{air,coil,des,in} &= \text{PsyHFnTdbW}(T_{air,in,des}, W_{air,in,des}) \\ h_{air,coil,des,out} &= \text{PsyHFnTdbW}(T_{air,out,des}, W_{air,out,des}) \end{aligned} \quad (10.19)$$

Where the inputs to those functions are the coil inlet design conditions. For coils in terminal units these are set at the system level to the system design supply air temperature. For zonal units they are set to design return air, mixed air, or outside air as appropriate to the unit. $T_{air,out,des}$ is set to the zone cooling design supply air temperature as specified in the *Zone:Sizing* inputs. $W_{air,out,des}$ is set to the zone cooling design supply air humidity ratio as specified in the *Zone:Sizing* inputs.

10.7.4.4 Design Water Flow Rate (m³/s) - System Coils

The design water volumetric flow rate is calculated using:

$$\dot{V}_{w,coil,des} = \frac{\dot{Q}_{coil,des}}{\rho_w c_{p,w} \Delta T_{w,des}} \quad (10.20)$$

Where $\Delta T_{w,des}$ is just the *Loop Design Temperature Difference* user input from *Sizing:Plant* (if the coil is in the outside air stream, 1/2 the *Loop Design Temperature Difference* is used). The design coil load $Load_{coil,des}$ is calculated from:

$$Load_{coil,des} = AirMassFlowRate_{coil,des} \cdot (h_{air,coil,des,in} - h_{air,coil,des,out}) \quad (10.21)$$

10.7.4.5 Design Water Flow Rate (m³/s) - Zone Coils

If the coil is part of an AirTerminal:SingleDuct:ConstantVolume:FourPipeInduction unit or an Zone-HVAC:FourPipeFanCoil, the chilled water flow rate is passed down from the terminal unit or fan coil sizing calculations. Otherwise the flow is set to:

$$\dot{V}_{w,coil,des} = \frac{\dot{Q}_{coil,des}}{\rho_w c_{p,w} \Delta T_{w,des}} \quad (10.22)$$

Where $\Delta T_{w,des}$ is just the *Loop Design Temperature Difference* user input from *Sizing:Plant*.

10.7.4.6 Design Air Flow Rate - System Coils

The design air volumetric flow rate for the system cooling coil is set to:

1. the design outside air flow rate if the coil is in the outside air stream;
2. the coil design flow rate from function `GetCoilDesFlowT` described in section “Initial Calculations”;
3. the design flow rate set by the parent component (such as a unitary system) containing the cooling coil.

10.7.4.7 Design Air Flow Rate - Zone Coils

Zone chilled water coils are always part of a zone HVAC component. In almost all cases the design flow rate is passed down from the design flow rate of the parent component. Otherwise if the parent component does cooling only the flow rate for the coil is set to the zone design cooling flow rate. And if the parent component does both cooling and heating, the coil flow rate is set to the maximum of the zone design cooling and heating flow rates.

10.7.4.8 Design Air Inlet Temperature - System Coils

The inlet air temperature depends on whether the coil is in the outside air stream and if it is not, whether or not there is outside air preconditioning.

- Coil in outside air stream: $T_{air,in,des} = T_{out,cool,at-peak}$ (the outside air temperature set at the design cooling peak).
- Coil in main air stream, no preconditioning of outside air: $T_{air,in,des} = T_{mix,cool,at-peak}$ (the mixed air temperature at the cooling design peak. Plus the design fan temperature rise due to fan heat, $+ T_{fan,heat,des}$, for blow through configuration - see Section 10.7.3).
- Coil in main air stream, outside air preconditioned. The outside air fraction is calculated as $f_{oa} = \dot{V}_{air,out,des} / \dot{V}_{cc,air}$, where $\dot{V}_{cc,air}$ is calculated above. Then $T_{air,in,des} = f_{oa}T_{precool} + (1 - f_{oa})T_{ret,cool,at-peak}$, where $T_{precool}$ is the specified *Precool Design Temperature* from *System:Sizing*, $T_{ret,cool,at-peak}$ is the return temperature at the system cooling peak load. Plus the design fan temperature rise due to fan heat, $+ T_{fan,heat,des}$, for blow through configuration - see Section 10.7.3).

10.7.4.9 Design Air Inlet Temperature - Zone Coils

The design inlet temperature depends on whether the coil is in a terminal unit or a zonal unit, and where the coil is positioned within the unit. The design fan temperature rise is added to coil inlet temperature for blow-through or subtracted from the coil outlet air temperature for draw-through. Fan heat in either case results in a higher design coil load - see Section 10.7.3.

1. For the `AirTerminal:SingleDuct:ConstantVolume:FourPipeInduction` terminal unit the design inlet temperature is set to the zone temperature at the time of the zone cooling peak, since the coil is located in the induced air stream: $T_{air,in,des} = T_{zone,cool,peak}$

2. For fan coil units the design inlet temperature is set to the mixed air temperature: $T_{air,in,des} = f_{oa}T_{oa,coolpeak} + (1 - f_{oa})T_{z,coolpeak}$, where $f_{oa} = \rho_a \dot{V}_{z,oa,des} / \dot{m}_{z,cool,des}$
3. In all other cases the design inlet temperature is set to the zone design cooling coil inlet temperature which is calculated in the zone sizing simulation and is basically the same calculation as the fan coil unit.

10.7.4.10 Design Air Outlet Temperature - System Coils

The outlet air temperature depends on whether the coil is in the outside air stream.

1. Coil in outside air stream: $T_{air,out,des} = T_{sys,des,precool}$ (the specified Precool Design Temperature from the Sizing:System object).
2. Coil in main air stream: the design outlet air temperature is set to the temperature calculated in the Initial Calculation section above.

10.7.4.11 Design Air Outlet Temperature - Zone Coils

If the coil is part of an AirTerminal:SingleDuct:ConstantVolume:FourPipeInduction unit, then:

$$\begin{aligned}
 \dot{Q}_{coil,des} &= c_{p,air} \rho_{air} \dot{V}_{w,coil,des} \Delta T_{w,des} \\
 T_1 &= T_{air,in,des} - \dot{Q}_{coil,des} / (\rho_{air} c_{p,air} \dot{V}_{air,coil,des}) \\
 T_2 &= T_{w,out,des} + 2 \\
 T_{air,out,des} &= \max(T_1, T_2)
 \end{aligned} \tag{10.23}$$

For all other cases $T_{air,out,des}$ is set to $T_{z,sup,des}$ (the zone design supply air temperature as specified in Sizing:Zone).

10.7.4.12 Design Inlet Air Humidity Ratio - System Coils

The design inlet humidity ratio depends on whether the coil is in the outside air stream and if it is not, whether or not there is outside air preconditioning.

- Coil in outside air stream: $W_{air,in,des} = W_{out,cool,at-peak}$ (the outside air humidity ratio at the design cooling peak).
- Coil in main air stream, no preconditioning of outside air: $W_{air,in,des} = W_{mix,cool,at-peak}$ (the mixed air humidity ratio at the cooling design peak).
- Coil in main air stream, outside air preconditioned. The outside air fraction is calculated as $f_{oa} = \dot{V}_{air,out,des} / \dot{V}_{cc,air}$, where $\dot{V}_{cc,air}$ is calculated above. Then $W_{air,in,des} = f_{oa}W_{precool} + (1 - f_{oa})W_{ret,cool,at-peak}$, where $W_{precool}$ is the specified *Precool Design Humidity Ratio* from *System:Sizing*, and $W_{ret,cool,at-peak}$ is the return humidity ratio at the system cooling peak load.

10.7.4.13 Design Air Inlet Humidity Ratio - Zone Coils

The design inlet humidity ratio depends on whether the coil is in a terminal unit or a zonal unit, and where the coil is positioned within the unit.

1. For the AirTerminal:SingleDuct:ConstantVolume:FourPipeInduction terminal unit the design inlet humidity ratio is set to the zone humidity ratio at the time of the zone cooling peak, since the coil is located in the induced air stream.
2. For fan coil units the design inlet humidity ratio is set to the mixed air humidity ratio: $W_{air,in,des} = f_{oa} W_{oa,coolpeak} + (1 - f_{oa}) W_{z,coolpeak}$, where $f_{oa} = \rho_a \dot{V}_{z,oa,des} / \dot{m}_{z,cool,des}$
3. In all other cases the design inlet humidity ratio is set to the zone design cooling coil inlet humidity ratio which is calculated in the zone sizing simulation and is basically the same calculation as the fan coil unit.

10.7.4.14 Design Outlet Air Humidity Ratio - System Coils

The outlet air humidity ratio depends on whether the coil is in the outside air stream.

- Coil in outside air stream: $W_{air,out,des} = W_{sys,des,precool}$ (the specified Precool Design Humidity Ratio from the Sizing:System object)
- Coil in main air stream: $W_{air,out,des} = \text{PsyWFnTdbRhPb}(T_{air,out,des}, 0.9, P_{air,std})$, where PsyWFnTdbRhPb is the EnergyPlus psychrometric function to calculate humidity ratio from drybulb temperature, relative humidity, and atmospheric pressure. The design outlet humidity ratio is being set to the humidity ratio at 90% relative humidity and design outlet temperature.

10.7.4.15 Design Outlet Air Humidity Ratio - Zone Coils

- If the coil is part of an AirTerminal:SingleDuct:ConstantVolume:FourPipeInduction unit, then:
- Get the dewpoint temperature at $W_{air,in,des}$: $T_{dp,in} = \text{PsyTdpFnWPb}(W_{air,in,des}, P_{air,std})$
- If $T_{dp,in} \leq T_{w,in,des}$ set $W_{air,out,des} = W_{air,in,des}$. Otherwise set $W_{air,out,des} = \min(\text{PsyWFnTdbRhPb}(T_{air,out,des}, 0.9, P_{air,std}), W_{air,in,des})$

10.7.4.16 Design Inlet Water Temperature - System Coils

The Design Inlet Water Temperature is set to the Design Loop Exit Temperature specified in the Sizing:Plant object for the water loop serving this coil.

10.7.4.17 Design Inlet Water Temperature - Zone Coils

The Design Inlet Water Temperature is set to the Design Loop Exit Temperature specified in the Sizing:Plant object for the water loop serving this coil.

10.7.5 Coil:Cooling:Water:DetailedGeometry Sizing

The sizing is done in subroutine *SizeWaterCoil*

10.7.5.1 Max Water Flow Rate of Coil

The calculation is identical to that done for *Coil:Cooling:Water*.

10.7.5.2 Number of Tubes per Row

$$N_{tube/row} = \text{Int}(13750 \cdot \dot{V}_{coil, water, max}) \quad (10.24)$$

$$N_{tube/row} = \text{Max}(N_{tube/row}, 3) \quad (10.25)$$

10.7.5.3 Fin Diameter

Depending on the duct type, get the coil design air flow rate.

For duct type = *main, other* or default

$$\dot{m}_{air, des} = \rho_{air} \cdot DesMainVolFlow_{sys} \quad (10.26)$$

for duct type = *cooling*

$$\dot{m}_{air, des} = \rho_{air} \cdot DesCoolVolFlow_{sys} \quad (10.27)$$

for duct type = *heating*

$$\dot{m}_{air, des} = \rho_{air} \cdot DesHeatVolFlow_{sys} \quad (10.28)$$

$$D_{fin} = 0.335 \cdot \dot{m}_{air, des} \quad (10.29)$$

10.7.5.4 Minimum Air Flow Area

Depending on the duct type, get the coil design air flow rate.

For duct type = *main, other* or default

$$\dot{m}_{air, des} = \rho_{air} \cdot DesMainVolFlow_{sys} \quad (10.30)$$

for duct type = *cooling*

$$\dot{m}_{air, des} = \rho_{air} \cdot DesCoolVolFlow_{sys} \quad (10.31)$$

for duct type = *heating*

$$\dot{m}_{air, des} = \rho_{air} \cdot DesHeatVolFlow_{sys} \quad (10.32)$$

$$A_{MinAirFlow} = 0.44 \cdot \dot{m}_{air, des} \quad (10.33)$$

10.7.5.5 Fin Surface Area

Depending on the duct type, get the coil design air flow rate.

For duct type = *main*, *other* or default

$$\dot{m}_{air,des} = \rho_{air} \cdot DesMainVolFlow_{sys} \quad (10.34)$$

for duct type = *cooling*

$$\dot{m}_{air,des} = \rho_{air} \cdot DesCoolVolFlow_{sys} \quad (10.35)$$

for duct type = *heating*

$$\dot{m}_{air,des} = \rho_{air} \cdot DesHeatVolFlow_{sys} \quad (10.36)$$

$$A_{FinSurf} = 78.5 \cdot \dot{m}_{air,des} \quad (10.37)$$

10.7.5.6 Total Tube Inside Area

$$A_{tube,total\ inside} = 4.4 * D_{tube,inside} * N_{tube\ rows} * N_{tubes/row} \quad (10.38)$$

Where $D_{tube,inside}$ is the tube inside diameter.

10.7.5.7 Tube Outside Surf Area

$$A_{tube,outside} = 4.1 * D_{tube,outside} * N_{tube\ rows} * N_{tubes/row} \quad (10.39)$$

Where $D_{tube,outside}$ is the tube outside diameter.

10.7.5.8 Coil Depth

$$Depth_{coil} = Depth_{tube\ spacing} * N_{tube\ rows} \quad (10.40)$$

10.7.6 CoilSystem:Cooling:Water

The sizing of water cooling coil components wrapped in this coil system is done in function *SizeWaterCoil* of module *WaterCoils*. See component sizing sections for *Coil:Cooling:Water* and *Coil:Cooling:Water:DetailedGeometry*.

10.7.7 Coil:Cooling:WaterToAirHeatPump:EquationFit Sizing

The sizing is done in subroutine *SizeHVACWaterToAir*.

10.7.7.1 Rated Air Flow Rate

The calculation is identical to that done for *Coil:Cooling:Water*.

10.7.7.2 Rated Water Flow Rate

The calculation is identical to that done for *Coil:Cooling:Water*, which is the coil design load divided by the *Loop Design Temperature Difference* user input from *Sizing:Plant*. If there is a companion heating coil, the heating coil design load is used so that both modes will have the same rated water flow rate. For sizing the plant loop serving this coil, only one half of this flow rate is used since both the cooling and heating coil will save a flow rate but only one of these coils will operate at a time.

10.7.7.3 Rated Total Cooling Capacity

The calculation for coil operating temperatures (inlet and outlet) are identical to that done for *Coil:Cooling:Water*. The following calculations are then performed to determine the rated total cooling capacity.

$$T_{WB,ratio} = \frac{T_{WB,air,in,des} + 273.15C}{283.15C} \quad (10.41)$$

$$T_{S,ratio} = \frac{29.44C + 273.15C}{283.15C} \quad (10.42)$$

where:

$T_{WB,ratio}$ = ratio of load-side inlet air wet-bulb temperature in Kelvin to a reference temperature

$T_{S,ratio}$ = ratio of source-side inlet water temperature in Kelvin to a reference temperature

$$TotCapTempModFac = TCC1 + TCC2(T_{WB,ratio}) + TCC3(T_{S,ratio}) + TCC4 + TCC5 \quad (10.43)$$

where:

TCC1 = user input for Total Cooling Capacity Coefficient 1

TCC2 = user input for Total Cooling Capacity Coefficient 2

TCC3 = user input for Total Cooling Capacity Coefficient 3

TCC4 = user input for Total Cooling Capacity Coefficient 4

TCC5 = user input for Total Cooling Capacity Coefficient 5

The 4th and 5th coefficient (TCC4 and TCC5) used in the above equation are multipliers for the load-side and source-side flow ratios, respectively. For sizing, these ratios are assumed to be 1.

The enthalpy of the entering air is then compared with the enthalpy of the exiting air. The calculations for air enthalpy are identical to that done for *Coil:Cooling:Water*. If the entering air enthalpy is less than the exiting air enthalpy, a reference value of 48,000 J/kg is used as the entering air enthalpy. If the TotCapTempModFac calculation above yields 0 as the result, a value of 1 is used in the following calculation. If the design air mass flow rate is determined to be less than a very small flow value (0.001 kg/s) or the capacity calculated here is less than 0, the coil total cooling capacity is set equal to 0.

$$\dot{Q}_{coil,des,total} = \frac{\dot{m}_{air,des}(H_{in} - H_{out})}{TotCapTempModFac} + \dot{Q}_{fan,heat,des} \quad (10.44)$$

Where:

- $\dot{Q}_{fan,heat,des}$: is the design fan heat (W) - see Section 10.7.3

10.7.7.4 Rated Sensible Cooling Capacity

The calculation for coil operating temperatures (inlet and outlet) are identical to that done for *Coil:Cooling:Water*. The following calculations are then performed to determine the rated sensible cooling capacity.

$$T_{DB,ratio} = \frac{T_{DB,air,in,des} + 273.15C}{283.15C} \quad (10.45)$$

$$T_{S,ratio} = \frac{29.44C + 273.15C}{283.15C} \quad (10.46)$$

where:

$T_{DB,ratio}$ = ratio of load-side inlet air dry-bulb temperature in Kelvin to a reference temperature

$$\begin{aligned} SensCapTempModFac = & SCC1 + SCC2(T_{DB,ratio}) + SCC3(T_{WB,ratio}) \\ & + SCC4(T_{S,ratio}) + SCC5 + SCC6 \end{aligned} \quad (10.47)$$

where:

SCC1 = user input for Sensible Cooling Capacity Coefficient 1

SCC2 = user input for Sensible Cooling Capacity Coefficient 2

SCC3 = user input for Sensible Cooling Capacity Coefficient 3

SCC4 = user input for Sensible Cooling Capacity Coefficient 4

SCC5 = user input for Sensible Cooling Capacity Coefficient 5

SCC6 = user input for Sensible Cooling Capacity Coefficient 6

The 5th and 6th coefficient (SCC5 and SCC6) used in the above equation are multipliers for the load-side and source-side flow ratios, respectively. For sizing, these ratios are assumed to be 1.

The dry-bulb temperature of the entering air is then compared with the dry-bulb temperature of the exiting air. The calculations for air dry-bulb temperature are identical to that done for *Coil:Cooling:Water*. If the entering air dry-bulb temperature is less than the exiting air dry-bulb temperature, a reference value of 24°C is used as the entering air dry-bulb temperature. If the SensCapTempModFac calculation above yields 0 as the result, a value of 1 is used in the following calculation. If the design air mass flow rate is determined to be less than a very small flow value (0.001 kg/s) or the capacity calculated here is less than 0, the coil sensible cooling capacity is set equal to 0.

$$\dot{Q}_{coil,des,sensible} = \frac{\dot{m}_{air,des} C_{p,air,des} (T_{DB,in} - T_{DB,out})}{SensCapTempModFac} + \dot{Q}_{fan,heat,des} \quad (10.48)$$

Where:

- $\dot{Q}_{fan,heat,des}$: is the design fan heat (W) - see Section 10.7.3

10.7.8 Coil:Cooling:WaterToAirHeatPump:VariableSpeedEquationFit Sizing

For the cooling coil of VS WSHP, we specify a nominal speed level. During the sizing calculation, the Rated Air Volume Flow Rate, the Rated Water Volume Flow Rate and the Rated Total

Cooling Capacity at the Selected Nominal Speed Level are determined in the same way as the *Coil:Cooling:WaterToAirHeatPump:EquationFit* object. The sensible heat transfer rate is not allowed for auto-sizing, instead, it is a function of the rated air and water flow rates, rated total cooling capacity and the Reference Unit SHR at the nominal speed level. The default nominal speed level is the highest speed. However, the model allows the user to select a nominal speed level rather than the highest.

10.7.8.1 Rated Air Flow Rate

The calculation is identical to that done for *Coil:Cooling:WaterToAirHeatPump:EquationFit*.

10.7.8.2 Rated Water Flow Rate

The calculation is identical to that done for *Coil:Cooling:WaterToAirHeatPump:EquationFit*, which is the coil design load divided by the *Loop Design Temperature Difference* user input from *Sizing:Plant*. If there is a companion heating coil, the heating coil design load is used so that both modes will have the same rated water flow rate. For sizing the plant loop serving this coil, only one half of this flow rate is used since both the cooling and heating coil will save a flow rate but only one of these coils will operate at a time.

10.7.8.3 Rated Total Cooling Capacity

The calculation for coil operating temperatures (inlet and outlet) are identical to that done for *Coil:Cooling:WaterToAirHeatPump:EquationFit*. The calculations for air enthalpy are similar to that done for *Coil:Cooling:WaterToAirHeatPump:EquationFit*. The difference is in calculating the total cooling capacity temperature modifier function at the selected nominal speed level, as below:

$$TotCapTempModFrac_{NominalSpeed} = a + b * WB_i + c * WB_i^2 + d * EWT + e * EWT^2 + f * WB_i * EWT \quad (10.49)$$

where:

WB_i = wet-bulb temperature of the air entering the heating coil, °C

EWT = entering water temperature, °C

a-f = regression curve-fit coefficients.

If the entering air enthalpy is less than the exiting air enthalpy, a reference value of 48,000 J/kg is used as the entering air enthalpy. If the *TotCapTempModFac* calculation above yields 0 as the result, a value of 1 is used in the following calculation. If the rated air mass flow rate is determined to be less than a very small flow value (0.001 kg/s) or the capacity calculated here is less than 0, the coil total cooling capacity is set equal to 0.

If $H_{in} > H_{out}$ Then

$$\dot{Q}_{coil,rated,total} = m_{air,rated}(H_{in} - H_{out})/TotCapTempModFrac_{NominalSpeed} \quad (10.50)$$

Else

$$\dot{Q}_{coil,rated,total} = m_{air,rated}(48000 - H_{out})/TotCapTempModFrac_{NominalSpeed} \quad (10.51)$$

End If

$$\dot{Q}_{coil,rated,total} = \dot{Q}_{coil,rated,total} + \dot{Q}_{fan,heat,des} \quad (10.52)$$

Where:

- $\dot{Q}_{fan,heat,des}$: is the design fan heat (W) - see Section 10.7.3

10.7.9 Coil:Heating:WaterToAirHeatPump:EquationFit Sizing

The sizing is done in subroutine *SizeHVACWaterToAir*.

10.7.9.1 Rated Air Flow Rate

The calculation is identical to that done for *Coil:Cooling:Water*.

10.7.9.2 Rated Water Flow Rate

The calculation is identical to that done for *Coil:Cooling:Water* , which is the coil design load divided by the *Loop Design Temperature Difference* user input from *Sizing:Plant*. For sizing the plant loop serving this coil, only one half of this flow rate is used since both the cooling and heating coil will save a flow rate but only one of these coils will operate at a time.

10.7.9.3 Rated Total Heating Capacity

The rated total heating capacity is set equal to the rated total cooling capacity.

10.7.10 Coil:Heating:WaterToAirHeatPump:VariableSpeedEquationFit Sizing

For the heating coil of VS WSHP, we specify a nominal speed level. During the sizing calculation, the Rated Air Volume Flow Rate and the Rated Water Volume Flow Rate are determined in the same way as the *Coil:Heating:WaterToAirHeatPump:EquationFit* object. On the other hand, the Rated Heating Capacity at the Selected Nominal Speed Level should be the same as the total cooling capacity of its corresponding cooling coil, which has to be sized first. The default nominal speed level will be the highest speed. However, the model allows the user to select a nominal speed level rather than the highest.

10.7.10.1 Rated Air Flow Rate

The calculation is identical to that done for *Coil:Cooling:WaterToAirHeatPump:EquationFit*.

10.7.10.2 Rated Water Flow Rate

The calculation is identical to that done for *Coil:Cooling:WaterToAirHeatPump:EquationFit*, which is the coil design load divided by the *Loop Design Temperature Difference* user input from *Sizing:Plant*. For sizing the plant loop serving this coil, only one half of this flow rate is used since both the cooling and heating coil will save a flow rate but only one of these coils will operate at a time.

10.7.10.3 Rated Total Heating Capacity

The rated total heating capacity is set equal to the rated total cooling capacity.

10.7.11 Coil:Heating:Water Sizing

The sizing is done in subroutine *SizeWaterCoil*.

10.7.11.1 Max Water Flow Rate of Coil

10.7.11.1.1 System Coils

With the coil load from the system design data array and the user specified (in a Sizing:Plant object) design hot water temperature fall, calculate the max water flow rate:

$$\dot{V}_{coil,water,max} = HeatCap_{sys} / (C_{p,water} \cdot \rho_{water} \cdot \Delta T_{plt,hw,des}) \quad (10.53)$$

10.7.11.1.2 Zone Coils

Using the zone design coil inlet and supply air conditions calculate the design coil load.

If the coil is not part of an induction unit then obtain the coil inlet temperature from the zone design data array:

$$T_{in,air} = DesHeatCoilInTemp_{zone}$$

If the coil is part of an induction unit take into account the induced air:

$$Frac_{minflow} = MinFlowFrac_{zone}$$

$$T_{in,air} = DesHeatCoilInTemp_{zone} * Frac_{minflow} + ZoneTempAtHeatPeak_{zone} * (1 - Frac_{minflow})$$

$$T_{out,air} = HeatDesTemp_{zone}$$

$$W_{out,air} = HeatDesHumRat_{zone}$$

If the coil is part of a terminal unit the mass flow rate is determined by the volumetric flow rate of the terminal unit:

$$\dot{m}_{air,des} = \rho_{air} \cdot \dot{m}_{air,des,tu} \quad (10.54)$$

Otherwise the design flow is obtained from the zone design data array:

$$\dot{m}_{air,des} = DesHeatMassFlow_{zone} \quad (10.55)$$

$$Q_{coil,des} = c_{p,air} \dot{m}_{air,des} \cdot (T_{out,air} - T_{in,air}) \quad (10.56)$$

Here $c_{p,air}$ is calculated at the outlet humidity and the average of the inlet and outlet temperatures.

With the coil load and the user specified (in a Sizing:Plant object) design hot water temperature decrease, calculate the max water flow rate:

$$\dot{V}_{coil,water,max} = Q_{coil,des} / (C_{p,water} \cdot \rho_{water} \cdot \Delta T_{plt,hw,des}) \quad (10.57)$$

10.7.11.2 UA of the Coil

To obtain the UA of the coil, we specify the model inputs (other than the UA) at design conditions and the design coil load that the coil must meet. Then we numerically invert the coil model to solve for the UA that will enable the coil to meet the design coil load given the specified inputs.

10.7.11.2.1 System Coils

The design coil load is the system design sensible cooling capacity:

$$Q_{coil,des} = HeatCap_{sys} \quad (10.58)$$

The required inputs for the simple coil model are:

$$T_{in,air} = HeatMixTemp_{sys} \quad (10.59)$$

$$W_{in,air} = HeatMixHumRat_{sys} \quad (10.60)$$

$$T_{in,water} = ExitTemp_{plt,hw,des} \quad (10.61)$$

$$\dot{m}_{in,water} = \rho_{water} \cdot \dot{V}_{coil,water,max} \quad (10.62)$$

Depending on the duct type, get the coil design air flow rate.

For duct type = *main*, *other* or default

$$\dot{m}_{in,air} = \rho_{air} \cdot DesMainVolFlow_{sys} \quad (10.63)$$

for duct type = *cooling*

$$\dot{m}_{in,air} = \rho_{air} \cdot DesCoolVolFlowsys \quad (10.64)$$

for duct type = *heating*

$$\dot{m}_{in,air} = \rho_{air} \cdot DesHeatVolFlow_{sys} \quad (10.65)$$

We now have all the data needed to obtain UA. The numerical inversion is carried out by calling subroutine *SolveRegulaFalsi*. This is a general utility routine for finding the zero of a function. In this case it finds the UA that will zero the residual function - the difference between the design coil load and the coil output divided by the design coil load. The residual is calculated in the function *SimpleHeatingCoilUAResidual*.

10.7.11.2.2 Zone Coils

If the coil is not part of an induction unit then obtain the coil inlet temperature from the zone design data array;

$$T_{in,air} = DesHeatCoilInTemp_{zone} \quad (10.66)$$

If the coil is part of an induction unit take into account the induced air:

$$Frac_{minflow} = MinFlowFrac_{zone} \quad (10.67)$$

$$T_{in,air} = DesHeatCoilInTemp_{zone} * Frac_{minflow} + \quad (10.68)$$

$$ZoneTempAtHeatPeak_{zone} * (1 - Frac_{minflow}) \quad (10.69)$$

$$W_{in,air} = DesHeatCoilInHumRat_{zone} \quad (10.70)$$

$$T_{in,water} = ExitTemp_{plt,hw,des} \quad (10.71)$$

$$\dot{m}_{in,water} = \rho_{water} \cdot \dot{V}_{coil,water,max} \quad (10.72)$$

$$T_{out,air} = HeatDesTemp_{zone} \quad (10.73)$$

$$W_{out,air} = HeatDesHumRat_{zone} \quad (10.74)$$

If the coil is part of a terminal unit the mass flow rate is determined by the volumetric flow rate of the terminal unit:

$$\dot{m}_{air,des} = \rho_{air} \cdot \dot{m}_{air,des,tu} \quad (10.75)$$

Otherwise the design flow is obtained from the zone design data array:

$$\dot{m}_{air,des} = DesHeatMassFlow_{zone} \quad (10.76)$$

$$\dot{Q}_{coil,des} = c_{p,air} \cdot \dot{m}_{air,des} \cdot (T_{out,air} - T_{in,air}) \quad (10.77)$$

Here $c_{p,air}$ is calculated at the outlet humidity and the average of the inlet and outlet temperatures.

We now have all the data needed to obtain UA. The numerical inversion is carried out by calling subroutine *SolveRegulaFalsi*. This is a general utility routine for finding the zero of a function. In this case it finds the UA that will zero the residual function - the difference between the design coil load and the coil output divided by the design coil load. The residual is calculated in the function *SimpleHeatingCoilUAResidual*.

10.7.12 Coil:Heating:Steam Sizing

The sizing is done in subroutine *SizeSteamCoil*.

10.7.12.1 Maximum Steam Flow Rate

10.7.12.1.1 System Coils

The maximum steam volumetric flow rate is calculated using:

$$\dot{V}_{coil,steam,max} = \frac{Load_{coil,des}}{\rho_{steam}(h_{fg} + c_{p,w} \cdot \Delta T_{sc})} \quad (10.78)$$

The steam density (ρ_{steam}) is for saturated steam at 100 °C (101325.0 Pa) and h_{fg} is the latent heat of vaporization of water at 100 °C (101325.0 Pa). $C_{p,w}$ is the heat capacity of saturated water (condensate) at 100 °C (101325.0 Pa) and ΔT_{sc} is the Degree of Subcooling defined in the Coil:Heating:Steam object input. The design coil load $Load_{coil,des}$ is calculated from:

$$Load_{coil,des} = \dot{m}_{air,des}(c_{p,air})(T_{air,coil,des,out} - T_{air,coil,des,in}) \quad (10.79)$$

The design air mass flow rate depends on the location of the coil (duct type). For duct type = *main*, the flow rate is set to $\rho_{air} * DesMainVolFlow_{sys} * MinSysAirFlowRatio$. If the coil is in a cooling duct the flow rate is set to $\rho_{air} * DesCoolVolFlow_{sys} * MinSysAirFlowRatio$. If the coil is in a heating duct the flow rate is set to $\rho_{air} * DesHeatVolFlow_{sys}$. If the coil is in any other kind of duct, the flow rate is set to $\rho_{air} * DesMainVolFlow_{sys}$.

For sizing, the design outlet air temperature ($T_{air,coil,des,out}$) is the Central Heating Design Supply Air Temperature specified in the Sizing:System object.

The design inlet air temperature depends on whether the coil is being sized for 100% outdoor air or minimum outdoor air flow (per 100% Outdoor Air in Heating input field in the Sizing:System object).

- 1) Sizing based on 100% Outdoor Air in Heating

$$T_{air,coil,des,in} = HeatOutTemp_{sys} \text{ (the outdoor air temperature at the design heating peak)}$$

- 2) Sizing based on minimum outdoor air flow. The outdoor air fraction is calculated as $Frac_{oa} = DesOutAirVolFlow_{sys} / DesVolFlow$. $DesVolFlow$ is $\dot{m}_{air,des} / \rho_{air}$.

$$T_{air,coil,des,in} = Frac_{oa}HeatOutTemp_{sys} + (1 - Frac_{oa}) HeatRetTemp_{sys} \text{ (see Table 10.2 System Sizing Data)}$$

10.7.12.1.2 Zone Coils

If the coil is part of an *AirTerminal:SingleDuct:** unit (e.g., *AirTerminal:SingleDuct:Constant-Volume:Reheat*, *AirTerminal:SingleDuct:VAV:Reheat*, *AirTerminal:SingleDuct:SeriesPIU:Reheat*, etc.), the maximum steam flow rate is set equal to the terminal unit's maximum steam flow rate. Otherwise (e.g., the zone-level coil is part of *ZoneHVAC:PackedTerminalAirConditioner*, *ZoneHVAC:UnitVentilator*, *ZoneHVAC:UnitHeater* or *ZoneHVAC:VentilatedSlab*) the calculation is similar to that at the system level. A design load is calculated:

$$Load_{coil,des} = \dot{m}_{air,des}(c_{p,air})(T_{air,coil,des,out} - T_{air,coil,des,in}) \quad (10.80)$$

where:

$$\dot{m}_{air,des} = DesHeatMassFlow_{zone} \text{ (see Table 10.1 Zone Sizing Data)}$$

$T_{air,coil,des,in} = DesHeatCoilInTemp_{zone}$ (see Table 10.1)

$T_{air,coil,des,out} = HeatDesTemp_{zone}$ (user input from Sizing:Zone object)

$c_{p,air}$ = Specific heat of air (evaluated at the average of inlet and outlet air temperatures, and at the zone heating design supply air humidity ratio $HeatDesHumRat_{zone}$ [user input from Sizing:Zone object])

$$\dot{V}_{coil,steam,max} = \frac{Load_{coil,des}}{\rho_{steam} (h_{fg} + c_{p,w} \cdot \Delta T_{sc})} \quad (10.81)$$

The terms in the denominator of this equation (ρ_{steam} , h_{fg} , etc.) are evaluated in the same way as described above for steam System Coils.

10.7.13 Sizing of Gas and Electric Heating Coils

The sizing calculation is done in subroutine *SizeHeatingCoil* in module *HeatingCoils*.

10.7.13.1 Nominal Capacity of the Coil

10.7.13.1.1 System Coils

The value is obtained from the system design array.

$$Cap_{nom} = HeatCap_{sys} \quad (10.82)$$

10.7.13.1.2 Zone Coils

The capacity is calculated from the design coil inlet and outlet conditions.

If the coil is not part of an induction unit then obtain the coil inlet temperature from the zone design data array;

$$T_{in,air} = DesHeatCoilInTemp_{zone} \quad (10.83)$$

If the coil is part of an induction unit take into account the induced air:

$$Frac_{minflow} = MinFlowFrac_{zone} \quad (10.84)$$

$$T_{in,air} = DesHeatCoilInTemp_{zone} * Frac_{minflow} + \quad (10.85)$$

$$ZoneTempAtHeatPeak_{zone} * (1 - Frac_{minflow}) \quad (10.86)$$

$$T_{out,air} = HeatDesTemp_{zone} \quad (10.87)$$

$$W_{out,air} = HeatDesHumRat_{zone} \quad (10.88)$$

$$Q_{coil,des} = C_{p,air} * DesHeatMassFlow_{zone} * (T_{out,air} - T_{in,air}) \quad (10.89)$$

Here $c_{p,air}$ is calculated at the outlet humidity and the average of the inlet and outlet temperatures.

10.7.14 DX Coil Sizing

The sizing calculations are done in subroutine *SizeDXCoil* in module *DXCoils*. This section covers the sizing of the objects

1. Coil:Cooling:DX:SingleSpeed
2. Coil:Heating:DX:SingleSpeed
3. Coil:Cooling:DX:TwoSpeed

10.7.14.1 Rated Air Volume Flow Rate

10.7.14.2 System Coils

The rated air flow rate is obtained from the system design array.

$$\dot{V}_{air, rated} = DesMainVolFlow_{sys} \quad (10.90)$$

10.7.14.3 Zone Coils

The rated air flow rate is the maximum of the heating and cooling design flow rates from the zone design array.

$$\dot{V}_{air, rated} = Max(DesCoolVolFlow_{zone}, DesHeatVolFlow_{zone}) \quad (10.91)$$

10.7.14.4 Rated Total Cooling Capacity

10.7.14.5 System Coils

The rated cooling capacity is obtained by dividing the peak cooling capacity by the *Cooling Capacity Modifier Curve* evaluated at peak mixed wetbulb and outdoor drybulb temperatures.

$$T_{mix} = CoolMixTemp_{sys} \quad (10.92)$$

$$W_{mix} = CoolMixHumRat_{sys} \quad (10.93)$$

$$T_{sup} = CoolSupTemp_{sys} \quad (10.94)$$

$$W_{sup} = CoolSupHumRat_{sys} \quad (10.95)$$

$$T_{outside} = CoolOutTemp_{sys} \quad (10.96)$$

$$r_{air} = PsyRhoAirFnPbTdbW(p_{air, std}, T_{mix}, W_{mix}) \quad (10.97)$$

$$h_{mix} = PsyHFnTdbW(T_{mix}, W_{mix}) \quad (10.98)$$

$$h_{sup} = PsyHFnTdbW(T_{sup}, W_{sup}) \quad (10.99)$$

$$T_{mix,wb} = PsyTwbFnTdbWPb(T_{mix}, W_{mix}, p_{air,std}) \quad (10.100)$$

$$CapModFac = CurveValue(CCapFTemp, T_{mix,wb}, T_{outside}) \quad (10.101)$$

$Q_{fan,heat,des}$ = design fan heat (W) - see Section 10.7.3

$$CCap_{peak} = \rho_{air} \cdot \dot{V}_{air,rated} \cdot (h_{mix} - h_{sup}) + \dot{Q}_{fan,heat,des} \quad (10.102)$$

$$CCap_{rated} = CCap_{peak} / CapModFac \quad (10.103)$$

We check that the design volume flow per total capacity is within the prescribed range:

$$FlowCapRatio = \dot{V}_{air,rated} / CCap_{rated} \quad (10.104)$$

If $FlowCapRatio < FlowCapRatio_{min}$ then

$$CCap_{rated} = \dot{V}_{air,rated} / FlowCapRatio_{min} \quad (10.105)$$

If $FlowCapRatio > FlowCapRatio_{max}$ then

$$CCap_{rated} = \dot{V}_{air,rated} / FlowCapRatio_{max} \quad (10.106)$$

where

$$FlowCapRatio_{min} = 0.00004027 m^3 / sperwatt(300cfm/ton) \quad (10.107)$$

and

$$FlowCapRatio_{max} = 0.00006041 m^3 / sperwatt(450cfm/ton) \quad (10.108)$$

The sizing calculation for DX cooling coils for 100% dedicated outdoor air system (DOAS) are identical to regular DX cooling coils. However, they operate at different flow to capacity ratio ranges and are within the prescribed range below:

$$FlowCapRatio_{min} = 0.00001677 m^3 / sperWatt(125cfm/ton) \quad (10.109)$$

and

$$FlowCapRatio_{max} = 0.00003355 m^3 / sperWatt(250cfm/ton) \quad (10.110)$$

10.7.14.6 Zone Coils

The rated cooling capacity for zone coils is calculated in the same manner as for system coils.

$$T_{mix} = DesCoolCoilInTemp_{zone} \quad (10.111)$$

$$W_{mix} = DesCoolCoilInHumRat_{zone} \quad (10.112)$$

$$T_{sup} = CoolDesTemp_{zone} \quad (10.113)$$

$$W_{sup} = CoolDesHumRat_{zone} \quad (10.114)$$

$$T_{outside} = T_{outside,desday,peak} \quad (10.115)$$

$$r_{air} = PsyRhoAirFnPbTdbW(p_{air,std}, T_{mix}, W_{mix}) \quad (10.116)$$

$$h_{mix} = PsyHFnTdbW(T_{mix}, W_{mix}) \quad (10.117)$$

$$h_{sup} = PsyHFnTdbW(T_{sup}, W_{sup}) \quad (10.118)$$

$$T_{mix,wb} = PsyTwbFnTdbWPb(T_{mix}, W_{mix}, p_{air,std}) \quad (10.119)$$

$$CapModFac = CurveValue(CCapFTemp, T_{mix,wb}, T_{outside}) \quad (10.120)$$

$$CCap_{peak} = \rho_{air} \cdot \dot{V}_{air,rated} \cdot (h_{mix} - h_{sup}) \quad (10.121)$$

$$CCap_{rated} = CCap_{peak} / CapModFac \quad (10.122)$$

We check that the design volume flow per total capacity is within the prescribed range:

$$FlowCapRatio = \dot{V}_{air,rated} / CCap_{rated} \quad (10.123)$$

If $FlowCapRatio < FlowCapRatio_{min}$ then

$$CCap_{rated} = \dot{V}_{air,rated} / FlowCapRatio_{min} \quad (10.124)$$

If $FlowCapRatio > FlowCapRatio_{max}$ then

$$CCap_{rated} = \dot{V}_{air,rated} / FlowCapRatio_{max} \quad (10.125)$$

where

$$FlowCapRatio_{min} = 0.00004027 m^3 / \text{sperwatt}(300cfm/ton) \quad (10.126)$$

and

$$FlowCapRatio_{max} = 0.00006041 m^3 / sperwatt(450 cfm/ton) \quad (10.127)$$

We check the design flow to the total cooling capacity ratio for dedicated zone outdoor unit DX cooling coils to be within the limits prescribed below:

$$FlowCapRatio_{min} = 0.00001677 m^3 / sperWatt(125 cfm/ton) \quad (10.128)$$

and

$$FlowCapRatio_{max} = 0.00003355 m^3 / sperWatt(250 cfm/ton) \quad (10.129)$$

10.7.14.7 Rated Total Heating Capacity

For Coil:Heating:DX:SingleSpeed the rated heating capacity is set equal to the cooling capacity.

10.7.14.8 Rated SHR

The rated sensible heat ratio (SHR) is calculated based upon empirical data from manufacturers. The rated SHR is fit to this empirical data using a linear function of the rated flow per capacity ratio. Separate correlations were established depending upon whether the DX coil is part of a Dedicated Outdoor Air system (DOAS).

$$SHR_{non-DOAS, rated} = 0.431 + 6086.0 * FlowCapRatio \quad (10.130)$$

$$SHR_{DOAS, rated} = 0.389 + 7684.0 * FlowCapRatio \quad (10.131)$$

For rated flow per capacity ratios outside of the min and max bounds defined above, the rated SHR is held constant using the respective relationships at their bounding rated flow per capacity ratios.

If the rated SHR results in outlet conditions above saturation, the SHR is adjusted to a condition at saturation with the same exiting enthalpy.

10.7.14.9 Evaporative Condenser Air Volume Flow Rate

The evaporative condenser air volume flow rate (m^3/s) is set to $0.000114 m^3/s$ per watt (850 cfm/ton) times the total rated cooling capacity.

10.7.14.10 Evaporative Condenser Air Volume Flow Rate, Low Speed

The evaporative condenser air volume flow rate, low speed (m^3/s) is set to $1/3$ times $0.000114 m^3/s$ per watt (850 cfm/ton) times the total rated cooling capacity.

10.7.14.11 Evaporative Condenser Pump Rated Power Consumption

The evaporative condenser pump rated power consumption is set equal to the total cooling capacity times 0.004266 watts pump power per watt capacity (15 W/ton).

10.7.14.12 Evaporative Condenser Pump Rated Power Consumption, Low Speed

The evaporative condenser pump rated power consumption, low speed, is set equal to 1/3 times the total cooling capacity times 0.004266 watts pump power per watt capacity (15 W/ton).

10.7.14.13 Rated Air Volume Flow Rate, low speed

The rated air volume flow rate, low speed, is set equal to 1/3 times the full rated air volume flow rate.

10.7.14.14 Rated Total Cooling Capacity, Low Speed

The rated total cooling capacity, low speed, is set equal to 1/3 times the full rated total cooling capacity.

10.7.14.15 Rated SHR, low speed

The rated sensible heat ratio, low speed, is set equal to the full speed SHR.

10.7.14.16 Resistive Defrost Heater Capacity

For the heat pump the resistive defrost heat capacity is set equal to the cooling capacity.

10.7.15 DX MultiSpeed Coil Sizing

The sizing calculations are done in subroutine *SizeDXCoil* in module *DXCoils*. This section covers the sizing of the objects

- Coil:Heating:DX:MultiSpeed
- Coil:Cooling:DX: MultiSpeed

The rated air volume flow rate, rated total cooling capacity, rated heating capacity, rated SHR, evaporative condenser air volume flow rate, evaporative condenser pump rated power consumption at the highest speed are sized in the same ways as DX Coil Sizing.

After the sizes are determined at the highest speed, the sizes in the rest of speeds are assumed to

$$Value_n = \frac{n}{NumberOfSpeed} * Value_{NumberOfSpeed} \quad (10.132)$$

where

$Value_n$ = Any autosizable variable at Speed n, except SHR

SHR_n = $SHR_{NumberOfSpeed}$

n = Speed Index number from 1 to NumberOfSpeed-1

NumberOfSpeed = The highest speed number

10.7.16 Coil:Cooling:DX:VariableSpeed Sizing

For the variable-speed DX cooling coil, we specify a nominal speed level. During the sizing calculation, the Rated Total Cooling Capacity at the Selected Nominal Speed Level is determined in the same way as the Coil:Cooling:DX:SingleSpeed object. If the user chooses to autosize the Rated Air Volume Flow Rate, the flow rate, as compared to the Rated Total Cooling Capacity, is sized to have the same ratio as the air volume flow rate to the total cooling capacity at the nominal speed, of the Reference Unit. The sensible heat transfer rate is not allowed for auto-sizing, instead, it is a function of the rated air flow, rated total cooling capacity and the Reference Unit SHR at the nominal speed level. The default nominal speed level is the highest speed. However, the model allows the user to select a nominal speed level rather than the highest.

Rated Total Cooling Capacity

The calculation for coil operating temperatures (inlet and outlet) are identical to that done for Coil:Cooling:DX:SingleSpeed. The calculations for air enthalpy are similar to that done for Coil:Cooling:DX:SingleSpeed. The difference is in calculating the total cooling capacity temperature modifier function at the selected nominal speed level, as below:

$$TotCapTempModFrac_{NominalSpeed} = a + b * WB_i + c * WB_i^2 + d * DB_o + e * DB_o T^2 + f * WB_i * DB_o \quad (10.133)$$

where

WB_i = wet-bulb temperature of the air entering the cooling coil, degC

DB_o = condenser entering air temperature, degC

a-f = regression curve-fit coefficients.

If the entering air enthalpy is less than the exiting air enthalpy, a reference value of 48,000 J/kg is used as the entering air enthalpy. If the $TotCapTempModFac$ calculation above yields 0 as the result, a value of 1 is used in the following calculation. If the rated air mass flow rate is determined to be less than a very small flow value (0.001 kg/s) or the capacity calculated here is less than 0, the coil total cooling capacity is set equal to 0.

If $H_{in} > H_{out}$ Then

$$\dot{Q}_{coil, rated, total} = m_{air, rated} (H_{in} - H_{out}) / TotCapTempModFrac_{NominalSpeed} \quad (10.134)$$

Else

$$\dot{Q}_{coil, rated, total} = m_{air, rated} (48000 - H_{out}) / TotCapTempModFrac_{NominalSpeed} \quad (10.135)$$

End If

$$\dot{Q}_{coil, rated, total} = \dot{Q}_{coil, rated, total} + \dot{Q}_{fan, heat, des} \quad (10.136)$$

Where:

- $\dot{Q}_{fan, heat, des}$: is the design fan heat (W) - see Section 10.7.3

The other sizing procedures, e.g. evaporative condenser pump, etc., are the same as Coil:Cooling:DX:SingleSpeed.

10.7.17 Coil:Heating:DX:VariableSpeed Sizing

For the variable-speed DX heating coil, we specify a nominal speed level. During the sizing calculation, the Rated Heating Capacity at the Selected Nominal Speed Level should be the same as the total cooling capacity of its corresponding cooling coil, which has to be sized first. The default nominal speed level will be the highest speed. However, the model allows the user to select a nominal speed level rather than the highest. If the user chooses to autosize the Rated Air Volume Flow Rate, the flow rate, as compared to the Rated Heating Capacity, is sized to have the same ratio as the air volume flow rate to the heating capacity at the nominal speed, of the Reference Unit. The other sizing procedures are the same as Coil:Heating:DX:SingleSpeed.

10.7.18 Pump Sizing

The loop pumps' autosizable inputs are design volume flow rate and design power consumption.

10.7.18.1 Design Volume Flow Rate

This is set equal to the design flow rate for the loop which is obtained from summing the needs of the components on the demand side of the loop. Each component on the plant loop registers its design flow rate and central routines sum them up.

10.7.18.2 Design Power Consumption

There are two methods available for calculating the design flow rate. The pump object has a input field to select which method to use.

The first, and original, method is selected by choosing PowerPerFlowPerPressure. And the design power is calculated using:

$$\dot{Q}_{nom} = H_{nom} \cdot \dot{V}_{nom} \cdot ScalingFactor / Eff_{mot} \quad (10.137)$$

where

Eff_{mot} is the motor efficiency, often the default value of 0.9. This is defined as the shaft power output in Watts divided by the electric power in Watts.

\dot{V}_{nom} is the design volume flow rate in m³/s.

$ScalingFactor$ is an input called Design Shaft Power per Unit Flow Rate per Unit Head, with a default of 1.282051 W/((m³/s)-Pa). (This is the inverse of 0.78 for impeller efficiency that was used prior to version 8.5.)

H_{nom} the nominal head, or pressure rise across the pump, is an input in Pascals.

The second method is selected by choosing PowerPerFlow. Then the power is calculated more simply and does not use head pressure or motor efficiency

$$\dot{Q}_{nom} = \dot{V}_{nom} \cdot ScalingFactor \quad (10.138)$$

where

$ScalingFactor$ is an input called Design Electric Power per Unit Flow Rate, with a default of 348701.1 W/(m³/s) or 22 W/gpm. The pump motor efficiency and head are still used to model the pump for its fluid heating. This method essentially finds a pump impeller and drive efficiency that when combined with the head and motor efficiency results in the desired power consumption per flow rate.

10.7.19 Electric Chiller Sizing

Generally chillers will need nominal cooling capacity, evaporator flow rate and condenser flow rate. All three quantities can be straightforwardly obtained using the user specified loop sizing data and the loop design flow rates. Chillers may also have a third plant loop connection for heat recovery and this flow rate can also be obtained.

All chillers on a loop are sized to meet the full loop load multiplied by a component-level sizing factor. This sizing factor is set by the user in the chiller input object. If there are multiple chillers on a loop that call for autosizing, they will all use their own sizing factor applied to the loop level flow rate.

10.7.19.1 Nominal Cooling Capacity

$$\dot{Q}_{chiller,nom} = C_{p,w} \cdot \rho_w \cdot \Delta T_{loop,des} \cdot \dot{V}_{loop,des} \cdot f_{size} \quad (10.139)$$

where

$C_{p,w}$ is the specific heat of evaporator loop fluid at 5°C;

ρ_w is the density of evaporator loop fluid at standard conditions (5.05°C);

$\Delta T_{loop,des}$ is the chilled water loop design temperature rise (from the chilled water loop's Sizing:Plant input data);

$\dot{V}_{loop,des}$ is the loop design volume flow rate.

f_{size} is the chiller's sizing factor.

10.7.19.2 Design Evaporator Volumetric Water Flow Rate

The evaporator flow rate is set equal to the loop's design flow rate multiplied by the chiller's sizing factor.

$$\dot{V}_{evap,des} = \dot{V}_{loop,des} \cdot f_{size} \quad (10.140)$$

10.7.19.3 Design Condenser Volume Flow Rate

The condenser flow rate is obtained by balancing the total heat rejected at full capacity with the heat transferred by the condenser fluid at the design temperature difference using the fluid properties for the condenser loop.

$$\dot{V}_{cond,des} = \dot{Q}_{chiller,nom} \cdot (1 + 1/COP_{chiller,nom}) / (\Delta T_{loop,des} \cdot C_{p,w} \cdot \rho_w) \quad (10.141)$$

where

$C_{p,w}$ is the specific heat of condenser loop fluid at design condenser inlet temperature;

ρ_w is the density of condenser loop fluid at standard conditions (5.05°C);

$\Delta T_{loop,des}$ is the condenser loop design temperature rise (from condenser loop's Sizing:Plant input data);

$COP_{chiller,nom}$ is the chiller's nominal COP.

10.7.19.4 Design Heat Recovery Volume Water Flow Rate

The chiller heat recovery volume flow rate, $\dot{V}_{hr,des}$, is obtained from the condenser volume flow rate modified by a capacity fraction.

$$\dot{V}_{hr,des} = \dot{V}_{cond,des} \cdot F_{HR,cap} \quad (10.142)$$

where

$F_{HR,cap}$ is user input from the field called Condenser Heat Recovery Relative Capacity Fraction.

10.7.20 Water to Water Heat Pump Sizing

Generally water to water heat pumps will need nominal capacity and fluid volume flow rates for both the load and source sides. The models for HeatPump:WaterToWater:EquationFit:Cooling and HeatPump:WaterToWater:EquationFit:Heating also need a reference power consumption.

10.7.20.1 Reference Load Side Flow Rate

The load side design fluid flow rate, $\dot{V}_{load,des}$, is set equal to the load side loop's total design flow rate multiplied by a component-level sizing factor.

$$\dot{V}_{load,des} = \dot{V}_{loop,des} \cdot f_{size} \quad (10.143)$$

where

$\dot{V}_{loop,des}$ is the loop design volume flow rate;

f_{size} is the heat pump's sizing factor.

10.7.20.2 Reference Capacity

The nominal capacity is determined from the loop design flow rate, loop design temperature difference and load side fluid properties.

$$\dot{Q}_{hp,nom} = C_{p,w} \cdot \rho_w \cdot \Delta T_{loop,des} \cdot \dot{V}_{loop,des} \cdot f_{size} \quad (10.144)$$

where

$C_{p,w}$ is the specific heat of load side loop fluid at standard conditions (5.05°C for cooling, 60.0°C for heating);

ρ_w is the density of load side loop fluid at standard conditions (5.05°C for cooling, 60.0°C for heating);

$\Delta T_{loop,des}$ is the load side loop design temperature rise (from load side loop's Sizing:Plant input data).

10.7.20.3 Reference Source Side Flow Rate

The source side design fluid flow rate, $\dot{V}_{source,des}$, is obtained by balancing the total heat supplied or rejected at full capacity with the heat transferred by the source side fluid at the design temperature difference using the fluid properties for the source side loop.

For the cooling heat pump, the heat rejected includes the compressor work,

$$\dot{V}_{source,des} = \dot{Q}_{hp,nom} \cdot (1 + 1/COP_{hp,nom}) / (\Delta T_{loop,des} \cdot C_{p,w} \cdot \rho_w) \quad (10.145)$$

For the heating heat pump, the heat supplied is reduced by the compressor work,

$$\dot{V}_{source,des} = \dot{Q}_{hp,nom} \cdot (1 - 1/COP_{hp,nom}) / (\Delta T_{loop,des} \cdot C_{p,w} \cdot \rho_w) \quad (10.146)$$

where

$COP_{hp,nom}$ is the reference coefficient of performance. This is from user input if reference power consumption is autosized.

10.7.20.4 Reference Power Consumption

The reference power consumption is the capacity divided by COP

$$P_{hp,nom} = \dot{Q}_{hp,nom} / COP_{hp,nom} \quad (10.147)$$

10.7.21 Boiler Sizing

Generally boilers will need nominal heating capacity and water volume flow rate. Both quantities can be straightforwardly obtained using the user specified loop sizing data and the loop design flow rates.

All boilers on a loop are sized to meet the full loop load multiplied by a component-level sizing factor. If there are multiple boilers on a loop that call for autosizing, they will all be assigned a heating capacity and flow rate using their own sizing factor.

10.7.21.1 Nominal Capacity

$$\dot{Q}_{boiler,nom} = C_{p,w} \cdot \rho_w \cdot \Delta T_{loop,des} \cdot \dot{V}_{loop,des} \cdot f_{size} \quad (10.148)$$

where

$C_{p,w}$ is the specific heat of water at the boiler design outlet temperature;

ρ_w is the density of water at standard conditions (5.05 °C);

$\Delta T_{loop,des}$ is the hot water loop design temperature decrease;

$\dot{V}_{loop,des}$ is the loop design volumetric flow rate.

f_{size} is the boiler's sizing factor.

10.7.21.2 Design Water Volume Flow Rate

$$\dot{V}_{des} = \dot{V}_{loop,des} \cdot f_{size} \quad (10.149)$$

10.7.22 Plant Heat Exchanger Sizing

The sizing of plant heat exchanger component (object: HeatExchanger:FluidToFluid) involves determining design flow rates for both sides, a UA value, and a nominal capacity for reporting. The component has a sizing factor for fine control and uses the design temperatures defined in the Sizing:Plant object.

The Loop Supply Side design flow rate, $\dot{V}_{Sup,des}$, is set equal to the design flow rate for that loop, multiplied by the component sizing factor, f_{comp} .

$$\dot{V}_{Sup,des} = \dot{V}_{loop,des} * f_{comp} \quad (10.150)$$

The Loop Demand Side design flow rate, $\dot{V}_{Dmd,des}$, is set equal to the Loop Supply Side design flow rate.

$$\dot{V}_{Dmd,des} = \dot{V}_{Sup,des} \quad (10.151)$$

The design heat transfer capacity and UA for the heat exchanger are calculated using the design temperatures for the two plant loops. The loop design temperature difference for the Loop Supply Side, $\Delta T_{SupLoop,Des}$, is used to determine a nominal capacity.

$$\dot{Q} = V_{Sup,des} \rho c_p \Delta T_{SupLoop,Des} \quad (10.152)$$

A loop-to-loop design temperature difference, $\Delta T_{LoopToLoop,Des}$, is determined depending on the nature of the plant loop connected to the Loop Supply Side. The Sizing:Plant object includes classifications for the type of loop that include Heating, Steam, Cooling, or Condenser. For Cooling and Condenser loop types, the loop design temperature difference is added to the design exit temperature for the Loop Supply Side, $T_{SupLoop,Exit}$. For Heating and Stem loop types, the loop design temperature difference is subtracted from the design exit temperature. This adjusted supply side temperature is then compared to the design exit temperature for the Loop Demand Side, $T_{DmdLoop,Exit}$.

$$\begin{aligned} \Delta T_{LoopToLoop,Des} &= (T_{SupLoop,Exit} + \Delta T_{SupLoop,Des}) - T_{DmdLoop,Exit} \quad (\text{Cooling, Condenser}) \\ \Delta T_{LoopToLoop,Des} &= (T_{SupLoop,Exit} - \Delta T_{SupLoop,Des}) - T_{DmdLoop,Exit} \quad (\text{Heating, Steam}) \end{aligned}$$

$$\Delta T_{LoopToLoop,Des} = MAX (ABS (\Delta T_{LoopToLoop,Des}), 2.0) \quad (10.153)$$

The UA (U-Factor Time Area Value) is determined by assuming that the target capacity can be delivered for the loop-to-loop temperature difference which after substituting and rearranging becomes:

$$UA = \frac{V_{Sup,des} \rho c_p \Delta T_{SupLoop,Des}}{\Delta T_{LoopToLoop,Des}} \quad (10.154)$$

A nominal capacity for the heat exchanger is determined from the design flow rates and UA (regardless of if they were automatically sized or input by the user) and the expected operating temperatures of the two loops. The loop operating temperatures are obtained from the input in Sizing:Plant object if it is present for that loop. If no Sizing:Plant is present then the loop's overall setpoint is used (if the loop's load scheme is DualSetpointDeadband then the average of the high and low setpoints is used). The full heat exchanger model is then calculated for the maximum loop flow rates and expected loop temperatures as inlets to the heat exchanger. The absolute value for the model result for heat transfer rate is then used as the capacity of the heat exchanger. This capacity is reported and may be used for controls based on operation scheme.

10.7.23 Humidifier Sizing

The rated power, or nominal electric power input of an Electric Steam Humidifier (Humidifier:Steam:Electric) is calculated from user specified rated capacity (m^3/s) and the enthalpy change of the water from a reference temperature (20.0°C) to saturated steam at 100.0°C . Autosizing procedure assumes that electrical heating element in the humidifier heat the water from the reference temperature and generate saturated steam at 100°C , and electric to thermal energy conversion efficiency of 100.0%.

10.7.23.1 Rated Power

$$P_{rated} = \dot{V}_{rated} \cdot \rho_w \cdot (h_{fg} + C_{p,w} \cdot \Delta T_w) \quad (10.155)$$

where

$C_{p,w}$ is the specific heat of water at average temperature $((100+20)/2 = 60.0^\circ\text{C})$, (J/kgK);

ρ_w is the density of water at standard conditions (5.05°C);

ΔT_w is the sensible temperature rise of water ($100.0 - 20.0 = 80.0^\circ\text{C}$);

\dot{V}_{rated} is the rated capacity of the humidifier in volumetric flow rate.

h_{fg} is the latent heat of vaporization of water at 100.0°C , (J/kg);

10.7.23.2 Gas Fired Humidifier Sizing

The rated power, or nominal gas use rate of a gas steam humidifier (Humidifier:Steam:Gas) is calculated from user specified rated volumetric capacity (m³/s) and the enthalpy change of the water from a reference temperature of 20.0°C to a saturated steam at 100.0°C . Autosizing procedure assumes that gas heater in the humidifier convert the water from the reference temperature and generate saturated steam at 100°C , using gas to thermal energy conversion rated thermal efficiency.

Rated Gas Use Rate

The rated or nominal gas use rate is given by:

$$Q_{NG,nom} = \frac{\dot{V}_{cap,nom} \rho_w (h_{fg} + c_{p,w} \Delta T_w)}{\eta_{rated}} \quad (10.156)$$

where:

$C_{p,w}$: specific heat of water at average temperature $((100+20)/2 = 60.0^\circ\text{C})$, (J/kgK);

ρ_w : density of water at standard condition (5.05°C);

ΔT_w : sensible temperature rise of water ($100.0 - 20.0 = 80.0^\circ\text{C}$);

$V_{cap,nom}$: rated or nominal capacity of the humidifier, (m³/s);

h_{fg} : latent heat of vaporization of water at 100.0°C , (J/kg);

η_{rated} : thermal efficiency at rated condition.

10.7.23.3 Rated Capacity

$$\dot{m}_w = \dot{m}_a (\omega_o - \omega_i) \quad (10.157)$$

where:

\dot{m}_w is water mass flow rate, kg/s;

\dot{m}_a is design air mass flow rate, kg/s;

ω_o is design outlet humidity ratio, kg-water/kg-air;

ω_i is design inlet humidity ratio, kg-water/kg-air.

The air mass flow rate and humidity ratios are determined based upon zone design conditions. If the unit is part of zone equipment, then:

$$\dot{m}_a = \text{Max}(\text{DesCoolVolFlow}_{zone}, \text{DesHeatVolFlow}_{zone}) \cdot \rho_a \quad (10.158)$$

$$\omega_i = \text{Min}(\text{OutHumRatAtCoolPeak}_{zone}, \text{OutHumRatAtHeatPeak}_{zone}) \quad (10.159)$$

$$\omega_o = \text{Max}(\text{ZoneHumRatAtCoolPeak}_{\text{zone}}, \text{ZoneHumRatAtHeatPeak}_{\text{zone}}) \quad (10.160)$$

where ρ_a is the density of air at design conditions, kg/s.

If the unit is part of the central air system, then check if outdoor air system is present. If outdoor air system is part of the air loop and design outdoor air flow rate is greater than zero, then:

$$\dot{m}_a = \text{DesOutAirVolFlow}_{\text{sys}} \cdot \rho_a \quad (10.161)$$

$$\omega_i = \text{Min}(\text{CoolOutHumRat}_{\text{sys}}, \text{HeatOutHumRat}_{\text{sys}}) \quad (10.162)$$

$$\omega_o = \text{Max}(\text{CoolSupHumRat}_{\text{sys}}, \text{HeatSupHumRat}_{\text{sys}}) \quad (10.163)$$

Otherwise, air mass flow rate is determined as follows:

For duct type = *main*:

$$\dot{m}_a = \text{DesMainAirVolFlow}_{\text{sys}} \cdot \rho_a \quad (10.164)$$

For duct type = *cooling*:

$$\dot{m}_a = \text{DesCoolVolFlow}_{\text{sys}} \cdot \rho_a \quad (10.165)$$

For duct type = *heating*:

$$\dot{m}_a = \text{DesHeatVolFlow}_{\text{sys}} \cdot \rho_a \quad (10.166)$$

For duct type = *other*:

$$\dot{m}_a = \text{DesMainVolFlow}_{\text{sys}} \cdot \rho_a \quad (10.167)$$

and the humidity ratios are:

$$\omega_i = \text{Min}(\text{CoolMixHumRat}_{\text{sys}}, \text{HeatMixHumRat}_{\text{sys}}) \quad (10.168)$$

$$\omega_o = \text{Max}(\text{CoolSupHumRat}_{\text{sys}}, \text{HeatSupHumRat}_{\text{sys}}) \quad (10.169)$$

10.7.24 Cooling Tower Sizing

The quantities needed to autosize a cooling tower include the design water flow rate, the nominal fan power and air flow rate, and the tower UA. This data may be need to be given at more than one operating point:, for instance - high speed fan, low speed fan and free convection.

EnergyPlus provides two input choices: the user can input the design water flow rate and tower UA at each operating point or the tower nominal capacity (and let the program calculate the water flow rate and UA). Choice of input method will affect the sizing calculations in ways noted below.

10.7.24.1 Design Water Flow Rate

If *Tower Performance Input Method = UFactorTimesAreaAndDesignWaterFlowRate* then

$$\dot{V}_{tower,w,des} = \dot{V}_{loop,des} \quad (10.170)$$

If *Tower Performance Input Method = NominalCapacity* then

$$\dot{V}_{tower,w,des} = 5.382E - 8 \cdot \dot{Q}_{tower,nom} \quad (10.171)$$

where $5.382 \cdot 10^{-08}$ is m^3/s per watt corresponds to the rule-of-thumb of sizing the tower flow rate at 3 gallons per minute per ton. For the CoolingTower:VariableSpeed:Merkel model with NominalCapacity input method, the user can input the value used to scale design water flow rate from nominal capacity and the default is $5.382 \cdot 10^{-08} \text{ m}^3/\text{s}/\text{W}$.

10.7.24.2 Fan Power at Design Air Flow Rate

The nominal fan power is sized to be 0.0105 times the design load.

If *Tower Performance Input Method = UFactorTimesAreaAndDesignWaterFlowRate* then

$$\dot{Q}_{tower,nom} = C_{p,w} \cdot \rho_w \cdot \dot{V}_{tower,w,des} \cdot \Delta T_{loop,des} \quad (10.172)$$

where

$C_{p,w}$ is the specific heat of water at the condenser loop design exit temperature;

ρ_w is the density of water at standard conditions (5.05°C);

$\Delta T_{loop,des}$ is the condenser water loop design temperature rise;

Finally,

$$\dot{Q}_{fan,nom} = 0.0105 \cdot \dot{Q}_{tower,nom} \quad (10.173)$$

For the CoolingTower:VariableSpeed:Merkel model, the design fan power is determined using a scaling factor, in units of Watts per Watt, that can be input by the user. The default value is 0.0105 which is the same as above.

10.7.24.3 Design Air Flow Rate

We assume a fan efficiency of 0.5 and a fan pressure rise of 190 Pascals. Then:

$$\dot{V}_{tower,air,des} = \dot{Q}_{fan,nom} \cdot 0.5 \cdot \rho_{air}/190 \quad (10.174)$$

where

ρ_{air} is the density of air at standard conditions.

For the CoolingTower:VariableSpeed:Merkel model, the design air flow rate is determined from the nominal capacity using a scaling factor, $f_{airflow/W}$, in units of $\text{m}^3/\text{s}/\text{W}$. The default value is $2.76316 \cdot 10^{-5}$. When the input field is left blank, the default is used as follows

$$\dot{V}_{tower,air,des} = \dot{Q}_{tower,nom} \cdot f_{airflow/W} \cdot \frac{101325}{P_{std,altitude}} \quad (10.175)$$

where $P_{std,altitude}$ is the standard barometric pressure for the location's elevation.

When the input field is filled with a hard value, the pressure scaling is not used:

$$\dot{V}_{tower,air,des} = \dot{Q}_{tower,nom} \bullet f_{air\ flow/W} \quad (10.176)$$

10.7.24.4 Tower UA Value at Design Air Flow Rate

To obtain the UA of the tower, we specify the model inputs (other than the UA) at design conditions and the design tower load that the tower must meet. Then we numerically invert the tower model to solve for the UA that will enable the tower to meet the design tower load given the specified inputs.

The design tower load is:

for *Tower Performance Input Method = UFactorTimesAreaAndDesignWaterFlowRate*

$$\dot{Q}_{tower,des} = C_{p,w} \cdot \rho_w \cdot \dot{V}_{tower,w,des} \cdot \Delta T_{loop,des} \quad (10.177)$$

for *Tower Performance Input Method = NominalCapacity*

$$\dot{Q}_{tower,des} = 1.25 \cdot \dot{Q}_{tower,nom} \quad (to\ allow\ for\ compressor\ heat) \quad (10.178)$$

where $f_{des,heat,ratio}$ is the ratio of actual heat rejection capacity to nominal capacity. This ratio is available as a user input with a default value of 1.25 (to allow for compressor heat).

Then we assign the inputs needed for the model:

$T_{in,air} = 35^\circ\text{C}$ (95°F design air inlet temperature)

$T_{in,air,wb} = 25.6^\circ\text{C}$ (78°F design air inlet wetbulb temperature)

W_{in} is calculated from the entering air drybulb and wetbulb.

The inlet water mass flow rate is just the design volumetric flow rate times the density of water.

The inlet water temperature is set slightly differently for the 2 input methods. For *UFactorTimesAreaAndDe*

$T_{in,water} = T_{loop,exit,des} + DT_{loop,des}$

For *NominalCapacity*:

$T_{in,water} = 35^\circ\text{C}$ (95°F design inlet water temperature).

We now have all the data needed to obtain UA. The numerical inversion is carried out by calling subroutine *SolveRegulaFalsi*. This is a general utility routine for finding the zero of a function. In this case it finds the UA that will zero the residual function - the difference between the design tower load and the tower output divided by the design tower load. The residual is calculated in the function *residualUA*.

10.7.24.5 Air Flow Rate at Low Fan Speed

The nominal air flow rate at low fan speed is set to a fraction of the full speed air flow rate. The fraction is available for user input in the field called Low Fan Speed Air Flow Rate Sizing Factor. The default is 0.5.

10.7.24.6 Fan Power at Low Fan Speed

The fan power at low fan speed is set to a fraction of the fan power at full speed. The fraction is available for user input in the field called Low Fan Speed Fan Power Sizing Factor. The default is 0.16.

10.7.24.7 Tower UA Value at Low Fan Speed

For *Tower Performance Input Method = UFactorTimesAreaAndDesignWaterFlowRate* the low speed UA is set to a fraction of the full speed UA. The fraction is available for user input in the field called Low Fan Speed U-Factor Times Area Sizing Factor. The default is 0.6. For *Tower Performance Input Method = NominalCapacity* the low speed UA is calculated in the same manner as the full speed UA using $\dot{Q}_{tower,nom,low\ speed}$ instead of $\dot{Q}_{tower,nom}$.

10.7.24.8 Air Flow Rate in Free Convection Regime

The free convection air flow rate is set to a fraction of the full air flow rate. The fraction is available for user input in the field called Free Convection Regime Air Flow Rate Sizing Factor. The default is 0.1.

10.7.24.9 Tower UA Value in Free Convection Regime

For *Tower Performance Input Method = UA and Design Water Flow Rate* the low speed UA is set to a fraction of the full speed UA. The fraction is available for user input in the field called Free Convection U-Factor Times Area Value Sizing Factor. The default is 0.1. For *Tower Performance Input Method = NominalCapacity* the low speed UA is calculated in the same manner as the full speed UA using $\dot{Q}_{tower,nom,freeconv}$ instead of $\dot{Q}_{tower,nom}$.

10.7.25 Fluid Cooler Sizing

The quantities needed to autosize a fluid cooler include the design water flow rate, the nominal fan power, air flow rate, and the fluid cooler UA. This data may need to be given at more than one operating point; for instance - high speed fan and low speed fan.

EnergyPlus provides two input choices: the user can input the design water flow rate and fluid cooler UA at each operating point or the fluid cooler nominal capacity and the water flow rate (and let the program calculate UA). Choice of input method will affect the sizing calculations in ways noted below.

10.7.25.1 Design Water Flow Rate

The design water flow rate is sized as follows:

$$\dot{V}_{fluidcooler,w,des} = \dot{V}_{loop,des} \quad (10.179)$$

10.7.25.2 Fan Power at Design Air Flow Rate

The nominal fan power is sized to be 0.0105 times the design load.

If *Performance Input Method = UFactorTimesAreaAndDesignWaterFlowRate*, then:

$$\dot{Q}_{fluidcooler,nom} = C_{p,w} \bullet \rho_w \bullet \dot{V}_{fluidcooler,w,des} \bullet \Delta T_{loop,des} \quad (10.180)$$

where:

$C_{p,w}$ is the specific heat of water at the condenser loop design exit temperature;

ρ_w is the density of water at standard conditions (5.05°C);

$\Delta T_{loop,des}$ is the condenser water loop design temperature rise;

Finally:

$$\dot{Q}_{fan,nom} = 0.0105 \bullet \dot{Q}_{fluidcooler,nom} \quad (10.181)$$

If *Performance Input Method = NominalCapacity*, then:

$$\dot{Q}_{fan,nom} = 0.0105 \bullet \dot{Q}_{fluidcooler,nom} \quad (10.182)$$

where $\dot{Q}_{fluidcooler,nom}$ is provided by the user.

10.7.25.3 Design Air Flow Rate

- For Performance Input Method = UFactorTimesAreaAndDesignWaterFlowRate

$$\dot{Q}_{fluidcooler,nom} = C_{p,w} \bullet \rho_w \bullet \dot{V}_{fluidcooler,w,des} \bullet \Delta T_{loop,des} \quad (10.183)$$

- For Performance Input Method = NominalCapacity, $\dot{Q}_{fluidcooler,nom}$ is provided by the user.

$$\dot{V}_{fluidcooler,air,des} = \dot{Q}_{fluidcooler,nom} / (T_{in,water} - T_{in,air}) * 4 \quad (10.184)$$

where:

$T_{in,water}$ = Design entering water temperature provided by the user

$T_{in,air}$ = Design air inlet temperature provided by the user

10.7.25.4 Fluid cooler UA Value at Design Air Flow Rate

To obtain the UA of the fluid cooler, we specify the model inputs (other than the UA) at design conditions and the design fluid cooler load that the fluid cooler must meet. Then we numerically invert the fluid cooler model to solve for the UA that will enable the fluid cooler to meet the design fluid cooler load given the specified inputs.

The design fluid cooler load is:

- For Performance Input Method = UFactorTimesAreaAndDesignWaterFlowRate

$$\dot{Q}_{fluidcooler,nom} = C_{p,w} \bullet \rho_w \bullet \dot{V}_{fluidcooler,w,des} \bullet \Delta T_{loop,des} \quad (10.185)$$

- For Performance Input Method = NominalCapacity, $\dot{Q}_{fluidcooler,nom}$ is provided by the user.

Then we assign the inputs needed for the model.

$T_{in,air}$ = Design air inlet temperature provided by the user

$T_{in,air,wb}$ = Design air inlet wetbulb temperature provided by the user

W_{in} is calculated from the entering air drybulb and wetbulb.

The inlet water mass flow rate is just the design entering volumetric flow rate times the density of water.

The inlet water temperature is set slightly differently for the 2 input methods. For

- *UFactorTimesAreaAndDesignWaterFlowRate*

$$T_{in,water} = T_{loop,exit,des} + \Delta T_{loop,des} \quad (10.186)$$

- *NominalCapacity*

$$T_{in,water} = \textit{Provided by the user} \quad (10.187)$$

We now have all the data needed to obtain UA. The numerical inversion is carried out by calling subroutine *SolveRegulaFalsi*. This is a general utility routine for finding the zero of a function. In this case it finds the UA that will zero the residual function - the difference between the design fluid cooler load and the fluid cooler output divided by the design fluid cooler load. The residual is calculated in the function *SimpleFluidCoolerUAResidual*.

10.7.25.5 Air Flow Rate at Low Fan Speed

The nominal air flow rate at low fan speed is set to a fraction of the full speed air flow rate. The fraction is available for user input in the field called Low Fan Speed Air Flow Rate Sizing Factor. The default is 0.5.

10.7.25.6 Fan Power at Low Fan Speed

The fan power at low fan speed is set to a fraction of the fan power at full speed. The fraction is available for user input in the field called Low Fan Speed Fan Power Sizing Factor. The default is 0.16.

10.7.25.7 Fluid cooler UA Value at Low Fan Speed

For *Performance Input Method = UFactorTimesAreaAndDesignWaterFlowRate* the low speed UA is set to a fraction of the full speed UA. . The fraction is available for user input in the field called Low Fan Speed U-Factor Times Area Sizing Factor. The default is 0.6. For *Performance Input Method = NominalCapacity* the low speed UA is calculated in the same manner as the full speed UA using $\dot{Q}_{fluidcooler,nom,low\ speed}$ instead of $\dot{Q}_{fluidcooler,nom}$.

10.7.26 Evaporative Fluid Cooler Sizing

The quantities needed to autosize an evaporative fluid cooler include the design water flow rate, the nominal fan power, air flow rate, and the fluid cooler UA. This data may need to be given at more than one operating point:, for instance - high speed fan and low speed fan.

EnergyPlus provides three input choices: the user can input the design water flow rate and fluid cooler UA at each operating point (*UFactorTimesAreaAndDesignWaterFlowRate*) or the fluid cooler design capacity and the water flow rate and let the program calculate UA (*UserSpecifiedDesignCapacity*) or only the fluid cooler design capacity and let the program calculate UA and the water flow rate (*StandardDesignCapacity*). Choice of input method will affect the sizing calculations in ways noted below.

10.7.26.1 Design Water Flow Rate

If *Performance Input Method = StandardDesignCapacity* then

$$\dot{V}_{fluidcooler,w,des} = 5.382E - 8 \cdot \dot{Q}_{fluidcooler,standarddesign} \quad (10.188)$$

Else

$$\dot{V}_{fluidcooler,w,des} = \dot{V}_{loop,des} \quad (10.189)$$

where $5.382 \cdot 10^{-08}$ is m^3/s per watt corresponds to the rule-of-thumb of sizing the fluid cooler flow rate at 3 gallons per minute per ton.

10.7.26.2 Fan Power at Design Air Flow Rate

The design fan power is sized to be 0.0105 times the design load.

If *Performance Input Method = UFactorTimesAreaAndDesignWaterFlowRate* then

$$\dot{Q}_{fluidcooler,design} = C_{p,w} \bullet \rho_w \bullet \dot{V}_{fluidcooler,w,des} \bullet \Delta T_{loop,des} \quad (10.190)$$

where

$C_{p,w}$ is the specific heat of water at the condenser loop design exit temperature;

ρ_w is the density of water at standard conditions (5.05 °C);

$\Delta T_{loop,des}$ is the condenser water loop design temperature rise;

Finally:

$$\dot{Q}_{fan,design} = 0.0105 \bullet \dot{Q}_{fluidcooler,design} \quad (10.191)$$

where $\dot{Q}_{fluidcooler,design}$ is the design capacity provided by the user for the other two performance input methods.

10.7.26.3 Design Air Flow Rate

We assume a fan efficiency of 0.5 and a fan pressure rise of 190 Pascals. Then

$$\dot{V}_{fluidcooler,air,des} = \dot{Q}_{fan,design} \bullet 0.5 \bullet \rho_{air} / 190 \quad (10.192)$$

where ρ_{air} is the density of air at standard conditions.

10.7.26.4 Fluid Cooler UA Value at Design Air Flow Rate

To obtain the UA of the evaporative fluid cooler, we specify the model inputs (other than the UA) at design conditions and the design fluid cooler load that the fluid cooler must meet. Then we numerically invert the fluid cooler model to solve for the UA that will enable the fluid cooler to meet the design fluid cooler load given the specified inputs.

The design fluid cooler load is:

- For *Performance Input Method = UFactorTimesAreaAndDesignWaterFlowRate*

$$\dot{Q}_{fluidcooler,design} = C_{p,w} \bullet \rho_w \bullet \dot{V}_{fluidcooler,w,des} \bullet \Delta T_{loop,des} \quad (10.193)$$

- For Performance Input Method = StandardDesignCapacity

$$\dot{Q}_{fluidcooler,design} = 1.25 \bullet \dot{Q}_{fluidcooler,standarddesign} \quad (to\ allow\ for\ compressor\ heat) \quad (10.194)$$

Then we assign the inputs needed for the model.

$$T_{in,air} = 35^{\circ}C \text{ (} 95^{\circ}F \text{ design air inlet temperature)}$$

$$T_{in,air,wb} = 25.6^{\circ}C \text{ (} 78^{\circ}F \text{ design air inlet wetbulb temperature)}$$

W_{in} is calculated from the entering air drybulb and wetbulb.

- For Performance Input Method = UserSpecifiedDesignCapacity

$$\dot{Q}_{fluidcooler,design} = \dot{Q}_{fluidcooler,userspecifieddesign} \quad (10.195)$$

where $f_{des,heat,ratio}$ is the ratio of actual heat rejection capacity to nominal capacity. This ratio is available as a user input with a default value of 1.25 (to allow for compressor heat)

Then we assign the inputs needed for the model.

$$T_{in,air} = \text{Design air inlet temperature provided by the user}$$

$$T_{in,air,wb} = \text{Design air inlet wetbulb temperature provided by the user}$$

W_{in} is calculated from the entering air drybulb and wetbulb.

The inlet water mass flow rate is just the design entering volumetric flow rate times the density of water.

The inlet water temperature is set slightly differently for the 3 input methods. For

- UFactorTimesAreaAndDesignWaterFlowRate

$$T_{in,water} = T_{loop,exit,des} + \Delta T_{loop,des} \quad (10.196)$$

- StandardDesignCapacity

$$T_{in,water} = 35^{\circ}C \text{ (} 95^{\circ}F \text{ design inlet water temperature)} \quad (10.197)$$

- UserSpecifiedDesignCapacity

$$T_{in,water} = \text{Provided by the user} \quad (10.198)$$

We now have all the data needed to obtain UA. The numerical inversion is carried out by calling subroutine *SolveRegulaFalsi*. This is a general utility routine for finding the zero of a function. In this case it finds the UA that will zero the residual function - the difference between the design fluid cooler load and the fluid cooler output divided by the design fluid cooler load. The residual is calculated in the function *SimpleEvapFluidCoolerUAResidual*.

10.7.26.5 Air Flow Rate at Low Fan Speed

The design air flow rate at low fan speed is set to a fraction of the full speed air flow rate. The fraction is available for user input in the field called Low Fan Speed Air Flow Rate Sizing Factor. The default is 0.5.

10.7.26.6 Fan Power at Low Fan Speed

The fan power at low fan speed is set to a fraction of the fan power at full speed. The fraction is available for user input in the field called Low Fan Speed Fan Power Sizing Factor. The default is 0.16.

10.7.26.7 Fluid Cooler UA Value at Low Fan Speed

For *Performance Input Method = UFactorTimesAreaAndDesignWaterFlowRate* the low speed UA is set to a fraction of the full speed UA. The fraction is available for user input in the field called Low Fan Speed U-Factor Times Area Sizing Factor. The default is 0.6. For *Performance Input Method = StandardDesignCapacity* (and similarly for *UserSpecifiedDesignCapacity method*) the low speed UA is calculated in the same manner as the full speed UA using $\dot{Q}_{fluidcooler,standarddesign,low speed}$ instead of $\dot{Q}_{fluidcooler,standarddesign}$.

10.7.27 Fan Coil Unit Sizing

Fan Coil units are compound components: each unit contains a fan, hot water coil, chilled water coil and outside air mixer. The inputs that may need to be autosized are the nominal unit air flow rate, the maximum hot and chilled water flow rates, and the design outside air flow rate. The data needed for sizing the units is obtained from the zone design arrays and the user specified plant sizing input.

10.7.27.1 Maximum Air Flow Rate

$$\dot{V}_{air,max} = \text{Max}(\text{DesCoolVolFlow}_{zone}, \text{DesHeatVolFlow}_{zone}) \quad (10.199)$$

10.7.27.2 Maximum Outside Air Flow Rate

$$\dot{V}_{outsideair,max} = \text{Min}(\text{MinOA}_{zone}, \dot{V}_{air,max}) \quad (10.200)$$

10.7.27.3 Maximum Hot Water Flow

$$T_{coil,in} = \text{DesHeatCoilInTemp}_{zone} \quad (10.201)$$

$$T_{coil,out} = \text{HeatDesTemp}_{zone} \quad (10.202)$$

$$\dot{Q}_{coil,des} = c_{p,air} \cdot \text{DesHeatMassFlow}_{zone} \cdot (T_{out,coil} - T_{in,coil}) \quad (10.203)$$

$$\dot{V}_{max,hw} = \dot{Q}_{coil,des} / (c_{p,w} \cdot \rho_w \cdot \Delta T_{loop,des}) \quad (10.204)$$

where:

$c_{p,air}$ is specific heat of air evaluated at the average of the inlet & outlet temperatures and the coil outlet humidity ratio, J/kgC.

$\dot{V}_{max,hw}$ is maximum hot water flow rate, m³/s.

$\dot{Q}_{coil,des}$ is heating coil design load, W.

$c_{p,w}$ is specific heat of hot water, J/kgC.

ρ_w is density of hot water, m³/kg.

$\Delta T_{loop,des}$ is hot water loop design temperature difference, ΔC.

10.7.27.4 Maximum Cold Water Flow

$$T_{coil,in} = DesColdCoilInTemp_{zone} \quad (10.205)$$

$$T_{coil,out} = ColdDesTemp_{zone} \quad (10.206)$$

$$W_{coil,in} = DesCoolCoilInHumRat_{zone} \quad (10.207)$$

$$W_{coil,out} = CoolDesHumRat_{zone} \quad (10.208)$$

$$H_{coil,in} = PsyHFnTdbW(T_{coil,in}, W_{coil,in}) \quad (10.209)$$

$$H_{coil,out} = PsyHFnTdbW(T_{coil,out}, W_{coil,out}) \quad (10.210)$$

$$\dot{Q}_{coil,des} = DesCoolMassFlow_{zone} \cdot (h_{in,coil} - h_{out,coil}) \quad (10.211)$$

$$\dot{V}_{max,cw} = \dot{Q}_{coil,des} / (c_{p,w} \cdot \rho_w \cdot \Delta T_{loop,des}) \quad (10.212)$$

where:

$c_{p,air}$ is specific heat of air evaluated at the average of the inlet & outlet temperatures and the coil outlet humidity ratio, J/kgC.

$\dot{V}_{max,cw}$ is maximum cold water flow rate, m³/s.

$\dot{Q}_{coil,des}$ is cooling coil design load, W.

$c_{p,w}$ is specific heat of cold water, J/kgC.

ρ_w is density of cold water, m³/kg.

$\Delta T_{loop,des}$ is cold water loop design temperature difference, ΔC.

10.7.28 Window Air Conditioner Sizing

Window air conditioners are compound components: each unit contains a fan, a DX coil and an outside air mixer. The inputs that may need to be autosized are the nominal unit air flow rate and the design outside air flow rate. The data needed for sizing the units is obtained from the zone design arrays.

10.7.28.1 Maximum Air Flow Rate

$$\dot{V}_{air,max} = DesCoolVolFlow_{max} \quad (10.213)$$

10.7.28.2 Maximum Outside Air Flow Rate

$$\dot{V}_{outsideair,max} = Min(MinOA_{zone}, \dot{V}_{air,max}) \quad (10.214)$$

10.7.29 Unit Ventilator Sizing

Unit ventilators are compound components: each unit contains an outdoor air mixer, a fan, a heating coil, and a cooling coil. The inputs that may need to be autosized are the maximum supply air flow rate and the maximum/minimum outside air flow rates. The data needed for sizing the units is obtained from the zone design arrays.

10.7.29.1 Maximum Air Flow Rate

If both the cooling and heating coil are present, then:

$$\dot{V}_{supplyair,max} = MAX(DesCoolVolFlow_{zone}, DesHeatVolFlow_{zone}) \quad (10.215)$$

If only the heating coil is present, then:

$$\dot{V}_{supplyair,max} = DesHeatVolFlow_{zone} \quad (10.216)$$

If only cooling coil is present, then:

$$\dot{V}_{supplyair,max} = DesCoolVolFlow_{zone} \quad (10.217)$$

If neither heating nor cooling coil is present, then:

$$\dot{V}_{supplyair,max} = MinOA_{zone} \quad (10.218)$$

10.7.29.2 Maximum Outside Air Flow Rate

$$\dot{V}_{outsideair,max} = \dot{V}_{air,max} \quad (10.219)$$

10.7.29.3 Minimum Outside Air Flow Rate

$$\dot{V}_{outsideair,min} = Min(MinOA_{zone}, \dot{V}_{air,max}) \quad (10.220)$$

10.7.30 Packaged Terminal Heat Pump Sizing

Packaged terminal heat pumps are compound components: each unit contains a supply air fan, a DX cooling coil, a DX heating coil, a GAS or ELECTRIC supplemental heating coil, and an outside air mixer. The inputs that may need to be autosized are the supply air and outside air volumetric air flow rates during cooling operation, heating operation, and when no cooling or heating is needed. In addition, the maximum supply air temperature from the supplemental heater can also be automatically selected. The data needed for sizing the units are obtained from the zone design arrays.

10.7.30.1 Supply air volumetric flow rate during cooling operation

$$\dot{V}_{SA,cooling} = MAX(DesCoolVolFlow_{zone}, DesHeatVolFlow_{zone}) \quad (10.221)$$

10.7.30.2 Supply air volumetric flow rate during heating operation

$$\dot{V}_{SA,heating} = MAX(DesCoolVolFlow_{zone}, DesHeatVolFlow_{zone}) \quad (10.222)$$

10.7.30.3 Supply air volumetric flow rate when no cooling or heating is needed

$$\dot{V}_{SA, no cool or heat} = MAX(DesCoolVolFlow_{zone}, DesHeatVolFlow_{zone}) \quad (10.223)$$

10.7.30.4 Outside air volumetric flow rate during cooling operation

$$\dot{V}_{OA,cooling} = MIN(MinOA_{zone}, \dot{V}_{SA,cooling}) \quad (10.224)$$

10.7.30.5 Outside air volumetric flow rate during heating operation

$$\dot{V}_{OA,heating} = MIN(MinOA_{zone}, \dot{V}_{SA,heating}) \quad (10.225)$$

10.7.30.6 Outside air volumetric flow rate when no cooling or heating is needed

$$\dot{V}_{OA, no cool or heat} = MIN(MinOA_{zone}, \dot{V}_{SA, no cool or heat}) \quad (10.226)$$

10.7.30.7 Maximum supply air temperature from supplemental heater

$$T_{SA,max} = HeatDesTemp_{zone} \quad (10.227)$$

10.7.31 MultiSpeed Heat Pump Sizing

MultiSpeed heat pumps are compound components: each unit contains a supply air fan, a multispeed DX cooling coil, a multispeed DX heating coil, and a GAS or ELECTRIC supplemental heating coil. The inputs that may need to be autosized are the supply air volumetric air flow rates during cooling operation, heating operation, and when no cooling or heating is needed. The data needed for sizing the units are obtained from the controlled zone design arrays.

10.7.31.1 Supply air volumetric flow rate during cooling operation at the highest speed

$$\dot{V}_{SA,cooling} = MAX(DesCoolVolFlow_{zone}, DesHeatVolFlow_{zone})/ZoneFraction \quad (10.228)$$

10.7.31.2 Supply air volumetric flow rate during heating operation at the highest speed

$$\dot{V}_{SA,heating} = MAX(DesCoolVolFlow_{zone}, DesHeatVolFlow_{zone})/ZoneFraction \quad (10.229)$$

10.7.31.3 Supply air volumetric flow rate when no cooling or heating is needed

$$\dot{V}_{SA, no\ cool\ or\ heat} = MAX(DesCoolVolFlow_{zone}, DesHeatVolFlow_{zone}) / ZoneFraction \quad (10.230)$$

where ZoneFraction = Fraction of the total volume flow that goes through the controlling zone.

10.7.31.4 Supply air volumetric flow rate during cooling operation at Speed n (1 to NumberOfSpeed-1)

$$\dot{V}_{SA, cooling, n} = \frac{n}{NumberOfSpeed} \dot{V}_{SA, cooling} \quad (10.231)$$

10.7.31.5 Supply air volumetric flow rate during heating operation at Speed n (1 to NumberOfSpeed-1)

$$\dot{V}_{SA, heating, n} = \frac{n}{NumberOfSpeed} \dot{V}_{SA, heating} \quad (10.232)$$

where:

n = Speed Index number from 1 to NumberOfSpeed-1

NumberOfSpeed = The highest speed number

10.7.32 Single Duct Terminal Units

These are all the EnergyPlus components whose names begin with “*AirTerminal:SingleDuct:*” (except for Cooled Beam units). This includes *Uncontrolled*, *ConstantVolume:Reheat*, *VAV:NoReheat*, *VAV:Reheat*, *VAV:Reheat:VariableSpeedFan*, *VAV:HeatAndCool:NoReheat*, *VAV:HeatAndCool:Reheat*, *SeriesPIU:Reheat*, *ParallelPIU:Reheat*, and *ConstantVolume:FourPipeInduction*. The inputs that may need to be autosized are the various maximum air flow rates through the unit, minimum air flow rates, and maximum hot water and/or chilled water flow rates if heating or cooling coils are present.

Note: all zone design flow rates and loads referenced below may have been altered by system sizing inputs. For instance, if the user specifies a *Cooling Design Air Flow Method = Flow/System* and specifies a *Cooling Design Air Flow Rate* the zone cooling design values will be altered to match the specified system flow rate.

10.7.32.1 Maximum Air Flow Rate

$$\dot{V}_{air, max, terminal} = Max(DesCoolVolFlow_{zone}, DesHeatVolFlow_{zone}) \quad (10.233)$$

10.7.32.2 Maximum Heating Air Flow Rate

$$\dot{V}_{air, max, heat, terminal} = DesHeatVolFlow_{zone} \quad (10.234)$$

10.7.32.3 Maximum Primary and Secondary Air Flow Rates

For the PIU terminal units, the maximum primary and secondary air flow rates are sized to the same value as the maximum total air flow rate.

10.7.32.4 Minimum Air Flow Rate

Basically minimum air flow rates are sized to the ventilation air requirement. This may be more or less complicated.

For the PIU's, the minimum primary air flow fraction is set to:

$$MinOA_{zone}/\dot{V}_{air,max,primary,terminal} \quad (10.235)$$

For other VAV terminal units:

$$\dot{V}_{air,min,terminal} = Frac_{air,min} * DesVolFlow_{zone} \quad (10.236)$$

where $Frac_{air,min}$ corresponds to the minimum flow fraction of the terminal unit. This value is provided as user input, typically as the field “Zone Minimum Air Flow Fraction.” For the VAV terminals that allow scheduling minimum flow fraction (e.g., AirTerminal:SingleDuct:VAV:Reheat), there are two ways that $Frac_{air,min}$ can be determined. If a value is entered in the input field Constant Minimum Air Flow Fraction, then it is always used for $Frac_{air,min}$. If the minimum air flow fraction method is “Schedule” and the Constant Minimum Air Flow Fraction is left blank, then the program uses the average of the minimum and maximum values in the schedule for $Frac_{air,min}$.

10.7.32.5 Fan On Flow Fraction

For the parallel PIU, this is set to the minimum primary air flow fraction.

10.7.32.6 Max Hot Water Flow

$$T_{coil,in} = DesHeatCoilInTemp_{zone} \quad (10.237)$$

$$T_{coil,out} = HeatDesTemp_{zone} \quad (10.238)$$

The coil load and max hot water flow rate are then:

$$\dot{Q}_{coil,des} = c_{p,air} \cdot \rho_{air} \cdot \dot{V}_{air,coil,heating} \cdot (T_{out,coil} - T_{in,coil}) \quad (10.239)$$

$$\dot{V}_{max,hw} = \dot{Q}_{coil,des} / (c_{p,w} \cdot \rho_w \cdot \Delta T_{loop,des}) \quad (10.240)$$

where $c_{p,air}$ is evaluated at the average of the inlet & outlet temperatures and the coil outlet humidity ratio.

The four-pipe induction unit sizes the heating coil differently: to meet the zone load rather than match the design zone supply temperature. The load on the hot water coil is then the zone load minus whatever the central system does.

$$\dot{Q}_{coil,des} = \dot{Q}_{zone,des} - c_{p,air} \rho_{air} \dot{V}_{air,primary,des} (T_{coil,in} - T_{zone,heatpeak}) \quad (10.241)$$

where:

$$T_{coil,in} = DesHeatCoilInTemp_{zone} \quad (10.242)$$

$$T_{zone,heatpeak} = ZoneTempAtHeatPeak_{zone} \quad (10.243)$$

$$\dot{V}_{air,primary,des} = \dot{V}_{air,max,terminal} / (1 + R_{induc}) \quad (10.244)$$

10.7.32.7 Max Chilled Water Flow

The chilled water flow for the four-pipe induction unit is sized analogously to the hot water flow.

10.7.33 Indirect Evaporative Cooler Sizing

The model for the object called EvaporativeCooler:Indirect:ResearchSpecial has a field for the secondary fan flow rate that can be autosized.

10.7.33.1 Secondary Fan Flow Rate

The secondary fan is not part of an airstream that is directly modeled in EnergyPlus. Because the primary side air flows can be autosized as part of the air system, it is convenient to also scale the size of the secondary flow. If the cooler is part of the main loop of a central air system, then the secondary fan flow rate is sized to equal to the main design flow rate.

$$\dot{V}_{fan,max} = DesMainVolFlow_{sys} \quad (10.245)$$

If the cooler is part of the outdoor air path of a central air system, then the secondary fan flow rate is sized to be the maximum of either the design minimum outdoor air flow rate or one-half of the main design flow rate.

$$\dot{V}_{fan,max} = MAX(DesOutAirVolFlow, 0.5 * DesMainVolFlow) \quad (10.246)$$

10.7.34 Secondary DX Coils Sizing

The secondary DX coils model does not have a standalone object and it is modeled as an add-on feature to the DX Coils. When the secondary DX coil is added to a primary DX cooling coil, the heat rejected to secondary zone is sensible only and is treated as internal gain, hence secondary air flow rate is not required in the model. Whereas when the secondary DX coil is added to a primary DX heating coil, then the heat removed from secondary zone may have sensible and latent components and is treated as internal gain. The sensible/latent component split among other parameters requires secondary coil air flow rate. Hence secondary coil air flow rate sizing is added based on the primary DX cooling coil only.

$$\dot{V}_{SecCoil} = \dot{V}_{PriHeatCoil} \cdot ScalingFactor \quad (10.247)$$

where:

$\dot{V}_{SecCoil}$ is the secondary coil design air flow rate (m³/s)

$\dot{V}_{PriHeatCoil}$ is the primary heating DX coil design air flow rate (kg/s)

ScalingFactor is the secondary DX coil air flow rate scaling factor.

10.7.35 Desiccant Dehumidifier Sizing

The sizing of dehumidifier with no fans is done in subroutine SizeDesiccantDehumidifier.

10.7.35.1 Nominal Process Air Flow Rate

If the unit is part of zone equipment, then:

$$\dot{V}_p = \text{Max}(\text{DesCoolVolFlow}_{zone}, \text{DesHeatVolFlow}_{zone}) \quad (10.248)$$

If the unit is part of the central air system, then check if outdoor air system is present. If outdoor air system is part of the air loop and design outdoor air flow rate is greater than zero, then:

$$\dot{V}_p = \text{DesOutAirVolFlow}_{sys} \quad (10.249)$$

Otherwise, nominal process air flow rate is determined as follows:
for duct type = *main*

$$\dot{V}_p = \text{DesMainVolFlow}_{sys} \quad (10.250)$$

for duct type = *cooling*

$$\dot{V}_p = \text{DesCoolVolFlow}_{sys} \quad (10.251)$$

for duct type = *heating*

$$\dot{V}_p = \text{DesHeatVolFlow}_{sys} \quad (10.252)$$

for duct type = *other*

$$\dot{V}_p = \text{DesMainVolFlow}_{sys} \quad (10.253)$$

10.7.36 Evaporative Cooler Sizing

The sizing of evaporative cooler objects is done in subroutine SizeEvapCooler.

10.7.36.1 Secondary Fan Flow Rate

$$\dot{V} = \text{DesMainVolFlow}_{sys} \quad (10.254)$$

Note that it is only applicable to indirect CELdek pad object.

10.7.36.2 Direct Pad Area

As from the continuity equation, the area of direct pad is directly determined by assuming face air velocity of 3m/s as:

$$A_{pad} = \frac{\text{DesMainVolFlow}_{sys}}{V} \quad (10.255)$$

where:

A_{pad} is area of direct pad, m²

V is face air velocity, m/s.

10.7.36.3 Direct Pad Depth

The solution of the following regression equation is used, assuming saturation effectiveness of 70% and face air velocity of 3m/s:

$$\begin{aligned} \epsilon = & 0.792714 + 0.958569D - 0.25193V - 1.03215D^2 + 0.0262659V^2 + 0.914869DV - 1.48241VD^2 \\ & - 0.018992DV^3 + 1.13137D^3V + 0.0327622D^2V^3 - 0.145384D^3V^2 \end{aligned} \quad (10.256)$$

where:

D is depth of pad, m

ϵ is saturation effectiveness.

10.7.37 Heat Recovery Sizing

The sizing of heat exchanger objects is done in subroutine SizeHeatRecovery.

10.7.37.1 Nominal Supply Air Flow Rate

If the unit is part of zone equipment, then:

$$\dot{V}_p = \text{Max}(\text{DesCoolVolFlow}_{zone}, \text{DesHeatVolFlow}_{zone}) \quad (10.257)$$

If the unit is part of the central air system, then check if outdoor air system is present. If outdoor air system is part of the air loop and design outdoor air flow rate is greater than zero, then:

$$\dot{V}_p = \text{DesOutAirVolFlow}_{sys} \quad (10.258)$$

Otherwise, nominal supply air flow rate is determined as follows:

for duct type = *main*

$$\dot{V}_p = \text{DesMainVolFlow}_{sys} \quad (10.259)$$

for duct type = *cooling*

$$\dot{V}_p = \text{DesCoolVolFlow}_{sys} \quad (10.260)$$

for duct type = *heating*

$$\dot{V}_p = \text{DesHeatVolFlow}_{sys} \quad (10.261)$$

for duct type = *other*

$$\dot{V}_p = \text{DesMainVolFlow}_{sys} \quad (10.262)$$

10.7.37.2 Nominal Supply Air Flow Rate

It is assumed to be equal to the nominal supply air flow rate.

10.7.38 Low Temperature Radiant System Sizing

The sizing is done in subroutine *SizeLowTempRadiantSystem*.

10.7.38.1 ZoneHVAC:LowTemperatureRadiant:Electric

10.7.38.1.1 Nominal Capacity

$$Cap = DesHeatLoad_{zone} \cdot HeatSizingFactor \quad (10.263)$$

10.7.38.2 ZoneHVAC:LowTemperatureRadiant:VariableFlow

10.7.38.2.1 Maximum Hot Water Flow

$$\dot{V}_h = \frac{DesHeatLoad_{zone} \cdot HeatSizingFactor}{\Delta T_h \cdot c_{p,h} \cdot \rho_h} \quad (10.264)$$

where

\dot{V}_h is maximum hot water flow rate, m³/s

$c_{p,h}$ is specific heat of hot water at reference condition (60°C), J/kgK

ρ_h is the density of water at reference condition (60°C), kg/m³.

10.7.38.2.2 Maximum Cool Water Flow

$$\dot{V}_c = \frac{DesCoolLoad_{zone} \cdot CoolSizingFactor}{\Delta T_c \cdot c_{p,c} \cdot \rho_c} \quad (10.265)$$

\dot{V}_c is maximum chilled water flow rate, m³/s

$c_{p,c}$ is specific heat of chilled water at reference condition (5°C), J/kgK

ρ_c is the density of chilled water at reference condition (5°C), kg/m³.

10.7.38.2.3 Hydronic Tubing Length

$$TubeLength = \frac{TotalSurfaceArea}{TubeSpacing} \quad (10.266)$$

Note that tube spacing is determined by the Tube Spacing field of the ConstructionProperty:InternalHeatSource input used to define the radiant surface(s) of this system. If the user has entered a spacing that is less than 0.01m or more than 1.0m, the sizing calculation will assume that the spacing is equal to 0.15m.

10.7.38.3 ZoneHVAC:LowTemperatureRadiant:ConstantFlow

10.7.38.3.1 Rated Flow Rate

The object provides both cooling and heating, and also operates in a single operating mode such as cooling-only or heating-only mode. Thus, the rated flow rate is determined, depending upon the operating mode of the unit. If the unit operates in a single operating mode, either design chilled water or hot water flow rate is chosen. The larger of the two is chosen if the unit provides both cooling and heating. The flow rates are determined in the same fashion to the variable flow system above.

10.7.38.3.2 Hydronic Tubing Length

The length of hydronic tube is determined as described in the variable flow radiant system above.

10.7.39 Unitary System Sizing

The AirloopHVAC:UnitarySystem object incorporates all coils types and fans as a complete packaged system. The fans and coils are optional allowing virtually any system type to be modeled. Sizing of this object depends on the coils selected. For single coil systems, the associated air flow rate is used as the operating flow rate (i.e., cooling or heating). For systems with both a cooling and heating coil, this methodology still applies except for DX systems (Heat Pumps) where the greater of the cooling or heating air flow rate is used. Heat pumps are defined as systems having both a DX cooling and DX heating coil. The inputs that may need to be autosized are the supply air volumetric air flow rates during cooling operation, heating operation, and when no cooling or heating is needed. The data needed for sizing the units are obtained from the zone design arrays.

10.7.39.1 Supply Air volumetric flow rate during cooling operation:

$$\dot{V}_{SA,cooling} = \text{DesCoolVolFlow}_{zone} / \text{ZoneFraction} \quad (10.267)$$

10.7.39.2 Supply Air volumetric flow rate during heating operation:

$$\dot{V}_{SA,heating} = \text{DesHeatVolFlow}_{zone} / \text{ZoneFraction} \quad (10.268)$$

10.7.39.3 Supply Air volumetric flow rate when DX coils are used as a system:

$$\dot{V}_{SA} = \max(\text{DesCoolVolFlow}_{zone}, \text{DesHeatVolFlow}_{zone}) / \text{ZoneFraction} \quad (10.269)$$

where ZoneFraction is the fraction of the total volume flow that goes through the controlling zone.

The unitary system object also allows scalable sizing as follows:

Flow Per Floor Area:

$$\dot{V}_{SA} = (\text{FlowPerFloorArea}) (\text{TotalFloorArea}) \quad (10.270)$$

Fraction of Autosized Cooling Value:

$$\dot{V}_{SA,cooling} = \dot{V}_{SA,des,cooling} (\text{FractionOfCoolingValue}) \quad (10.271)$$

Fraction of Autosized Heating Value:

$$\dot{V}_{SA,heating} = \dot{V}_{SA,des,heating} (\text{FractionOfHeatingValue}) \quad (10.272)$$

Flow Per Cooling Capacity:

$$\dot{V}_{SA,cooling} = \dot{Q}_{coil,des,cooling} (\text{FractionOfCoolingValue}) \quad (10.273)$$

Flow Per Heating Capacity:

$$\dot{V}_{SA,heating} = \dot{Q}_{coil,des,heating} (\text{FractionOfHeatingValue}) \quad (10.274)$$

10.7.39.4 Maximum Supply Air Temperature

The maximum supply air temperature can also be automatically selected. The value is determined from the Sizing:Zone or Sizing:System object depending on where the object is used in the simulation (i.e., as zone or air loop equipment). Maximum supply air temperature

$$T_{SA,max} = \text{HeatDesTemp}_{ZoneOrSystem} \quad (10.275)$$

10.7.39.5 Single Zone VAV Temperature Limits

The minimum and maximum supply air temperature limits for the single zone VAV model are calculated using a fraction of the control zone design load and the low speed fan operating air volume flow rate. When using the single zone VAV model, the minimum and maximum supply air temperature limits are used to control the system when low speed fan operation under low load conditions and to modulate the fan speed to limit the outlet air temperature at higher zone loads. These limits are not enforced once the system fan speed reaches the maximum. See Figure 16.27.

$$T_{sup} = T_{zone,at-peak} + \frac{\dot{Q}_{sens,at-peak} * frac}{\rho_{air} c_{p,air} \dot{V}_{air,min}} \quad (10.276)$$

where:

T_{sup} is the supply air temperature limit to meet a fraction of the zone design load, (°C)

$T_{zone,at-peak}$ is the zone air temperature at the time of peak design load, (°C)

$\dot{Q}_{sens,at-peak}$ is the zone design cooling or heating load, (W) (negative for cooling)

frac is the fraction of zone design load at minimum fan speed, 50% for the single zone VAV model

ρ_{air} is the density of air at standard conditions, (kg/m³)

$c_{p,air}$ is the specific heat of zone air, (J/kg K)

$\dot{V}_{air,min}$ is the air volume flow rate at minimum fan speed, (m³/s)

10.8 Zone Outdoor Air Design Data

Outdoor air design data may be required for many aspects of a building computer model. Sizing of HVAC equipment, infiltration and ventilation, and specific outdoor air requirements for different zone types are a few examples where required outdoor air quantities may vary. Since there would be a significant chance for data input errors if each individual aspect of the simulation model allowed for independent input of outdoor air design data, this general object is used to define outdoor air design data and this data set may be used throughout the building simulation model.

The design data is provided as a group of inputs that are recognized by designers as standard practice. This information may be used individually or used as a group to calculate summations or maximums of the entered data. These design data include values for:

- Outdoor air per person
- Outdoor air per zone floor area
- Outdoor air per zone
- Outdoor air changes per hour

This design data is entered in an outdoor air design data object and may be referenced by other objects during the simulation. A single specification for outdoor air design data may be used by all other appropriate objects within EnergyPlus, or multiple outdoor air design data objects may be specified and these design data objects may be used as necessary by other objects when outdoor air design quantities vary for any reason.

10.8.1 Design Outdoor Air Calculation

The outdoor air design data is entered as a group and referenced through name association to this group of design data (Ref. DesignSpecification:OutdoorAir). The reference name in the following example is “ZoneOAData”.

A DesignSpecification:OutdoorAir example:

```
DesignSpecification:OutdoorAir,
ZoneOAData,                !- Name
Maximum,                   !- Outdoor Air Method
0.00944,                   !- Outdoor Air Flow per Person {m3/s}
0.00305;                   !- Outdoor Air Flow per Zone Floor Area {m3/s-m2}
,                           !- Outdoor Air Flow per Zone
,                           !- Outdoor Air Flow Air Changes per Hour
Min OARequirements Sched; !- Outdoor Air Flow Rate Fraction Schedule Name
```

Given this set of data, the quantity of outdoor air is calculated based on the Outdoor Air Method specified in each outdoor air design data object. In this example, the maximum of the per person and per zone floor area is used to establish the outdoor air quantity.

As previously mentioned, this group of outdoor air design data is reference by other objects used in the simulation. The reference is by the *name* of the outdoor air design data object. Any reference to this name by other objects simply means that the object referencing this data set will use the values specified in this common object. Note that a zone name is not included in the list of data and the calculation of occupancy, zone floor area, or zone volume is implied through this named reference and *the connection to a zone via the referencing object*. For example, if a terminal unit references an outdoor air design data object, the zone served by that terminal unit is used to determine the occupancy, zone floor area, and zone volume in the following calculations.

$$OA_{people} = Occ_{zone} (OAFlowperPerson) \quad (10.277)$$

$$OA_{floor\ area} = A_{zone} (OAFlowperFloorArea) \quad (10.278)$$

$$OA_{zone} = (OAFlowperZone) \quad (10.279)$$

$$OA_{ACH} = V_{zone} \left(OAFlowAirChangesperHour / 3600 \right) \quad (10.280)$$

where:

OA_{people} = outdoor air volume flow rate based on occupancy, [m³/s]

Occ_{zone} = number of occupants in zone, [people]

$OAFlowperPerson$ = outdoor air volume flow rate per person, [m³/s-person]

$OA_{floor\ area}$ = outdoor air volume flow rate based on zone floor area, [m³/s]

A_{zone} = zone floor area, [m²]

$OAF_{\text{flowperFloorArea}}$ = outdoor air volume flow rate per zone floor area, $[\text{m}^3/\text{s-m}^2]$

OA_{zone} = zone outdoor air volume flow rate, $[\text{m}^3/\text{s}]$

$OAF_{\text{flowperZone}}$ = outdoor air volume flow rate per zone, $[\text{m}^3/\text{s}]$

OA_{ACH} = outdoor air volume flow rate based on air changes per hour, $[\text{m}^3/\text{s}]$

V_{zone} = zone volume, $[\text{m}^3]$

$OAF_{\text{flowAirChangesperHour}}$ = outdoor air volume flow in air changes per hour, $[\text{m}^3/\text{s-m}^3]$

Given the calculations for each specific type of design data, the method used to calculate the outdoor air design data is then based on a user selected method for this specific outdoor air design data object. The outdoor air methods used to calculate the outdoor air quantity and the associated value for outdoor air volume flow rate are shown here.

Flow/Person $\Rightarrow OA_{\text{people}}$

Flow/Area $\Rightarrow OA_{\text{floor area}}$

Flow/Zone $\Rightarrow OA_{\text{zone}}$

AirChanges/Hour $\Rightarrow OA_{ACH}$

Sum $\Rightarrow OA_{\text{people}} + OA_{\text{floor area}} + OA_{\text{zone}} + OA_{ACH}$

Maximum $\Rightarrow \text{MAX}(OA_{\text{people}}, OA_{\text{floor area}}, OA_{\text{zone}}, OA_{ACH})$

If an Outdoor Air Flow Rate Fraction Schedule Name is specified, the flow rate determined above will be multiplied by the current schedule value.

Examples of objects that reference the outdoor air design data object are:

- Sizing:Zone
- AirTerminal:SingleDuct:VAV:NoReheat
- AirTerminal:SingleDuct:VAV:Reheat
- AirTerminal:DualDuct:VAV:OutdoorAir
- ZoneHVAC:FourPipeFanCoil
- ZoneHVAC:IdealLoadsAirSystem
- Controller:MechanicalVentilation

Chapter 11

Operational Faults

11.1 Introduction to HVAC Operational Faults Modeling

Most of the buildings, either new or old, have operational faults in the sensors, controllers, meters, equipment and systems. Being able to model and simulate these faults and their impact on energy performance of buildings is crucial to improve accuracy of building simulations and to support the retrofit of buildings. To date, the main practitioner use of EnergyPlus has been for new construction design. With the new high priority attached by USDOE to retrofit and improved operation of existing buildings, there is a need to extend the capabilities of EnergyPlus to model existing buildings, including faulty operation:

- Retrofit analysis: starts with calibrated simulation; the ability to estimate the severity of common faults is expected to improve the accuracy and transparency of the calibrated model and hence the increase accuracy of the analysis of different retrofit measures.
- Commissioning providers can use the fault models to demonstrate the saving to be expected from fixing faults found in retro-commissioning
- Support for building operation by using the calibrated model, including unfixed faults, as a real-time reference model to detect, and verify the diagnosis of, newly occurring faults.

The users in these cases are practitioners, not power users, so it is needed to implement the fault models using conventional EnergyPlus objects rather than the EMS, which, in any case, could only be used to model limited types of faults.

EnergyPlus contains a number of objects to model operational faults of sensors, meters, equipment and systems. The current implementation allows the modeling of a number of fault types that categorized as: (1) sensor faults with air economizers (e.g., outdoor air temperature sensor) (2) thermostat/humidistat offset faults, (3) fouling or scaling at air side or water side components (e.g., heating and cooling coil, air filter, cooling tower), (4) sensor faults with plant components (e.g., chiller supply water temperature sensor offset).

11.2 Operational Faults Modeling

11.2.1 Sensor Faults with Air Economizers

11.2.1.1 Symptom

The sensor readings deviate from the actual air conditions due to sensor offset, which leads to inappropriate operations of the air economizer and thus undesired resulting indoor conditions.

11.2.1.2 Modeling Approach

There are a number of sensors installed to support the air economizer operations. The sensors may be of different types. The objects used by EnergyPlus to model the sensor faults are as follows:

- FaultModel:TemperatureSensorOffset:OutdoorAir
- FaultModel:HumiditySensorOffset:OutdoorAir
- FaultModel:EnthalpySensorOffset:OutdoorAir
- FaultModel:TemperatureSensorOffset:ReturnAir
- FaultModel:EnthalpySensorOffset:ReturnAir

11.2.2 Thermostat/Humidistat Offset

11.2.2.1 Symptom

The zone air temperature/relative humidity readings deviate from the actual zone air conditions due to thermostat/humidistat offset, and thus leads to inappropriate operations of the HVAC system and undesired resulting indoor conditions.

11.2.2.2 Modeling Approach

The thermostat offset fault is described in the object FaultModel:ThermostatOffset, which refers to the object ZoneControl:Thermostat. The humidistat offset fault is described in the object FaultModel:HumidistatOffset, which refers to the object ZoneControl:Humidistat. The effect of an offset in a thermostat/humidistat whose sole use is for the calculation of difference between the set-points and the design values can be modeled as an equal and opposite offset in the thermostat/humidistat:

$$T_{s,f} = T_{s,ff} - \Delta T \quad (11.1)$$

$$RH_{s,f} = RH_{s,ff} - \Delta RH \quad (11.2)$$

where:

$T_{s,f}$ is the thermostat value in the faulty case, °C

$T_{s,ff}$ is the thermostat value in the fault-free case (design value), °C

$RH_{s,f}$ is the humidistat value in the faulty case

$RH_{s,ff}$ is the humidistat value in the fault-free case (design value)

$\Delta T/\Delta RH$ difference between the thermostat/humidistat readings and the actual zone air conditions. Positive values mean that the readings is higher than the actual air conditions.

For the humidistat that is independent of the thermostat, ΔRH can be described by a pre-defined schedule. For the humidistat offset that is caused by the thermostat offset, ΔRH is related with both the thermostat offset level as well as the indoor air conditions which are dynamic, and therefore cannot be described with a pre-defined schedule. In this case, the humidistat offset level is calculated each time step.

$$\Delta RH = RH_{s,ff} - f(T_{real}, W_{s,f}) \quad (11.3)$$

where:

T_{real} is the real-time temperature of the indoor air (real value), °C

$W_{s,f}$ is the humidistat ratio corresponding to $T_{real} - \Delta T$ and $RH_{s,ff,kgWater/kgDryAir}$.

Note that the thermostat/humidistat settings are related with two major processes within EnergyPlus: one is the design load calculations and HVAC system sizing, and the other is the HVAC system operations. Only the latter is affected by the thermostat/humidistat offset fault, while the former is not. Therefore, the size of the corresponding HVAC equipment in the faulty cases is the same as that in the fault-free cases.

When EMS is used to overwrite the ZoneControl:Thermostat/ZoneControl:Humidistat values, the offsets are applied to the EMS values rather than the original Thermostat/Humidistat values.

11.2.3 Heating and Cooling Coil Fouling

11.2.3.1 Symptom

Reduced overall heat transfer coefficient (UA) causes reduced coil capacity, resulting in unmet loads and/or increased water flow rate and decreased water side temperature difference (“low delta-T” syndrome).

11.2.3.2 Modeling Approach - General

The coil fouling fault is described in the object **FaultModel:Fouling:Coil**. The fault model currently applies only to the ‘simple’ water coils: **Coil:Heating:Water** and **Coil:Cooling:Water**.

The **FaultModel:Fouling:Coil** object allows the user to describe the fouling information in either of the two methods: **FouledUARated** or **FoulingFactor**.

Using **FouledUARated** method, user specifies the value of UAfouled directly. Using **FoulingFactor** method user specifies air/water side fouling factor, and the UAfouled value is further calculated via the equations shown below.

$$UA_{fouled} = \left[\frac{1}{UA_{air}} + R_{foul} + \frac{1}{UA_{water}} \right]^{-1} \quad (11.4)$$

where:

UA_{air} is the heat transfer coefficient of the coil on the air side, W/K

UA_{fouled} is the overall heat transfer coefficient of the fouled coil, W/K

UA_{water} is the heat transfer coefficient of the coil on the water side, W/K

R_{foul} is the fouling thermal insulance factor (the reciprocal of a heat transfer coefficient), K/W.

R_{foul} is determined by:

$$R_{foul} = \frac{r_{air}}{A_{air}} + \frac{r_{water}}{A_{water}} \quad (11.5)$$

where:

r_{air} is the air side fouling factor, $m^2\cdot K/W$

r_{water} is the water side fouling factor, $m^2\cdot K/W$

A_{air} is the air side coil surface area, m^2

A_{water} is the water side coil surface area, m^2 .

Given the input of the object based on the outside coil surface area and the inside to outside coil surface area ratio, this results in:

$$R_{foul} = \frac{r_{water}}{A_{out} * A_{ratio}} + \frac{r_{air}}{A_{out}} \quad (11.6)$$

where:

A_{out} is the Outside Coil Surface Area (in contact with the air), m^2 .

A_{ratio} is the Inside to Outside Coil Surface Area Ratio.

The pressure drop associated with the fouling is ignored in the current implementation.

An Availability schedule is used to schedule the fault on or off. A Severity Schedule is also used to represent the severity of the fault, or Fault Fraction. Schedule value of 1 (default) means that the fault is applied as is.

11.2.3.3 Modeling Approach - Heating Coil

When applied to a **Coil:Heating:Water**, before the fault is applied, the current, non-fouled, UA (`WaterCoil(CoilNum).UACoilVariable`) is first determined

FouledUARated: If method **FouledUARated** is used, we try to set the new UA' to the UA_{fouled} entered in the Fouling Object, adjusting for Fault Severity $FaultFrac$

$$UA' = \left[\frac{FaultFrac}{UA_{fouled}} + \frac{(1 - FaultFrac)}{UA} \right]^{-1} \quad (11.7)$$

FoulingFactor: If method **FoulingFactor** is used:

$$R_{foul} = FaultFrac \cdot \left[\frac{r_{water}}{A_{out} * A_{ratio}} + \frac{r_{air}}{A_{out}} \right] \quad (11.8)$$

$$UA' = \left[\frac{1}{UA} + R_{foul} \right]^{-1} \quad (11.9)$$

Note that we do not allow bettering the coil UA , so the final result in either cases is $UA' = \min(UA, UA')$

11.2.3.4 Modeling Approach - Cooling Coil

When applied to a **Coil:Cooling:Water**, before the fault is applied, the current, non-fouled, UA_{water} (`WaterCoil(CoilNum).UACoilExternal`) and UA_{air} (`WaterCoil(CoilNum).UACoilInternal`) are first determined.

FoulingFactor:

If method **FoulingFactor** is used, the air-side and water-side fouling are applied respectively:

$$UA'_{air} = \left[\frac{1}{UA_{air}} + FaultFrac \cdot \frac{r_{air}}{A_{out}} \right]^{-1} \quad (11.10)$$

$$UA'_{water} = \left[\frac{1}{UA_{water}} + FaultFrac \cdot \frac{r_{water}}{A_{out} * A_{ratio}} \right]^{-1} \quad (11.11)$$

FouledUARated:

If method **FouledUARated** is used, the total UA_{fouled} of the coil is specified, but we still have to split the fouling between External (air) and Internal (water).

So we start by calculating the current split ratio S_R between internal and external, and will use it for the new split:

$$S_R = UA_{water}/UA_{air} \quad (11.12)$$

$$\begin{aligned} UA_{water} &= S_R \cdot UA_{air} \\ UA'_{water} &= S_R \cdot UA'_{air} \end{aligned} \quad (11.13)$$

$$\begin{aligned} UA &= \left[\frac{1}{UA_{air}} + \frac{1}{UA_{water}} \right]^{-1} \\ UA &= \left[\frac{1}{UA_{air}} + \frac{1}{S_R \cdot UA_{air}} \right]^{-1} \\ UA &= \frac{UA_{air} \cdot S_R}{1 + S_R} \end{aligned} \quad (11.14)$$

$$UA' = \left[\frac{FaultFrac}{UA_{fouled}} + \frac{(1 - FaultFrac)}{UA} \right]^{-1} \quad (11.15)$$

$$\frac{UA'_{air} \cdot S_R}{S_R + 1} = \left[\frac{FaultFrac}{UA_{fouled}} + \frac{(1 - FaultFrac)}{\frac{UA_{air} \cdot S_R}{S_R + 1}} \right]^{-1} \quad (11.16)$$

$$\begin{aligned} UA'_{air} &= \left[\frac{FaultFrac \cdot S_R}{(S_R + 1) \cdot UA_{fouled}} + \frac{(1 - FaultFrac)}{UA} \right]^{-1} \\ UA'_{water} &= S_R \cdot UA'_{air} \end{aligned} \quad (11.17)$$

Note that we do not allow bettering the coil UA, so the final result in either cases is $UA' = \min(UA, UA')$

11.2.4 Air Filter Fouling

11.2.4.1 Symptom

Increased air loop system resistance, resulting in a different system curve. This directly affects the operation of corresponding fans. More specifically, it may lead to variations of the fan pressure rise, fan energy consumption, as well as the enthalpy of the fan outlet air. It may also lead to a reduction in the airflow rate and thus affects the performance of other system components (e.g., heat transfer performance of heating/cooling coils).

11.2.4.2 Modeling Approach

The fouling air filter fault is described in the object `FaultModel:Fouling:AirFilter`, which refers to the fan objects that describe the associated fan. The fan object can be `Fan:ConstantVolume`, `Fan:OnOff`, or `Fan:VariableVolume`. The design pressure rise variations of the associated fan in the faulty cases are described by the Pressure Fraction Schedule specified in `FaultModel:Fouling:AirFilter` object, which is used as a multiplier to the fault-free fan design pressure rise specified in the fan object. The variations of the design air flow rate of the fan can then be calculated with the Pressure Fraction Schedule and Fan Curve. When EMS is used to overwrite the the pressure/MassFlow, the EMS values are used.

The effect of the fouling air filter on the fan performance is related with a number of factors, including the fan types, fan curves, and system design and operating conditions. In general, there are three possible situations to be addressed in modeling dirty air filters:

(a) **The required airflow rate can be maintained by the variable speed fan running at higher speed.**

In this case, the fan operation state changes from point A (intersection of the fan curve corresponding to a lower speed and the system curve with clean filters) to point B (intersection of the fan curve corresponding to a higher speed and the system curve with dirty filters), as shown in Figure 11.1. Point B corresponds to a higher fan pressure rise than Point A, and the same air flow rate.

Figure 11.1: Effect of dirty air filter on variable speed fan operation – flow rate maintained

The required airflow rate m can be maintained while the fan pressure rise ΔP is increased to ΔP_{df} . This leads to higher fan power $\dot{Q}_{tot,df}$ and higher power entering the air $\dot{Q}_{toair,df}$, and thus changes the specific enthalpies of the fan outlet air stream ($h_{out,df}$).

$$f_{flow,df} = m/m_{design,df} \quad (11.18)$$

$$f_{pl,df} = c_1 + c_2 * f_{flow,df} + c_3 * f_{flow,df}^2 + c_4 * f_{flow,df}^3 + c_5 * f_{flow,df}^4 \quad (11.19)$$

$$\dot{Q}_{tot,df} = f_{pl,df} \times m_{design,df} \times \Delta P_{df} / (e_{tot} \times \rho_{air}) \quad (11.20)$$

$$\dot{Q}_{shaft,df} = e_{motor} \times \dot{Q}_{tot,df} \quad (11.21)$$

$$\dot{Q}_{toair,df} = \dot{Q}_{shaft,df} + (\dot{Q}_{tot,df} - \dot{Q}_{shaft,df}) \times f_{motortoair} \quad (11.22)$$

$$h_{out,df} = h_{in} + \dot{Q}_{toair,df}/m \quad (11.23)$$

where:

e_{tot} is the motor efficiency

f_{flow} is the flow fraction or part-load ratio

f_{pl} is the part load factor

m is the air mass flow in kg/s

h_{in} is the inlet air stream specific enthalpies in J/kg

h_{out} is the outlet air stream specific enthalpies in J/kg

\dot{Q}_{tot} is the fan power in watts

\dot{Q}_{toair} is the power entering the air in watts

\dot{Q}_{shaft} is the fan shaft power in watts

ΔP is the fan pressure increase in Pascal

$_{design}$ is for the parameters in the design condition

$_{df}$ is for the parameters in the dirty filter case.

(b) The variable speed fan cannot increase in speed sufficiently to maintain the required airflow rate.

In this case, the fan operation state changes from point A (intersection of the fan curve corresponding to a lower speed and the system curve with clean filters) to point B (intersection of the fan curve corresponding to a higher speed and the system curve with dirty filters), as shown in Figure 11.2. Point B corresponds to a higher fan pressure rise and a lower air flow rate than Point A.

Figure 11.2: Effect of dirty air filter on variable speed fan operation – flow rate reduced

The airflow rate m is reduced to m_{df} while the fan design pressure rise ΔP is increased to ΔP_{df} . Similarly to case (a), the fan power (\dot{Q}_{tot}), the power entering the air (\dot{Q}_{toair}), and the specific

enthalpies of the fan outlet air stream (h_{out}) are all affected. Different from case (a), however, the fan power (\dot{Q}_{tot}) may either increase or decrease, depending on the degree of the airflow rate decrease and pressure rise increase. Also note that $f_{flow,df}$ is always 1 in this case, since the fan runs at its maximum speed.

$$f_{flow,df} = 1 \quad (11.24)$$

$$f_{pl,df} = c_1 + c_2 * f_{flow,df} + c_3 * f_{flow,df}^2 + c_4 * f_{flow,df}^3 + c_5 * f_{flow,df}^4 \quad (11.25)$$

$$\dot{Q}_{tot,df} = f_{pl,df} \times m_{design,df} \times \Delta P_{df} / (e_{tot} \times \rho_{air}) \quad (11.26)$$

$$\dot{Q}_{shaft,df} = e_{motor} \times \dot{Q}_{tot,df} \quad (11.27)$$

$$\dot{Q}_{toair,df} = \dot{Q}_{shaft,df} + (\dot{Q}_{tot,df} - \dot{Q}_{shaft,df}) \times f_{motortoir} \quad (11.28)$$

$$h_{out,df} = h_{in} + \dot{Q}_{toair,df} / m_{design,df} \quad (11.29)$$

where:

e_{tot} is the motor efficiency

f_{flow} is the flow fraction or part-load ratio

f_{pl} is the part load factor

m is the air mass flow in kg/s

h_{in} is the inlet air stream specific enthalpies in J/kg

h_{out} is the outlet air stream specific enthalpies in J/kg

\dot{Q}_{tot} is the fan power in Watts

\dot{Q}_{toair} is the power entering the air in Watts

\dot{Q}_{shaft} is the fan shaft power in Watts

ΔP is the fan pressure increase in Pascal

$_{design}$ is for the parameters in the design condition

$_{df}$ is for the parameters in the dirty filter case.

(c) The constant speed fan cannot maintain the design airflow rate.

In this case, the fan operation state changes from point A (intersection of the fan curve and the system curve with clean filters) to point B (intersection of the fan curve and the system curve with dirty filters), as shown in Figure 11.3. Point B corresponds to a higher fan pressure rise and a lower air flow rate than Point A.

Similarly to case (b), the airflow rate m is reduced to m_{df} while the fan pressure rise ΔP is increased to ΔP_{df} . This results in the variations of the fan power (\dot{Q}_{tot}), the power entering the air (\dot{Q}_{toair}), and the specific enthalpies of the fan outlet air stream (h_{out}).

$$\dot{Q}_{tot,df} = m_{design,df} \times \Delta P_{df} / (e_{tot} \times \rho_{air}) \quad (11.30)$$

$$\dot{Q}_{shaft,df} = e_{motor} \times \dot{Q}_{tot,df} \quad (11.31)$$

$$\dot{Q}_{toair,df} = \dot{Q}_{shaft,df} + (\dot{Q}_{tot,df} - \dot{Q}_{shaft,df}) \times f_{motortoir} \quad (11.32)$$

Figure 11.3: Effect of dirty air filter on constant speed fan operation

$$h_{out,df} = h_{in} + \dot{Q}_{toair,df} / m_{design,df} \quad (11.33)$$

where:

e_{tot} is the motor efficiency

m is the air mass flow in kg/s

h_{in} is the inlet air stream specific enthalpies in J/kg

h_{out} is the outlet air stream specific enthalpies in J/kg

\dot{Q}_{tot} is the fan power in Watts

\dot{Q}_{toair} is the power entering the air in Watts

\dot{Q}_{shaft} is the fan shaft power in Watts

ΔP is the fan pressure increase in Pascal

$_{design}$ is for the parameters in the design condition

$_{df}$ is for the parameters in the dirty filter case.

11.2.5 Chiller Supply Water Temperature Sensor Offset

11.2.5.1 Symptom

The chiller supply water temperature readings deviate from the actual water temperature levels due to sensor offset at the evaporator outlet. This can lead to incorrect chiller supply water temperature, and thus the inappropriate and inefficient chiller operations.

11.2.5.2 Modeling Approach

The fault applies to a number of chiller types, namely:

- Chiller:Electric
- Chiller:Electric:EIR
- Chiller:Electric:ReformulatedEIR
- Chiller:ConstantCOP
- Chiller:EngineDriven
- Chiller:CombustionTurbine
- Chiller:Absorption
- Chiller:Absorption:Indirect

These chillers can have different flow modes:

- *ConstantFlow* for constant pumping with flow controlled by chiller to operate at full design flow rate.
- *LeavingSetpointModulated* for variable pumping with flow controlled by chiller to vary flow to target a leaving temperature setpoint.
- *NotModulated* for either variable or constant pumping with flow controlled by the external plant system.

(a) Constant Flow Chillers

For the chillers with *ConstantFlow* and *NotModulated*, local control is provided by resetting the leaving water temperature. The actual evaporator outlet water temperature value at faulty operations can be obtained via:

$$T_{evap-o,f} = T_{evap-o,ff} - \Delta T \quad (11.34)$$

where:

$T_{evap-o,f}$ is the evaporator outlet temperature in the faulty case (actual value)

$T_{evap-o,ff}$ is the evaporator outlet temperature in the fault-free case (reading value)

ΔT is the difference between the temperature reading and the actual temperature.

Then the evaporator capacity can be calculated with:

$$Q_{evap,f} = m_{evap} \times C_p \times (T_{evap-i} - T_{evap-o,f}) \quad (11.35)$$

where:

m_{evap} is the evaporator water flow rate (design value, actual value)

$Q_{evap,f}$ is the actual evaporator capacity in the faulty case

$T_{evap-o,f}$ is the evaporator outlet temperature value in the faulty case (actual value)

T_{evap-i} is the evaporator inlet temperature value.

(b) Variable Flow Chillers

For the variable flow chillers with internal water flow rate controls to target a leaving temperature setpoint (type *LeavingSetpointModulated*), the actual evaporator outlet water temperature value at faulty operations can be obtained via:

$$T_{evap-o,f} = T_{evap-o,ff} - \Delta T \quad (11.36)$$

where:

$T_{evap-o,f}$ is the evaporator outlet temperature in the faulty case (actual value)

$T_{evap-o,ff}$ is the evaporator outlet temperature in the fault-free case (reading, design value)

ΔT is the difference between the temperature reading and the actual temperature.

The water flow rate at faulty operations can be obtained via:

$$m_{evap,f} = Q_{evap,ff} / (C_p \times (T_{evap-i} - T_{evap-o,ff})) \quad (11.37)$$

where:

$m_{evap,f}$ is the evaporator water flow rate in the faulty case (actual value)

$Q_{evap,ff}$ is the evaporator capacity in the fault-free case (required value)

$Q_{evap,f}$ is the actual evaporator capacity in the faulty case (actual value)

$T_{evap-o,ff}$ is the evaporator outlet temperature in the fault-free case (reading, design value)

T_{evap-i} is the evaporator inlet temperature value

ΔT is the difference between the temperature reading and the actual temperature.

Then the evaporator capacity can be calculated with:

$$Q_{evap,f} = m_{evap,f} \times C_p \times (T_{evap-i} - T_{evap-o,f}) \quad (11.38)$$

where:

$m_{evap,f}$ is the evaporator water flow rate in the faulty case (actual value)

$Q_{evap,f}$ is the actual evaporator capacity in the faulty case (actual value)

$T_{evap-o,f}$ is the evaporator outlet temperature value in the faulty case (actual value)

T_{evap-i} is the evaporator inlet temperature value

Note that operational faults only affect the HVAC operations, not the system design. Therefore, the fault model will only be applied at real weather simulations instead of the sizing and warm-up simulations. If the faulty sensor leads to a supply water temperature level that goes beyond the limits defined in the chiller object, the predefined bound values will be used as the actual supply water temperature $T_{evap-o,f}$.

If there are multiple chillers operating together with one shared faulty supply water temperature sensor, one fault object needs to be created for every chiller that is affected.

11.2.6 Condenser Supply Water Temperature Sensor Offset

11.2.6.1 Symptom

The condenser supply water temperature readings deviate from the actual water temperature levels due to sensor offset at the condenser inlet. Because this is usually used as the condenser loop temperature setpoint, the fault may affect the actual performance of cooling tower and condenser. It can result in inappropriate tower operations such as fan and pump cycling and water bypass.

11.2.6.2 Modeling Approach

The fault applies to a number of cooling tower types, namely:

- CoolingTower:SingleSpeed
- CoolingTower:TwoSpeed
- CoolingTower:VariableSpeed

- CoolingTower:VariableSpeed:MERKEL

The effect of an offset in a condenser supply water temperature sensor whose sole use is for calculation of the difference between the set-points and the actual values can be modeled as an equal and opposite offset:

$$T_{tower-o,f} = T_{tower-o,ff} - \Delta T \quad (11.39)$$

where:

$T_{tower-o,f}$ is the tower outlet temperature in the faulty case (actual value)

$T_{tower-o,ff}$ is the tower outlet temperature in the fault-free case (reading value)

ΔT is the difference between the temperature reading and the actual temperature.

Note that the fault affects the tower in both the free convection cooling mode when fan is off and normal cooling mode when fan is on. Also note that if the faulty sensor temperature goes beyond the sensor bounds (e.g., min/max condenser loop temperature defined in object *CondenserLoop*, or the min/max setpoint values defined in object *SetpointManager:FollowOutdoorAirTemperature*), the predefined bound values will be used as the actual temperature.

11.2.7 Cooling Tower Fouling

11.2.7.1 Symptom

The fault of scaling widely exists in the cooling tower operations. It occurs when deposits get clogged, usually caused by poor water quality and treatment. It is reported that the removal of scale deposits is one of the biggest expenses in the cooling tower maintenance. Scale deposits can reduce the overall heat transfer coefficient (UA), affecting both the tower effectiveness and energy efficiency.

11.2.7.2 Modeling Approach

The fault applies to a number of cooling tower types, namely:

- CoolingTower:SingleSpeed
- CoolingTower:TwoSpeed
- CoolingTower:VariableSpeed:MERKEL

The fault model allows the user to describe the fouling using UA reduction factor, which is the ratio between the UA value at fouling case and that at fault free case. The factor is applicable to both the Design UA and Free Convection UA of the tower.

$$UA_{tower,f} = UA_{tower,ff} \times F_{UA} \quad (11.40)$$

where:

$UA_{tower,f}$ is the U-factor times area values in the faulty case

$UA_{tower,ff}$ is the U-factor times area values in the fault-free case

F_{UA} is the factor describing the tower UA reduction due to fouling.

11.2.8 Coil Supply Air Temperature Sensor Offset

11.2.8.1 Symptom

The coil supply air temperature readings deviate from the actual air temperature levels due to sensor offset at the coil outlet. Because coil outlet node are often used as the setpoint node for coil control, the fault may affect the actual performance of the coils. It can result in inappropriate coil operations such as coil on/off mode and water-side flow rate control, and therefore affect the coil energy consumption. Since the coil outlet air temperature deviate from the design level, the operations and performance of other components (e.g., other dcoils) at the downstream may also be affected.

11.2.8.2 Modeling Approach

EnergyPlus can model a number of coil types, some of which are temperature-based control and the others are load-based control. The proposed fault model will be applied to the ones with temperature-based control, namely:

- Coil:Heating:Electric
- Coil:Heating:Gas
- Coil:Heating:Steam
- Coil:Heating:Desuperheater
- Coil:Heating:Water
- Coil:Cooling:Water
- Coil:Cooling:Water:Detailedgeometry

The effect of an offset in a coil supply air temperature sensor whose sole use is for calculation of the difference between the set-points and the actual values can be modeled as an equal and opposite offset:

$$T_{coil-o,f} = T_{coil-o,ff} - \Delta T \quad (11.41)$$

where:

$T_{coil-o,f}$ is the coil outlet temperature in the faulty case (actual value)

$T_{coil-o,ff}$ is the coil outlet temperature in the fault-free case (reading value)

ΔT is the difference between the temperature reading and the actual temperature.

Note that *Coil:Heating:Water*, *Coil:Cooling:Water*, and *Coil:Cooling:Water:Detailedgeometry* are controlled via *Controller:WaterCoil*, while the other coil types are controlled with an internal *Temperature Setpoint Node*. For the water coils, users need to specify a *Controller:WaterCoil* object that corresponds to the faulty water coil.

11.2.9 Hot-water Boilers Fouling

11.2.9.1 Symptom

The fouling fault of boilers may occur when deposits get clogged at the water side of boilers, usually caused by poor water quality and treatment. The scale deposits can reduce the capacity and efficiency of the boiler. This further impacts the boiler operations by changing the part load ratio and the related operation/performance parameters.

11.2.9.2 Modeling Approach

The fault applies to the hot water boiler model described by the object Boiler:HotWater. It does not apply to the steam boilers which do not have water-based heat exchangers.

The model allows the user to describe the fault using a dynamic fouling factor. The reference factor indicates the decrease of the nominal capacity of the boiler, which is the ratio between the nominal capacity at fouling case and that at fault free case. The nominal thermal efficiency is decreased correspondingly.

$$Q_{boiler,f} = Q_{boiler,ff} \times F_{boiler} \quad (11.42)$$

$$Eff_{boiler,f} = Eff_{boiler,ff} \times F_{boiler} \quad (11.43)$$

where:

$Q_{boiler,f}$ is the nominal boiler capacity in the faulty case

$Q_{boiler,ff}$ is the nominal boiler capacity in the fault-free case

$Eff_{boiler,f}$ is the nominal boiler thermal efficiency in the faulty case

$Eff_{boiler,ff}$ is the nominal boiler thermal efficiency in the fault-free case

F_{boiler} is the factor describing the boiler capacity and efficiency reduction due to fouling.

Note that operational faults only affect the HVAC operations, not the system design. Therefore, the fault model will only be applied at real weather simulations instead of the sizing and warm-up simulations.

11.2.10 Water-cooled Chiller Fouling

11.2.10.1 Symptom

The fouling fault of chillers may occur when deposits get clogged at the water-cooled condensers, usually caused by poor water quality and treatment. The scale deposits can reduce the capacity and efficiency of the chiller. This further impacts the chiller operations by changing the part load ratio and the related operation/performance parameters.

11.2.10.2 Modeling Approach

The fault applies to a number of chiller types that can have water-cooled condensers, namely:

- Chiller:Electric
- Chiller:Electric:EIR
- Chiller:Electric:ReformulatedEIR
- Chiller:ConstantCOP
- Chiller:EngineDriven
- Chiller:CombustionTurbine

The fault does not apply to the absorption chillers that do not have water-based heat exchangers.

The model allows the user to describe the fault using a dynamic fouling factor. The reference factor indicates the decrease of the reference capacity of the chiller, which is the ratio between the nominal capacity at fouling case and that at fault free case. The reference COP is decreased correspondingly.

$$Q_{chiller,f} = Q_{chiller,ff} \times F_{chiller} \quad (11.44)$$

$$COP_{chiller,f} = COP_{chiller,ff} \times F_{chiller} \quad (11.45)$$

where:

$Q_{chiller,f}$ is the reference chiller capacity in the faulty case

$Q_{chiller,ff}$ is the reference chiller capacity in the fault-free case

$COP_{chiller,f}$ is the reference chiller COP in the faulty case

$COP_{chiller,ff}$ is the reference chiller COP in the fault-free case

$F_{chiller}$ is the factor describing the chiller capacity and efficiency reduction due to fouling.

Note that operational faults only affect the HVAC operations, not the system design. Therefore, the fault model will only be applied at real weather simulations instead of the sizing and warm-up simulations.

11.2.11 Evaporative Coolers Fouling

11.2.11.1 Symptom

The fouling fault may occur at indirect wet-coil evaporative coolers, where the cooling water is sprayed directly on the tubes. This usually occurs at the wet coil tubes caused by the dust in the air. The fouling can reduce the effectiveness of the tube and further impact the evaporative cooler operations by changing the related operation/performance parameters.

11.2.11.2 Modeling Approach

The fault applies to the wetted coil evaporative cooler described by object Evaporative-Cooler:Indirect:WetCoil. The fault does not apply to direct evaporative coolers or the dry coil indirect evaporative coolers where there is no water-cooled coil.

The model allows the user to describe the fault using a dynamic fouling factor. The reference factor indicates the decrease of the indirect stage efficiency, which is the ratio between the indirect stage efficiency at fouling case and that at fault free case.

$$Eff_{EvapCooler,f} = Eff_{EvapCooler,ff} \times F_{EvapCooler} \quad (11.46)$$

where:

$Eff_{EvapCooler,f}$ is the indirect stage efficiency in the faulty case

$Eff_{EvapCooler,ff}$ is the indirect stage efficiency in the fault-free case

$F_{EvapCooler}$ is the factor describing the evaporative cooler efficiency reduction due to fouling.

Note that operational faults only affect the HVAC operations, not the system design. Therefore, the fault model will only be applied at real weather simulations instead of the sizing and warm-up simulations.

Chapter 12

Demand Limiting

Demand limiting, or demand management, is a strategy for reducing a building's demand for utilities, e.g., electricity. Utility companies typically charge a monthly fee for “demand charges” that is based on the peak demand during a certain time period. Often the peak demand charge is set by one exceptional day that is much higher than the peak demand for an average day during the month. Therefore, to save utility costs, it is in the interest of building owners to find ways to manage the demand on peak days. While demand management is generally concerned with the demand for electricity, the future will likely see demand management of other utilities, such as natural gas or water.

Demand limiting controls shut off or reduce the power to non-essential loads in order to reduce the overall building demand. Some typical controls:

- shut off or dim electric lights, equipment, or HVAC systems
- reset the thermostatic setpoints on HVAC systems
- reduce ventilation load thus electricity demand
- reduce the load of a set of similar components by rotating one or more components “off” for a short time interval
- turn on generators to meet some or all of the building's demand.

The demand limiting controls implemented in EnergyPlus are intended to allow some of the more common demand limiting strategies. The DemandManagerAssignmentList object is a high level control that makes demand limiting decisions based on a list of possible demand limiting strategies. Each demand limiting strategy is described in a separate DemandManager object. Each DemandManager object controls a group of similar load objects of the same type, such as DemandManager:Lights, DemandManager:ElectricEquipment, DemandManager:Thermostats, or DemandManager:Ventilation objects.

12.1 Algorithm

In EnergyPlus the DemandManagerAssignmentList and DemandManager objects are simulated by the Demand Manager module. The Demand Manager is built into the overall solution method for the program. For each zone time step, the program executes three major segments of code:

* exterior energy use

- zone heat balance (surface heat balances, internal gains, and air flows)
- HVAC system simulation (air and plant loops)

The exterior energy use segment is completely independent of the zone heat balance and HVAC system simulation. Exterior energy use handles energy use accounting for exterior lights and exterior equipment that are outside of the building and are not part of the zone heat balance. The zone heat balance segment includes all of the surface heat balances, internal heat gains, and air flows. The HVAC system simulation includes air and plant loops with their associated HVAC components. The behaviour of the HVAC system depends on the results of the zone heat balance. The HVAC system simulation operates on a variable “system” time step which is automatically shortened if necessary for stability.

The Demand Manager is called after the first pass through the HVAC system simulation, before the system time step is shortened. After evaluating the DemandManagerAssignmentList object, the Demand Manager decides if demand limiting is required. If demand limiting is required, the individual DemandManager objects are surveyed to determine which loads can be limited. Based on the *Demand Manager Priority* selected, the Demand Manager then decides which DemandManager objects should be activated. In turn, the activated DemandManager objects set the demand limiting hooks on their respective load objects. Finally, depending on the type of DemandManager objects that were activated, one or more of the major segments of code must be called to be resimulated because the load conditions have changed. The code segments depend on the type of DemandManager and the relationship of its load objects to the overall solution method. The table below shows the different DemandManager types and the related code segments that must be resimulated.

Table 12.1: Demand Manager Types and Resimulation.

Demand Manager Type	Resimulate Exterior Energy	Resimulate Zone Heat Balance	Resimulate HVAC System
DemandManager:ExteriorLights	X		
DemandManager:Lights		X	X
DemandManager:ElectricEquipment		X	X
DemandManager:Thermostats			X
DemandManager:Ventilation			X

All demand limiting controls are disabled during warmup days and sizing runs.

12.1.1 Sequential Priority

If the *Demand Manager Priority* field of the DemandManagerAssignmentList object is set to SEQUENTIAL, each DemandManager in the list is activated in sequence from first to last until demand is reduced below the limit or until all managers are activated. A DemandManager is skipped if it

cannot reduce the demand. Possible reasons that a manager cannot reduce demand include:

- not enough load to limit
- not available because of its *Availability Schedule*
- already activated; load limited during a previous time step.

For each DemandManager in the list that is successfully activated, one or more of the major code segments must be called to be resimulated (see above). The DemandManagerAssignmentList object is then reevaluated to determine if further demand limiting is required before the next DemandManager is activated.

The implication of sequential priority is that a DemandManagerAssignmentList with many DemandManagers may make many passes through the Demand Manager before all demand limiting decisions are finalized. Each pass requires an additional resimulation of the current time step. In some cases this could significantly slow down the overall simulation runtime. The use of the *Minimum Limit Duration* field can help to ensure that not every DemandManager is being activated at every time step.

12.1.2 All Priority

If the *Demand Manager Priority* field of the DemandManagerAssignmentList object is set to ALL, all DemandManagers in the list are activated simultaneously to achieve the maximum demand reduction. This priority option requires only one final resimulation after all DemandManagers are activated.

Chapter 13

Alternative Modeling Processes

13.1 AirflowNetwork Model

13.1.1 Overview

The AirflowNetwork model provides the ability to simulate the performance of an air distribution system, including supply and return leaks, and calculate multizone airflows driven by outdoor wind and forced air during HVAC system operation. The pressure and airflow model described here was developed based on AIRNET (Walton 1989). This detailed model is used to simulate thermal conduction and air leakage losses for constant volume air distribution systems (e.g., in residential or light commercial buildings). The multizone airflow calculations are performed at the HVAC system time step which, among other benefits, allows for modeling hybrid ventilation systems.

13.1.2 Model Description

The input object AirflowNetwork:SimulationControl provides access to the airflow network method, which consists of a set of nodes connected by airflow components through linkages. The objects AirflowNetwork:Multizone:Zone, AirflowNetwork:Multizone:ExternalNode, and AirflowNetwork:Distribution:Node represent airflow nodes. The objects AirflowNetwork:Multizone:Surface and AirflowNetwork:Distribution:Linkage represent airflow linkages. The other objects with a relationship between pressure and airflow represent airflow components.

The AirflowNetwork model consists of three sequential steps:

- Pressure and airflow calculations
- Node temperature and humidity calculations
- Sensible and latent load calculations

The pressure and airflow calculations determine pressure at each node and airflow through each linkage given wind pressures and forced airflows. Based on the airflow calculated for each linkage, the model then calculates node temperatures and humidity ratios given zone air temperatures and zone humidity ratios. Using these node temperatures and humidity ratios, the sensible and latent loads from duct system conduction and leakage are summed for each zone. The sensible and latent loads obtained in this step are then used in the zone energy balance equations to predict HVAC system loads and to calculate the final zone air temperatures, humidity ratios, and pressures.

The present AirflowNetwork model may only be applied to a single heating and cooling system that uses a single air distribution system (a single AirLoopHVAC object). The model excludes the impact of the air and duct system thermal capacitance.

13.1.3 Pressure and Airflow Calculations

The EnergyPlus airflow network consists of a set of nodes linked by airflow components. Therefore, it is a simplified airflow model, compared to detailed models such as those used in computational fluid dynamics (CFD) models. The node variable is pressure and the linkage variable is airflow rate. A brief description is presented below. A detailed description of the airflow network model may be found in the work of Walton (1989), Dols and Walton (2002), and Walton and Dols (2003).

13.1.3.1 Initialization

Newton's method is used to solve for node air pressures and it requires an initial set of values for the node pressures. There are two initialization methods available. The first is linear initialization and equivalent to Initialization flag = 0. These initial values may be obtained by including in each airflow component a linear approximation relating airflow to pressure drop:

$$\dot{m}_i = C_i \rho \frac{\Delta P_i}{\mu} \quad (13.1)$$

where:

- \dot{m}_i = Air mass flow rate at i-th linkage [kg/s]
- C_i = Air mass flow coefficient [m³]
- ΔP_i = Pressure difference across the i-th linkage [Pa]
- μ = Air viscosity [Pa-s]

This initialization handles stack effects very well and tends to establish the proper direction for the airflows. The linear approximation is provided by the laminar regime.

The second initialization method assumes the initial pressures are zero and uses Newton's method directly.

13.1.3.2 Convergence criteria

Conservation of air mass flow rate at each linkage provides the convergence criterion. When the sum of mass flow rates in all the linkages approaches zero within the convergence tolerance, the solution has converged. The solution is assumed to have converged when the sum is less than the convergence value, in order to reduce the number of iterations and obtain sufficient accuracy. There are two convergence criteria used in the AirflowNetwork model: Relative airflow convergence tolerance and Absolute airflow convergence tolerance.

$$Relative\ airflow\ tolerance = \frac{|\sum \dot{m}_i|}{\sum \dot{m}_i} \quad (13.2)$$

$$Absolute\ airflow\ tolerance = \left| \sum \dot{m}_i \right| \quad (13.3)$$

The relative airflow tolerance is equivalent to the ratio of the absolute value of the sum of all network airflows to the sum of the network airflow magnitudes. The absolute airflow tolerance is the summation of the absolute value of all network airflows. The solution has converged when both of these convergence criteria have been met.

13.1.3.3 Linkage models

A linkage used in the AirflowNetwork model has two nodes, inlet and outlet, and is linked by a component which has a relationship between airflow and pressure. The pressure difference across each component in a linkage is assumed to be governed by Bernoulli's equation:

$$\Delta P = \left(P_n + \frac{\rho V_n^2}{2} \right) - \left(P_m + \frac{\rho V_m^2}{2} \right) + \rho g (z_n - z_m) \quad (13.4)$$

where:

- ΔP = Total pressure difference between nodes n and m [Pa]
- P_n, P_m = Entry and exit static pressures [Pa]
- V_n, V_m = Entry and exit airflow velocities [m/s]
- ρ = Air density [kg/m³]
- g = Acceleration due to gravity [9.81 m/s²]
- z_n, z_m = Entry and exit elevations [m]

By rearranging terms and adding wind pressure impacts, the above equation may be rewritten in the format used by the airflow network model:

$$\Delta P = P_n - P_m + P_S + P_W \quad (13.5)$$

where:

- P_n, P_m = Total pressures at nodes n and m [Pa]
- P_S = Pressure difference due to density and height differences [Pa]
- P_W = Pressure difference due to wind [Pa]

The Input Output Reference provides the relationship between airflow and pressure for the most of the components (Ref. AirflowNetwork Model). The relationship between airflow and pressure for the AirflowNetwork:Multizone:Component:DetailedOpening, AirflowNetwork:Multizone:Component:SimpleOpening, and AirflowNetwork:Multizone:Component:-HorizontalOpening objects are provided in detail in this reference.

The schematic drawing of a possible air flow pattern through a detailed vertical opening (AirflowNetwork:Multizone:Component:DetailedOpening) is shown in Figure 13.1. The equations used below are extracted from the COMIS Fundamentals manual (1990).

The air density is assumed to be a linear function of height:

$$\rho_i(z) = \rho_{0i} + b_i z \quad (13.6)$$

Figure 13.1: The general problem of gravitational flow through a vertical opening

The pressure difference is assumed to be linear and simulate the effect of turbulence:

$$\Delta P_t = P_{t0} + b_t z \quad (13.7)$$

The reference pressures on each side are given at the bottom of the opening. By assuming the Bernoulli hypothesis on both sides, the pressure difference can be defined at any level of z as:

$$P_1(z) - P_2(z) = (P_{01} - P_{02}) - g [(\rho_{01}z + b_1 z^2/2) - (\rho_{02}z + b_2 z^2/2)] + (P_{t0} + b_t z) \quad (13.8)$$

The velocity at any level z is given by

$$v(z) = \sqrt{2 \frac{P_1(z) - P_2(z)}{\rho}} \quad (13.9)$$

The locations of the two possible neutral planes are given by an equilibrium in pressure which leads to a zero velocity point. By assuming the left terms in the equation above to be zero, one may have:

$$g(b_1 - b_2)z^2/2 + [g(\rho_{01} - \rho_{02}) - b_t]z + (-P_{01} + P_{02} - P_{t0}) = 0 \quad (13.10)$$

This equation above can have two, one, or zero real solutions. The zero solution represents a one-way flow through the opening and may be expressed in the following equation:

$$\dot{m} = C_d \theta \int_{z=0}^{z=H} \rho \nu(z) W dz \quad (13.11)$$

The one real solution represents two-way (bi-directional) flow, which may be written in the following equations.

$$\dot{m}_{0,z1} = C_d \theta \int_{z=0}^{z=z1} \rho \nu(z) W dz \quad (13.12)$$

$$\dot{m}_{z1,H} = C_d \theta \int_{z=z1}^{z=H} \rho \nu(z) W dz \quad (13.13)$$

The two real solutions represent three-way flow, which may be written in the following equations.

$$\dot{m}_{z2,H} = C_d \theta \int_{z=z2}^{z=H} \rho \nu(z) W dz \quad (13.14)$$

$$\dot{m}_{z1,z2} = C_d \theta \int_{z=z1}^{z=z2} \rho \nu(z) W dz \quad (13.15)$$

$$\dot{m}_{z2,H} = C_d \theta \int_{z=z2}^{z=H} \rho \nu(z) W dz \quad (13.16)$$

where:

C_d = Discharge coefficient [dimensionless]

θ = Area reduction factor [dimensionless]

W = Opening width [m]

The discharge coefficient, opening width, opening height, and start height factor are modulated based on opening factors. A detailed description of opening factor calculations may be found in the Input Output Reference (Ref. `AirflowNetwork:Multizone:Zone`, `AirflowNetwork:Multizone:Surface`, and `AirflowNetwork:Multizone:Component:DetailedOpening`).

The above calculation procedure is used for a normal rectangular window. For a horizontally pivoted rectangular window, the calculation procedure is slightly different. A schematic drawing of a horizontally-pivoted window is shown in Figure 13.2.

Figure 13.2: Schematic drawing of a horizontally-pivoted window

The opening angle α (0-90°) is linearly proportional to the window opening factor (0-1.0). An

opening factor of 1.0 is equal to an opening angle of 90°. The heights in the pivoted area are expressed as:

$$h2 = AxisHeight(1 - \cos(\alpha)) \quad (13.17)$$

$$h4 = AxisHeight + (WindowHeight - AxisHeight) \cos(\alpha) \quad (13.18)$$

When $z < h2$ or $z > h4$, where z is the distance from the bottom of the window, the integration procedure is the same as the procedure for a normal rectangular window. When $h2 < z < h4$, the window width W in the above equations is modified as:

$$W_{pivot} = \sqrt{\frac{1}{\frac{1}{W^2} + \frac{1}{(2(AxisHeight - z) \tan(\alpha))^2}}} \quad (13.19)$$

The mass flow rate in the pivoted area becomes:

$$\dot{m}_{pivot} = C_d \theta \int_{z=h2}^{z=h4} \rho \nu(z) W_{pivot} dz \quad (13.20)$$

It should be pointed out that the discharge coefficient is modulated based on opening factors, while opening width, opening height, and start height factor do not apply for a horizontally-pivoted window. The actual window width and height are used to calculate airflows for a horizontally-pivoted window.

The schematic drawing of air flow patterns through a simple vertical opening (AirflowNetwork:Multizone:Component:SimpleOpening) is shown in Figure 13.3. The equations used below are available from Walton (1989).

The air density for each node is assumed to be constant. The hydrostatic equation is used to relate pressures at various heights for each node:

$$P_n(y) = P_{0n} - \rho_n g y \quad (13.21)$$

$$P_m(y) = P_{0m} - \rho_m g y \quad (13.22)$$

where:

P_{0n}, P_{0m} = Pressure at nodes (zones) n and m at $y = 0$, the reference elevation of the opening [Pa]

ρ_n, ρ_m = Air densities of zones n and m [kg/m³]

P_n, P_m = Reference pressures of zones n and m [Pa]

It is assumed that the velocity of the airflow as a function of height is given by the orifice equation (Brown and Solvason 1962):

$$v(y) = C_d \sqrt{2 \frac{P_n(y) - P_m(y)}{\rho}} \quad (13.23)$$

Figure 13.3: Schematic of large opening and associated three flow patterns

where:

C_d = Discharge coefficient [dimensionless]

ρ = Density of the air going through the opening [kg/m³]

The neutral height, Y , where the velocity of the air is zero, may be calculated in the following equation:

$$Y = \frac{P_{on} - P_{0m}}{g(\rho_n - \rho_m)} \quad \text{or} \quad \frac{P_{om} - P_{0n}}{g(\rho_m - \rho_n)} \quad (13.24)$$

When the neutral plane is within the opening (first pattern in Figure 13.3), two-way (bi-directional) flows occur. The total flow through a large opening is the sum of both flows.

$$\dot{m}_{0,Y} = C_d \theta \int_{y=0}^{y=Y} \rho \nu(y) W dy \quad (13.25)$$

$$\dot{m}_{Y,H} = C_d \theta \int_{y=Y}^{y=H} \rho \nu(y) W dy \quad (13.26)$$

When the neutral plane is below or above the large opening (second and third pattern in Figure 13.3), one-way flow occurs.

$$\dot{m} = C_d \theta \int_{y=0}^{y=H} \rho \nu(y) W dy \quad (13.27)$$

The opening width is modulated based on opening factors. A detailed description of opening factor calculations may be found in the Input Output Reference (Ref. `AirflowNetwork:Multizone:Zone`, `AirflowNetwork:Multizone:Surface`, and `AirflowNetwork:Multizone:Component:DetailedOpening`).

The above two objects are used to simulate airflows across large vertical openings. The simple opening component (`AirflowNetwork:Multizone:Component:SimpleOpening`) assumes the pressure difference across the opening is a function of height varied from opening bottom to top, so that two-way flow may be obtained if appropriate (Walton 1989). The Detailed Opening component (`AirflowNetwork:Multizone:Component:DetailedOpening`) assumes both the pressure difference across the opening and air density are a function of height, so that three-way flow may be obtained (COMIS 1990). If these opening models would be used for horizontal openings, the pressure difference across the opening and air density remain constant, so that only one-way flow is possible using the detailed and simple opening components which are meant for vertical or near-vertical openings. In reality, there are two-way flows (air recirculation) across a large horizontal opening caused by buoyancy due to temperature and pressure difference and forced flow driven by air pressure difference only. Therefore, a horizontal opening component (`AirflowNetwork:Multizone:Component:HorizontalOpening`) is available to simulate airflows across large horizontal openings with the possibility of two-way flow by combining forced and buoyancy airflows together.

The model for horizontal openings consists of forced airflow, buoyancy airflow, purge pressure and sloping plane. The model is mainly from a NIST report presented by Cooper (1989). The

sloping plane (Bolmqvist and Sandberg 2004) portion of the model was added to allow for staircase simulations.

For simplicity, a two zone building (upper and lower zones) connected by a large horizontal opening is used to describe the model, as shown in Figure 13.4. Forced and buoyancy airflows are described separately below.

Figure 13.4: Air movements across a horizontal opening

13.1.3.3.1 Forced airflows

The air mass flow rate is determined by the pressure difference across the opening. The relationship between pressure and airflow is the same as AIRNET for a component (see AirflowNet-

work:Multizone:Component:SimpleOpening description above). Since the height of the opening is constant, the forced airflow is unidirectional. A positive value for pressure difference indicates flow direction is from the lower zone to the upper zone across the opening, while a negative value represents flow in the opposite direction. The following description addresses forced air mass flow rates and partial derivatives for three possible scenarios of pressure difference:

Scenario 1

$$P_L = P_U \quad (13.28)$$

$$\dot{m}_U = \dot{m}_L = 0 \quad (13.29)$$

where:

P_L = Air pressure in the lower zone [Pa]

P_U = Air pressure in the upper zone [Pa]

\dot{m}_U = Air mass flow rate from the lower zone to the upper zone driven by forced airflow pressure difference [kg/s]

\dot{m}_L = Air mass flow rate from the upper zone to the lower zone driven by forced airflow pressure difference [kg/s]

Scenario 2

$$P_L > P_U \quad (13.30)$$

$$\dot{m}_U = 0 \quad (13.31)$$

$$\dot{m}_L = \rho_L A C_d \left(\frac{2\Delta P}{\rho_{ave}} \right)^{0.5} \quad (13.32)$$

$$\frac{\partial \dot{m}_L}{\partial P_L} = \rho_L A C_d \left(\frac{1}{2\Delta P \rho_{ave}} \right)^{0.5} \quad (13.33)$$

where:

ρ_L = Air density in the lower zone [kg/m³]

A = Opening area [m²]

C_d = Discharge coefficient [Dimensionless]

ρ_{ave} = Average air density between the lower and upper zones [Pa]

ΔP = Pressure difference $P_L - P_U$ [Pa]

Scenario 3

$$P_L < P_U \quad (13.34)$$

$$\dot{m}_L = 0 \quad (13.35)$$

$$\dot{m}_U = -\rho_U A C_d \left(\frac{2|\Delta P|}{\rho_{ave}} \right)^{0.5} \quad (13.36)$$

$$\frac{\partial \dot{m}_U}{\partial P_L} = \rho_U A C_d \left(\frac{1}{2|\Delta P| \rho_{ave}} \right)^{0.5} \quad (13.37)$$

where:

- ρ_U = Air density in the upper zone [kg/m³]
- A = Opening area [m²]
- C_d = Discharge coefficient [Dimensionless]
- ρ_{ave} = Average air density between the lower and upper zones [Pa]
- ΔP = Pressure difference $P_L - P_U$ [Pa]

13.1.3.3.2 Buoyancy airflows

Buoyancy flow only occurs when the air density in the upper zone is greater than the air density in the lower zone. The flow is bi-directional and the amount of upper flow is equal to the lower flow across the opening. The following discussion assumes the air density in the upper zone is greater than the air density in the lower zone. Otherwise, the buoyancy flow rate is equal to zero. It is also assumed that the maximum buoyancy flow occurs when the pressure difference across the opening due to forced airflows is zero. The maximum buoyancy flow may be expressed as a part of Cooper's model:

$$\dot{m}_{buo,max} = \rho_{ave} \cdot 0.055 \left(\frac{g |\Delta \rho| D_H^5}{\rho_{ave}} \right)^{0.5} \quad (13.38)$$

where:

- $\dot{m}_{buo,max}$ = Buoyancy mass flow rate at zero forced airflow pressure difference [kg/s]
- g = Gravity acceleration [m/s²]
- D_H = Hydraulic diameter [m]
- ρ_{ave} = Average air density between the lower and upper zones [kg/m³]
- $\Delta \rho$ = Density difference between the lower and upper zones [kg/m³]

13.1.3.3.3 Combined airflows

When forced and buoyancy flows co-exist, it is possible to have either unidirectional or bi-directional flows. For example, when the upward force due to pressure difference is greater than the buoyancy force (downward), unidirectional flow occurs. Bi-directional flow only occurs when the upward imposed force is less than the buoyancy force. The critical pressure between unidirectional and bi-directional flows is called the purge pressure (Tan and Jaluria 1992). The purge pressure is

a function of opening geometry and the buoyancy force ($\Delta P/(g\Delta D_H)$) and may be expressed as (Cooper 1998):

$$\Delta P_{Flood} = \left| C_{Shape}^2 \frac{g\Delta\rho D_H^5}{2A^2} \right| \quad (13.39)$$

where:

$$\begin{aligned} \Delta P_{Flood} &= \text{Purging pressure [Pa]} \\ g &= \text{Gravity acceleration [m/s}^2\text{]} \\ D_H &= \text{Hydraulic diameter [m]} \\ A &= \text{Opening area [m}^2\text{]} \\ \Delta\rho &= \text{Density difference between the lower and upper zones [kg/m}^3\text{]} \\ C_{Shape} &= \text{Shape factor [dimensionless]} \end{aligned}$$

$$C_{Shape} = \left\{ \begin{array}{ll} 0.754 & \text{for a circle opening} \\ 0.942(w/D) & \text{for a rectangle opening} \end{array} \right\} \quad (13.40)$$

where:

$$\begin{aligned} w &= \text{Opening width [m]} \\ D &= \text{Opening depth [m]} \end{aligned}$$

As mentioned above, when the air pressure difference between two zones is zero there is the maximum bi-directional flow due to the buoyancy force. When the pressure difference increases from 0 and is less than $|\Delta P_{Flood}|$, there is some bi-directional flow across the opening, but less than the maximum flow. If the pressure difference keeps increasing and exceeds $|\Delta P_{Flood}|$, there is no bi-directional flow. Cooper's model assumes the buoyancy flow varies linearly with pressure difference.

$$\dot{m}_{buo} = \left\{ \begin{array}{ll} \dot{m}_{buo,max} \cdot \left(1 - \frac{|\Delta P|}{|\Delta P_{Flood}|} \right) & \text{If } \Delta\rho > 0 \text{ and } \frac{|\Delta P|}{|\Delta P_{Flood}|} < 1 \\ 0 & \text{Otherwise} \end{array} \right\} \quad (13.41)$$

The total air flow across the opening is based on superposition of the forced and buoyancy flows, and may be expressed for three different pressure difference scenarios as follows:

a. $P_L = P_U$

$$\dot{m}_U = \dot{m}_{buo} \quad (13.42)$$

$$\dot{m}_L = \dot{m}_{buo} \quad (13.43)$$

$$\frac{\partial \dot{m}_L}{\partial P_L} = 0 \quad (13.44)$$

b. $P_L > P_U$

$$\dot{m}_U = \dot{m}_{buo} \quad (13.45)$$

$$\dot{m}_L = \rho_L A C_d \left(\frac{2\Delta P}{\rho_{ave}} \right)^{0.5} + \dot{m}_{buo} \quad (13.46)$$

$$\frac{\partial \dot{m}_L}{\partial P_L} = \rho_L A C_d \left(\frac{1}{2\Delta P \rho_{ave}} \right)^{0.5} - \frac{\dot{m}_{buo, max}}{|\Delta P_{Flood}|} \quad (13.47)$$

where:

- ρ_L = Air density in the lower zone [kg/m³]
- A = Opening area [m²]
- C_d = Discharge coefficient [dimensionless]
- ρ_{ave} = Average air density between the lower and upper zones [Pa]
- ΔP = Pressure difference $P_L - P_U$ [Pa]

c. $P_L < P_U$

$$\dot{m}_L = \dot{m}_{buo} \quad (13.48)$$

$$\dot{m}_U = -\rho_U A C_d \left(\frac{2|\Delta P|}{\rho_{ave}} \right)^{0.5} + \dot{m}_{buo} \quad (13.49)$$

$$\frac{\partial \dot{m}_U}{\partial P_L} = \rho_U A C_d \left(\frac{1}{2|\Delta P| \rho_{ave}} \right)^{0.5} + \frac{\dot{m}_{buo, max}}{|\Delta P_{Flood}|} \quad (13.50)$$

13.1.3.3.4 Sloping Plane

Figure 13.5: A Staircase is attached to the horizontal opening.

When a staircase is introduced as shown in Figure 13.5, the effective opening area will be used to replace A (opening area) in the above equations. The effective area may be estimated as (Bolmqvist and Sandberg 2004):

$$A_{eff} = A \sin \alpha (1 + \cos \alpha) \quad (13.51)$$

where:

- A_{eff} = Effective area of horizontal opening [m^2]
- A = Area of horizontal opening [m^2]
- α = Angle between the stair plane and horizontal opening plane [degrees]

Note: the hydraulic diameter calculation is based on the effective opening area, while the opening depth remains the same.

Figure 13.6 demonstrates possible forced and buoyancy flow rates at different ratios of pressure difference to purging pressure across a horizontal opening when the upper zone air density is greater than the lower zone air density. The pressure difference is the lower zone pressure minus the upper zone pressure. Otherwise, the buoyancy flow is zero. In addition, when the absolute ratio is above 1, the buoyancy flow is also zero. The following table provides a brief description for the legend listed in Figure 13.6.

Table 13.1: Legend Description

Legend	Description
Forced downward	Forced flow rate from upper to lower at $P - P < 0$
Forced upward	Forced flow rate from lower to upper at $P - P > 0$
Buoyancy upward	Total upward flow rate due to buoyancy only at $P - P < 0$
Buoyancy downward	Total downward flow rate due to buoyancy only at $P - P > 0$
Combined downward	Total downward flow at $P - P < 0$ (Forced downward + buoyancy upward)
Combined upward	Total upward flow at $P - P > 0$ (Forced upward + buoyancy downward)

13.1.3.4 Wind pressure calculations

The wind pressure is determined by Bernoulli's equation, assuming no height change or pressure losses:

$$p_w = C_p \rho \frac{V_{ref}^2}{2} \quad (13.52)$$

where:

Figure 13.6: Flow rates at different pressure differences

p_w = Wind surface pressure relative to static pressure in undisturbed flow [Pa]

ρ = Air density [kg/m³]

V_{ref} = Reference wind speed at local height [m/s]

C_p = Wind surface pressure coefficient [dimensionless]

V_{ref} may be expressed as (Ref, Local Wind Speed Calculations)

$$V_{ref} = V_{met} \left(\frac{\delta_{met}}{z_{met}} \right)^{\alpha_{met}} \left(\frac{z}{\delta} \right)^{\alpha} \quad (13.53)$$

C_p is a function of location on the building envelope and wind direction. When Wind Pressure Coefficient Type = “INPUT”, the C_p values are explicitly defined in the input for Air-flowNetwork:Multizone:Wind Pressure Coefficient Values. When Wind Pressure Coefficient Type = “AVERAGE-SURFACE CALCULATION” and the building shape is rectangular, the program uses the following equations to calculate wind pressure coefficient (C_p) values for different wind directions. For a low rise building, the normalized surface pressure coefficient may be written as (Swami and Chandra 1988):

$$C_{p,n} = 0.6 \cdot \ln \left[\frac{1.248 - 0.703 \sin(\alpha/2) - 1.175 \sin^2(\alpha) + 0.131 \sin^3(2\alpha G)}{+ 0.769 \cos(\alpha/2) + 0.07 G^2 \sin^2(\alpha/2) + 0.717 \cos^2(\alpha/2)} \right] \quad (13.54)$$

where:

- $C_{p,n}$ = C_p value at a given angle between wind direction and the outward normal of the surface under consideration [dimensionless]
 α = Angle between wind direction and outward normal of wall under consideration [deg]
 G = Natural log of the ratio of the width of the wall under consideration to the width of the adjacent wall [dimensionless]
 n = Index of incident angle at 30-degree increments

For walls of a high rise building, a two-dimensional array of surface-averaged wind pressure coefficients is generated based on wind incident angle and side ratio. The wind pressure coefficients are provided in 2001 ASHRAE Fundamentals Handbook, p. 16.5, Fig. 7, “Surface Averaged Wall Pressure Coefficients for Tall Buildings”. The original work was performed by Atkins et al. (1979). The incident angle has an increment of 30 degrees. The side ratio values are 0.25, 1.0, and 4.0. For a given incident angle and building aspect ratio, the program uses linear interpolation to calculate the corresponding wind pressure coefficient $C_{p,n}$.

For the roof of a high rise building, a two-dimensional array of surface-averaged wind pressure coefficients is also generated based on wind incident angle and side ratio. The wind pressure coefficients are provided in 2001 ASHRAE Fundamentals Handbook, p. 16.6, Fig. 9, “Surface Averaged Roof Pressure Coefficients for Tall Buildings”. The original work was performed by Holmes (1986). The incident angle has an increment of 30 degrees. The side ratio values are 0.25, 1.0, and 4.0. At a given wind incident angle and building aspect ratio, the program uses linear interpolation to calculate the corresponding wind pressure coefficient $C_{p,n}$.

The wind surface pressure at the given incident angle can be calculated by combining the above two equations:

$$p_{w,n} = C_{p,n} \rho \frac{V_{ref}^2}{2} \quad (13.55)$$

13.1.3.5 Solution method

Based on the relationship between airflow rate and pressure drop for each component, a system of equations for all components can be assembled together in an $n \times n$ square matrix, where n is the number of nodes. Newton’s method is used to iteratively solve for the air pressure at each node. A new estimated vector for all node pressures, $\{P\}^*$, is computed from the current estimated vector of node pressures, $\{P\}$, by:

$$\{P\}^* = \{P\} - \{C\} \quad (13.56)$$

where the correction vector, $\{C\}$, is computed by the matrix relationship:

$$[J] \{C\} = \{B\} \quad (13.57)$$

$\{B\}$ is a column vector with each component given by:

$$B_n = \sum_i \dot{m}_i \quad (13.58)$$

where n is the node number and i indicates all flow paths connecting node n to other nodes, and $[J]$ is the square Jacobian matrix whose elements are given by:

$$J_{n,m} = \sum_i \frac{\partial \dot{m}}{\partial P_m} \quad (13.59)$$

13.1.3.6 Convergence acceleration

The convergence tolerance is used to check the sum of the mass flow rates by applying mass conservation. The convergence acceleration equation shown below is used to correct the node pressures to more rapidly obtain a solution. By assuming a constant ratio of correction values from one iteration to the next, the following method is applied:

$$P_n^* = P_n - C_n/(1 - r) \quad (13.60)$$

where:

- r = the ratio of C_n for the current iteration to its value for the previous iteration [dimensionless]
- C_n = Correction value at the n-th node [Pa]
- P_n = Estimated pressure at the n-th node [Pa]
- P_n^* = Corrected pressure at the n-th node used in the next iteration [Pa]

This method is similar to a Steffensen iteration (Conte and de Boor 1972) which is used as a fixed-point iteration method for individual nonlinear equations.

The iteration correction method presented in the above equation gives a variable factor. When the solution is close to convergence, the solution method converges quadratically. By limiting cases where the value of r is less than some value, such as -0.5, the solution will not interfere with the rapid convergence. It has not been proven that the convergence acceleration equation will always lead to convergence, but it can be shown that it will not prevent convergence. Newton's method converges when the estimated solution values are within some distance, called the radius of convergence, or the correct solution. Applying the convergence acceleration equation when $-1 < r < 0$, will cause a smaller correction than Newton's method, which therefore, can not force the iterations outside the radius of convergence. When $r < -1$, the solution diverges in an oscillatory fashion. When $r > 1$, the solution also diverges, but in a nonoscillatory manner. For $0 < r < 1$, the solution is approached from one direction. In all three cases, the convergence acceleration equation applies as long as r is truly constant over several iterations. However, for the last case, this involves a true extrapolation of correction factor which is very sensitive to the accuracy of r . This is most extreme for the case of $r = 1$, which would cause an infinite correction.

13.1.4 Node Temperature Calculations

13.1.4.1 General

A brief description of the air node temperature calculation is given below. A detailed description can be found in the work of Swami et al. (1992). The following equation is used to calculate temperature distribution across a duct element at the given airflow rate and inlet air temperature:

$$\dot{m}C_p \frac{dT}{dx} = UP(T_\infty - T) \quad (13.61)$$

where:

- C_p = Specific heat of airflow [J/kg-K]
- \dot{m} = Airflow rate [kg/s]
- P = Perimeter of a duct element [m]
- T = Temperature as a field variable [°C]
- T_∞ = Temperature of air surrounding the duct element [°C]
- U = Overall heat transfer coefficient [W/m²-K]

$$U = \frac{1}{\frac{1}{h_i} + \frac{1}{h_o} + \sum \frac{t_j}{k_j}} \quad (13.62)$$

- h_i = Inside heat transfer coefficient [W/m²-K]
- h_o = Outside heat transfer coefficient [W/m²-K]
- t_j = Thickness at j-th layer [m]
- k_j = Thermal conductivity at j-th layer [W/m-K]

The outlet air temperature at the end of the duct ($x = L$) is:

$$T_o = T_\infty + (T_i - T_\infty) \cdot \exp\left(-\frac{UA}{\dot{m}C_p}\right) \quad (13.63)$$

where:

- T_i = Inlet air temperature [°C]
- T_o = Outlet air temperature [°C]
- T_∞ = Temperature of air surrounding the duct element [°C]
- A = Surface area (Perimeter * Length) [m²]

The heat transfer by convection to ambient, Q , is:

$$Q = \dot{m}C_p(T_\infty - T_i) \left[1 - \exp\left(-\frac{UA}{\dot{m}C_p}\right)\right] \quad (13.64)$$

The outlet air temperature can be calculated using the above equation at the given inlet air temperature. Since the inlet temperature at one linkage is the outlet temperature for the connected linkage, the outlet air temperatures at all nodes are solved simultaneously. A square linear system assembled by the AirflowNetwork model is expressed below:

$$\{M\}[T] = [B] \quad (13.65)$$

where:

- $\{M\}$ = Airflow matrix
- $[T]$ = Temperature vector
- $[B]$ = Given boundary conditions

The zone air temperatures and primary air loop component (fan and coils) outlet conditions are used as prescribed conditions in the AirflowNetwork model. In addition, the temperature difference across zone loop components (terminal units) is held constant during the calculations. For example, thermal zone temperatures calculated during the previous system time step are used as prescribed temperatures when calculating all other node temperatures. The zone air temperature is assumed constant (prescribed) throughout the AirflowNetwork iterative solution. The fan and coil outlet air temperatures, and terminal unit temperature differences are assumed constant within an AirflowNetwork iteration. The sensible heat gains calculated during the AirflowNetwork solution are then used to predict a new zone air temperature.

13.1.4.2 Duct Radiation

The duct-surface user-defined view factors object defines the view factor from the duct to the zone surfaces. Because the view factors, duct surface area, and temperatures are known, the heat gain to the duct can be directly calculated and applied to the duct air heat balance to determine the outlet temperature. The duct heat gain is then treated as a direct heat loss from each participating surface. Once the heat loss to the duct for each surface is calculated, the surface temperatures are adjusted to maintain the surface energy balance.

Radiation is treated as point loads heat source/sink on the zone surfaces and the duct. These point loads will be added or subtracted using the same implementation strategy as the convective load for the ducts to the zone air. The radiative rate of energy transfer between the duct (d) and a given surface (s) for two grey surfaces can be written as shown below.

$$\dot{Q}_{d \rightarrow s} = \frac{\sigma(T_d^4 - T_s^4)}{\frac{1-\epsilon_d}{f_e A_d \epsilon_d} + \frac{1}{f_e A_d F_{d \rightarrow s}} + \frac{1-\epsilon_s}{A_s \epsilon_s}} \quad (13.66)$$

where:

- σ = Steffan-Boltzmann constant [W/m²-K⁴]
- T_d = Duct surface temperature [C]
- T_s = Zone surface temperature [C]
- ϵ_d = Duct grey body emissivity [-]
- ϵ_s = Zone surface grey body emissivity [-]
- A_d = Duct surface area [m²]
- A_s = Zone surface area [m²]
- f_e = Duct exposure fraction [-]
- $F_{d \rightarrow s}$ = Duct-to-surface view factor

13.1.5 Node Humidity Ratio Calculations

A brief description of the air node humidity ratio calculation is given below. A detailed description can found in the work of Swami et al. (1992). The following equation is used to calculate humidity ratio distribution across a duct element at the given airflow rate and inlet air humidity ratio:

$$\dot{m} \frac{dW}{dx} = U_m P (W_\infty - W) \quad (13.67)$$

where:

- \dot{m} = Airflow rate [kg/s]
- P = Perimeter of a duct element [m]
- W = Humidity ratio [kg/kg]
- W_∞ = Humidity ratio of air surrounding the duct element [kg/kg]
- U_m = Overall moisture transfer coefficient [kg/m²-s]

$$U_m = \frac{1}{\frac{1}{h_{m,i}} + \frac{1}{h_{m,o}} + \sum \frac{t_j}{D_j}} \quad (13.68)$$

- $h_{m,i}$ = Inside moisture transfer coefficient [kg/m²-s]
- $h_{m,o}$ = Outside moisture transfer coefficient [kg/m²-s]
- t_j = Thickness at j-th layer [m]
- D_j = Moisture diffusivity at j-th layer [kg/m-s]

The outlet air humidity ratio at the end of the duct ($x = L$) is:

$$W_o = W_\infty + (W_i - W_\infty) \cdot \exp\left(-\frac{U_m A}{\dot{m}}\right) \quad (13.69)$$

where:

- W_i = Inlet air humidity ratio [kg/kg]
- W_o = Outlet air humidity ratio [kg/kg]
- A = Surface area (Perimeter * Length) [m²]

The moisture transfer by convection to ambient, Q_m , is

$$Q_m = \dot{m} \cdot (W_\infty - W_i) \left[1 - \exp\left(-\frac{U_m A}{\dot{m}}\right) \right] \quad (13.70)$$

The outlet air humidity ratio can be calculated using the above equation at the given inlet air humidity ratio. Since the inlet humidity ratio at one linkage is the outlet humidity ratio for the connected linkage, the outlet air humidity ratio at all nodes are solved simultaneously. A square linear system assembled by the AirflowNetwork model is expressed below:

$$\{M_m\}[W] = [B_m] \quad (13.71)$$

where:

$$\begin{aligned} \{M_m\} &= \text{Airflow matrix} \\ [W] &= \text{Humidity ratio vector} \\ [B_m] &= \text{Given boundary conditions} \end{aligned}$$

The zone air humidity ratios and primary air loop component (fan and coils) outlet conditions are used as prescribed conditions in the AirflowNetwork model. For example, thermal zone humidity ratios calculated during the previous system time step are used as prescribed humidity ratios when calculating all other node humidity ratios. The zone air humidity ratio is assumed constant (prescribed) throughout the AirflowNetwork iterative solution. The coil outlet air humidity ratio is assumed constant within an AirflowNetwork iteration. The latent heat gains calculated during the AirflowNetwork solution are then used to predict a new zone air humidity ratio.

13.1.6 Sensible and Latent Load Calculations

The zone sensible and latent loads calculated in the AirflowNetwork model consist of multizone, duct conduction and leakage. In addition, the impact of infiltration and mixing is accounted for in this calculation. The multizone load only includes incoming airflows from outside (infiltration) and other adjacent zones (mixing) with and without forced-air fan operation. It is divided into two terms: variable and constant. The constant term is the sum of the mass flow rate multiplied by the specific heat for both infiltration and mixing. The variable term includes the impact of zone and outdoor air temperature. Each of these terms is used in the zone energy balance equation. The sensible load items from the multizone load calculations may be written as follows:

$$MCP_{airflow} = \dot{m}_{inf}C_p + \sum (\dot{m}_{mix}C_p) \quad (13.72)$$

$$MCPT_{airflow} = \dot{m}_{inf}C_pT_{amb} + \sum (\dot{m}_{mix}C_pT_{zone}) \quad (13.73)$$

where:

$$\begin{aligned} MCP_{airflow} &= \text{Sum of air mass flow rate multiplied by specific heat for infiltration and mixing [W/K]} \\ MCPT_{airflow} &= \text{Sum of air mass flow rate multiplied by specific heat and temperature for infiltration and mixing [W]} \\ \dot{m}_{inf} &= \text{Incoming air mass flow rate from outdoors [kg/s]} \\ \dot{m}_{mix} &= \text{Incoming air mass flow rate from adjacent zones [kg/s]} \\ T_{amb} &= \text{Outdoor air dry-bulb temperature [°C]} \\ T_{zone} &= \text{Adjacent zone air temperature [°C]} \end{aligned}$$

The latent load items from multizone load calculations may be written as follows:

$$M_{airflow} = \dot{m}_{inf} + \sum \dot{m}_{mix} \quad (13.74)$$

$$MW_{airflow} = \dot{m}_{inf} W_{amb} + \sum \dot{m}_{mix} W_{zone} \quad (13.75)$$

where:

$M_{airflow}$	= Sum of air mass flow rates for infiltration and mixing [kg/s]
$MW_{airflow}$	= Sum of air mass flow rate multiplied by humidity ratio for infiltration and mixing [kg/s]
\dot{m}_{inf}	= Incoming air mass flow rate from outdoors [kg/s]
\dot{m}_{mix}	= Incoming air mass flow rate from adjacent zones [kg/s]
W_{amb}	= Outdoor air humidity ratio [kg/kg]
W_{zone}	= Adjacent zone air humidity ratio [kg/kg]

The air distribution system (ADS) loads due to duct conduction and leakage depend on the air distribution system component (e.g., duct) location. The air distribution system sensible and latent loads are calculated for each zone as follows:

$$Q_{ADS,i} = \sum_j Q_{cond(i,j)} + \sum_j Q_{leak(i,j)} \quad (13.76)$$

$$Q_{ADS,m,i} = \sum_j Q_{cond,m(i,j)} + \sum_j Q_{leak,m(i,j)} \quad (13.77)$$

where:

$Q_{ADS,i}$	= Total sensible load in the i-th zone due to ADS losses [W]
$Q_{cond(ij)}$	= Duct wall conduction loss at the j-th duct located in the i-th zone [W]
$Q_{leak(ij)}$	= Sensible supply leak loss at the j-th linkage located in the i-th zone [W]
$Q_{ADS,m,i}$	= Total latent load in the i-th zone due to ADS losses [kg/s]
$Q_{cond,m(ij)}$	= Duct wall vapor diffusion loss at the j-th duct located in the i-th zone [kg/s]
$Q_{leak,m(ij)}$	= Latent supply leak loss at the j-th linkage located in the i-th zone [kg/s]

13.1.7 Impacts of Supply Air Constant Volume Fan Control on Load: Cycling vs. Continuous

The AirflowNetwork model currently allows two types of constant volume fans: Fan:ConstantVolume and Fan:OnOff. The Fan:ConstantVolume object has only one type of supply air fan operation

mode: continuous fan, cycling compressor (ContinuousFanWithCyclingCompressor). However, the Fan:OnOff has two types of supply air fan operation modes: cycling fan, cycling compressor (CyclingFanAndCompressor) or continuous fan, cycling compressor (ContinuousFanWithCyclingCompressor). The CyclingFanAndCompressor operation mode is frequently referred to as “AUTO fan”, where the compressor(s) and supply air fan operate in unison to meet the zone heating or cooling load, and cycle off together when the heating or cooling load has been met. The ContinuousFanWithCyclingCompressor operation mode is often referred to as “fan ON”, where the compressor(s) cycle on and off to meet the zone heating or cooling load but the supply air fan operates continuously regardless of compressor operation. The supply air fan operation mode is specified in an HVAC system object based on a given fan operation mode schedule (e.g., AirLoopHVAC:UnitaryHeatCool object).

The determination of the zone sensible and latent loads caused by multizone airflows and forced air distribution system operation is dependent on the supply air fan operation mode (see Sensible and Latent Load Calculations section above). The zone loads calculated by the AirflowNetwork model are added to zone sensible and latent balances in the ZonePredictorCorrector module to calculate zone air temperatures and humidity ratios (see Integration of the AirflowNetwork Model section below). For the case of continuous fan/cycling compressor, the zone loads during forced air distribution system operation are calculated with the system design air mass flow rate without modification, since the system air node conditions (temperature and humidity) reflect the average values for the time step considering the coil/fan on and off periods during the time step.

For the case of cycling fan/cycling compressor, where the forced air distribution system can operate for a portion of the simulation time step, the airflows are determined based on the air distribution system part-load ratio (ratio of the average air mass flow rate for the time step divided by the design air mass flow rate). The **airflows** for the AirflowNetwork:Distribution:Linkage objects are reported during the air distribution system on cycle, since no airflow is assumed during the system off cycle. The **airflows** for the AirflowNetwork:Multizone:Surface objects are weighted by the air distribution system part-load ratio. The **zone loads** are the sum of energy losses during both the air distribution system on and off cycle at each system time step. The energy losses when the air distribution system is on are calculated using the system “on” air flow rate multiplied by the air distribution system run time fraction. The energy losses when the air distribution system is off are obtained from the multizone airflow calculations (without forced air through the air distribution system) and these losses are multiplied by (1.0 - system run time fraction), assuming no airflows through the air distribution system when the fan is off. The formulas used to calculate airflows and zone loads are given below:

Airflow

$$\text{Airflow} = \text{Airflow during ADS on cycle} * \text{ADS Part-load ratio} + \text{Airflow during ADS off cycle} * (1.0 - \text{ADS Part-load ratio})$$

where:

ADS = Air Distribution System

Zone load

System run time fraction = Maximum run time fraction of coils and fans in the air distribution system

Zone energy losses = Zone energy loss during ADS on cycle * System run time fraction + Zone energy loss during ADS off cycle * (1.0 - System run time fraction)

The calculation of loads due to multizone airflow, without forced air distribution system operation, is performed when the HVAC system is first simulated during a simulation time step (FirstHVACIteration = True). The calculation of loads due to air distribution system operation is performed on subsequent iterations within the same simulation time step when the mass flow rate at the supply air fan inlet is greater than 0.0 (and FirstHVACIteration = False).

13.1.8 Airflow Calculation Procedure using A Supply Variable Air Volume Fan

The AirflowNetwork model currently also allows a variable air volume fan type as Fan:VariableVolume. The allowed terminal type is AirTerminal:SingleDuct:VAV:Reheat only. Other types of terminals will be added later.

In general, the supply fan air flow rate in a VAV central system is determined by a sum of terminal flow rates when the AirflowNetwork model is not applied. When the AirflowNetwork model is applied and the supply air fan flow rate is given, each terminal flow is determined by pressure resistance of each supply air pathway. It is possible that the delivered air flow rate from the pressure resistance at each terminal may be totally different from the desired flow rate determined by terminal units. Therefore, it is not easy to meet both requirements. The following compromised approach, including possible supply and return leaks in an air distribution system, is implemented.

1. Set up terminal airflows in the AirflowNetwork module based on the SimVAV subroutine in the HVACSingleDuctSystem module.
2. Require AirflowNetwork:Distribution:Component:LeakageRatio objects to define supply leaks, so that the values of the Effective Leakage Ratio field are used to decide the supply fan flow rates. The base of the ratio will be actual supply fan flow rate, instead of the maximum fan flow rate used in the constant volume fan systems.
3. Assign the supply fan airflow rate based on the sum of all terminal flow rates and all supply leak ratios until it reaches the maximum fan flow rate

$$\dot{m}_{fan} = \frac{\sum_i^n \dot{m}_{i,terminal}}{1 - \sum_j^k F_j} \quad (13.78)$$

where:

\dot{m}_{fan}	= The supply fan flow rate
$\dot{m}_{i,terminal}$	= The flow rate at the i th terminal, which is determined in the subroutine SimVAV in the HVACSingleDuctSystem module
n	= Number of terminals
F_j	= The fraction of the supply fan flow rate at the j -th supply leak, given in the AirflowNetwork:Distribution:Component:LeakageRatio objects.
k	= Number of supply leaks

4. If the calculated supply fan flow rate is above the maximum limit of the supply fan flow rate, and the supply leak ratios remain the same, the supply fan flow rate is set to the maximum limit, and the terminal flow rates are reduced proportionally weighted by a ratio of the maximum supply fan flow rate by input to the calculated supply fan flow rate. Therefore, a sum of all terminal rates and all supply leak rates is equal to the maximum supply fan rate.

$$R = \frac{\dot{m}_{fan,max}}{\dot{m}_{fan,cal}} \quad (13.79)$$

$$\dot{m}_{i,terminal,final} = \dot{m}_{i,terminal} \cdot R \quad (13.80)$$

where:

R	= The ratio of the maximum fan flow rate given in the inputs to the requested fan flow rate based on the above equation
$\dot{m}_{fan,max}$	= The maximum supply fan flow rate by input
$\dot{m}_{fan,cal}$	= The calculated supply fan flow rate
$\dot{m}_{i,terminal,final}$	= The final flow rate at each terminal adjusted by the ratio

13.1.9 Airflow Calculation Procedure using inputs of Intrazone nodes and linkages

The inputs of both AirflowNetwork:IntraZone:Node and AirflowNetwork:IntraZone:Linkage objects are treated as normal model nodes and linkages. Therefore, the calculation procedures are the same as above.

13.1.10 Integration of the AirflowNetwork Model

The loads calculated by the AirflowNetwork model are integrated into the EnergyPlus heat balance equation in a similar manner as described elsewhere in this document in the section “Basis for the Zone and System Integration”. The mass flow rate summations and sensible and latent loads described in the previous section are included in the calculation of zone temperature and humidity ratio.

The revised zone temperature update equation becomes:

$$T_z^t = \frac{\sum_{i=1}^{N_{sl}} \dot{Q}_i + \sum_{i=1}^{N_{surfaces}} h_i A_i T_{si} + MCPT_{airflow} + \dot{m}_{sys} C_p T_{supply} + Q_{ADS_z} - \left(\frac{C_z}{\delta t}\right) \left(-3T_z^{t-\delta t} + \frac{3}{2}T_z^{t-2\delta t} - \frac{1}{3}T_z^{t-3\delta t}\right)}{\frac{11}{6} \frac{C_z}{\delta t} + \sum_{i=1}^{N_{surfaces}} h_i A + MCP_{airflow} + \dot{m}_{sys} C} \quad (13.81)$$

where $MCPT_{airflow}$ is the sum of mass flow rate multiplied by specific heat and temperature for infiltration and mixing, $Q_{ADS,z}$ is the added total sensible load in the zone due to Air Distribution System losses, and $MCP_{airflow}$ is the sum of mass flow rate multiplied by specific heat for infiltration and mixing as calculated in the AirflowNetwork model described above.

The revised coefficient (B) used in the zone humidity ratio calculation is shown below:

$$B = \sum k g_{mass,sched-loads} + MW_{airflow} + \dot{m}_{sys,in} W_{sys} + \sum_{i=1}^{surfs} A_i h_{mi} \rho_{air_z} W_{surfs_i} + Q_{ADS_{m,z}} \quad (13.82)$$

where $MW_{airflow}$ is the sum of mass flow rate multiplied by humidity ratio for infiltration and mixing and $Q_{ADS,m,z}$ is the added total latent (moisture) load in the zone due to Air Distribution System losses from the AirflowNetwork model described above. This coefficient is used in the prediction of moisture as described in the section “Moisture Predictor-Corrector” found elsewhere in this document.

13.1.11 Model Output

The available outputs from the AirflowNetwork model are described in the EnergyPlus Input Output Reference manual.

13.1.12 Single Sided Wind Pressure Coefficient Algorithm

The approach in the single sided (SS) model is based on correlating the flow rate into the room through one or more openings with local flow conditions at the openings. These are in one façade of a rectangular building of width WB, depth DB and height HB. There is a vertical wind profile $U(z)$ approaching the building, which generates a local flow U_L parallel to the façade (whose value depends on location, building geometry and wind direction).

Consider first the 2-aperture case, where air flows in through one opening of area A_{in} and exits through another of equal area. Let us denote the flow rate of ambient air into the room by Q , and define a dimensionless flow rate Q' by

$$Q' = Q / (A_{in} U_{ref}), \quad (13.83)$$

where U_{ref} is a reference velocity taken as the undisturbed wind speed $U(z_{ref})$ at a reference height $z_{ref} = 10\text{m}$. There is a pressure difference $\Delta p(t)$ between the two opening locations, with time-averaged mean value $\overline{\Delta p}$ and standard deviation $\sigma_{\Delta p}$.

There are three principal mechanisms determining the flow rate:

- (a) Mean pressure difference: a non-zero mean value for the difference in pressure at the two opening locations, $\overline{\Delta p}$, drives a flow that scales as $\overline{\Delta p}^{1/2}$.

- (b) Unsteady pressure difference: turbulence drives a fluctuating pressure difference between the two openings, resulting in a net addition of air from the outside. This is characterized by the standard deviation of the pressure difference signal, $\sigma_{\Delta p}$ and the associated flow rate adds to that arising from $\overline{\Delta p}$. It includes periodic Strouhal forcing ('pumping') at relevant wind angles. Note that this contribution is non-zero even when the mean pressure difference is zero.
- (c) Shear layer mechanism: when there is small or zero mean pressure difference between the two opening locations, the local flow parallel to the façade causes a mixing layer to grow over the length of the opening resulting in the incorporation of ambient air. This scales with U_L .

Our model therefore views the flow rate as comprising contributions from each of these as appropriate, i.e.

$$Q' = [a_p |\Delta c_p| + a_\sigma \sigma_{\Delta c_p}]^{1/2} + a_s U'_L \quad (13.84)$$

where a_p , a_σ and a_s are constants, the mean and fluctuating pressure difference terms have been written as pressure coefficients

$$\Delta c_p = \frac{\overline{\Delta p}}{\frac{1}{2} \rho U_{\text{ref}}^2}, \quad (13.85)$$

$$\sigma_{\Delta c_p} = \frac{\sigma_{\Delta p}}{\frac{1}{2} \rho U_{\text{ref}}^2}, \quad (13.86)$$

ρ being the ambient air density and

$$U'_L = \frac{U_L}{U_{\text{ref}}}. \quad (13.87)$$

The pressure-difference mechanisms (a) and (b) are dominant for the 2-opening case and (c) is negligible, while, in contrast, in the case of a single opening, shear is dominant. Hence we take $a_s = 0$ for 2-opening cases and $a_p = a_\sigma = 0$ for one opening. Henceforth we focus on the 2-opening case, although a procedure is given at the end of the section for how to approximate a greater number by just two.

Figure 13.7 shows the geometry of this case in plan view. The two openings are a distance s apart in a façade of width WB whose normal has azimuthal angle φ_n . The wind azimuthal direction is φ_w , so that its direction relative to the façade is

$$\theta = \varphi_w - \varphi_n. \quad (13.88)$$

In these definitions, $0^\circ \leq \varphi_n, \varphi_w \leq 360^\circ$, while $|\theta| \leq 180^\circ$. Note that if θ initially falls outside the range indicated it should be replaced by $\text{sign}(\theta) [|\theta| - 360^\circ]$.

According to the above discussion, the flow rate is modeled as comprising two terms, arising, respectively, from the mean and fluctuating components of the pressure difference between the two aperture locations:

$$Q' = (a_p |\Delta c_p| + a_\sigma \sigma_{\Delta c_p})^{1/2} \quad (13.89)$$

There are two parts to deriving the detailed form of the model:

1. Express the mean and fluctuating pressures in terms of other physical quantities that are more readily accessible. EnergyPlus does not have the information on variations in pressure that is needed to compute Δc_p and $\sigma_{\Delta c_p}$. Analysis of wind tunnel pressure data (Linden et al., 2013) allows for the derivation of simple expressions for these quantities in terms of the wind direction and opening separation s .

Figure 13.7: Plan view of building with 2-opening façade.

2. Find the coefficients a_p and a_σ . This is achieved here by analysis of ventilation rate data (Linden et al., 2013), and using linear regression on the data.

13.1.12.1 Estimation of pressure difference coefficients

The analysis of pressure data carried out showed that the contributions to the right-hand side of Equation 13.89 can be written to first order as

$$\Delta c_p = f(s', \theta) \quad (13.90)$$

and

$$\sigma_{\Delta c_p} = g(s', \theta) \quad (13.91)$$

where the dimensionless separation $s' = s/WB$,

$$f(s', \theta) = s' \cdot \Pi(\theta), \quad (13.92)$$

and

$$g(s', \theta) = \Sigma_0 + s' \cdot \Sigma(\theta). \quad (13.93)$$

That is, to a first approximation the pressure difference mean and standard deviation vary linearly with opening separation, each modulated by its own function of relative wind angle θ .

The formulae for the components are as follows.

$$\Pi(\theta) = \begin{cases} 0.44 \operatorname{sgn}(\theta) \sin(2.67|\theta|), & |\theta| \leq \theta_0 \\ -0.69 \operatorname{sgn}(\theta) \sin(288 - 1.6|\theta|), & \theta_0 \leq |\theta| \leq 180^\circ. \end{cases} \quad (13.94)$$

$$\theta_0 = 67.5^\circ \quad (13.95)$$

$$\Sigma(\theta) = 0.423 - 1.63 \times 10^{-3} |\theta| \quad (13.96)$$

Figure 13.8: Mean pressure difference, Δc_p predicted by Equations 13.94 and 13.95, compared with experimental data. The façade containing the openings is facing South and the separation is large ($s' = 0.85$).

$$\Sigma_0 = 0.24 \quad (13.97)$$

Figures 13.8 and 13.9 show an example of Δc_p and $\sigma_{\Delta c_p}$ generated by Equations 13.94 through 13.97, respectively, compared with the data.

This completes item 1 above, i.e. the approximation of the two pressure coefficient terms in Equation 13.89 in terms of the dimensionless opening separation and the relative wind angle. There remains item 2, i.e. fitting the flow rate data to the formula-generated pressure parameters to determine the constants a_p and a_σ . When this was carried out, the best fit was found to occur with $a_p = 0.173$ and $a_\sigma = 0.042$. Figure 13.10 shows the comparison between the flow rate prediction and the experimental data.

Combining with the previous results we have

$$\frac{Q}{A_{\text{in}} U_{\text{ref}}} = (0.01 + [0.173|\Pi(\theta)| + 0.042\Sigma(\theta)] s')^{1/2} \quad (13.98)$$

The flow Q is defined to be positive when opening #1 is the inlet and opening #2 is the outlet. Since Δp is defined as $p_1 - p_2$, this can occur when $\Delta c_p > 0$, which in turn corresponds to certain relative wind angles, i.e.

$$\begin{aligned} Q &< 0 \text{ otherwise} \\ Q &> 0 \text{ if } 0^\circ < \theta < \theta_0 \text{ or } -180^\circ < \theta < -\theta_0 \end{aligned} \quad (13.99)$$

Note that the sense of Q is not necessarily well-defined for all such angles, e.g. when the unsteady contribution in Equation 13.89 is significant: nevertheless, we retain this definition for all angles.

Figure 13.9: Standard deviation of pressure difference, $\sigma_{\Delta c_p}$, predicted by Equations 13.96 and 13.97, compared with experimental data. The façade containing the openings is facing South and the separation is large ($s' = 0.85$).

13.1.12.2 Inversion of flow rate to equivalent pressure difference

Finally, we invert the flow rate to obtain the equivalent pressure difference. The purpose of this procedure is to allow incorporation of the model into the network airflow part of EnergyPlus, which requires pressure coefficients to calculate the flow rate: in this way the model will become essentially transparent to the user. A nodal representation of the 2-aperture single-sided case is shown in Figure 13.11.

Here, 0 is the ambient, 1 is at the upstream outer surface, 2 is at the downstream outer surface, and R is the room.

Let the openings have areas A_1 and A_2 , not necessarily equal, and a discharge coefficient C_d , which is assumed equal, and let Q be the flow rate through the system. Then it can be shown that the pressure difference between the two openings, Δp_{12} , is related to the flow rate by

$$\frac{\Delta p_{12}}{\frac{1}{2}\rho V^2} = \frac{1}{C_d^2} \left(\frac{Q/A_{\text{eff}}}{V} \right)^2 \quad (13.100)$$

where the effective area A_{eff} is defined by

$$A_{\text{eff}} = \frac{A_1 A_2}{(A_1^2 + A_2^2)^{1/2}} \quad (13.101)$$

and V is a reference velocity. The left-hand side of Equation 13.100 is a pressure coefficient, $\Delta c_{p,12}^{E+}$, say, and our task is to express this in terms of the flow rate in Equation 13.98 but using the definition of a pressure coefficient appropriate to EnergyPlus.

Figure 13.10: Comparison of predicted flow rates with experimental data. Each graph shows experimental data (red diamonds) plotted against model prediction (gray squares). Cases in the left-hand column, (a)-(c), are for $s' = 0.75$, those in right-hand column, (d)-(f), $s' = 0.32$. The three rows are for 2-story isolated, 4-story isolated and 2-story with low density surroundings, respectively.

Figure 13.11: Pressure network for 2-opening single-sided room.

The first step is to re-write Equation 13.100 as follows:

$$\Delta c_{p,12}^{E+} = \frac{1}{C_d^2} \left(\frac{A_{in}}{A_{eff}} \right)^2 \left(\frac{U_{ref}}{V} \right)^2 Q'^2 \quad (13.102)$$

where $Q' = Q/(A_{in}U_{ref})$ is the non-dimensional flow rate of Equation 13.98, which is expressed in terms of Q , the window area A_{in} and the wind speed at 10 m height, U_{ref} .

The factor $(A_{in}/A_{eff})^2 = 2$, since $A_1 = A_2 = A_{in}$, and therefore $A_{eff} = A_{in}/\sqrt{2}$. The factor (U_{ref}/V) relating the velocity scale used in the correlation with that used in the EnergyPlus pressure coefficient may be simplified by noting the following.

EnergyPlus assumes the surface pressure due to wind, p_w , is derived from a pressure coefficient C_p using the local wind speed at *window height*, $V_{ref}(z_{win})$, i.e.

$$p_w = \rho_a [V_{ref}(z_{win})]^2 C_p / 2 \quad (13.103)$$

Hence the reference velocity $V = V_{ref}(z_{win})$.

EnergyPlus characterizes the vertical wind profile as a power law in z , defined in terms of the local atmospheric boundary layer depth δ and a power law exponent α . EnergyPlus also uses an “interpolation” formula to derive the above local wind speed from that measured at the meteorological site, U_{met} , according to

$$V_{ref}(z) = U_{met} \left(\frac{\delta_{met}}{z} \right)^{\alpha_{met}} \left(\frac{z}{\delta} \right)^{\alpha} \quad (13.104)$$

where the subscript “met” denotes conditions at the meteorological site, and the default values are $z_{met} = 10$ m, $\delta_{met} = 270$ m and $\alpha_{met} = 0.14$. The user can change the site parameters from their default values.

The correlation in Equation 13.98 assumes the reference velocity is the wind speed at 10 m, which will be taken as the local velocity at the building, $V_{ref}(10)$. Combining these results, the pressure coefficient representing the difference in pressure between the two openings is given by

$$\Delta c_{p,12}^{E+} = \frac{1}{C_d^2} \left[\frac{V_{ref}(10)}{V_{ref}(z_{win})} \right]^2 (0.02 + [0.346|\Pi(\theta)| + 0.084\Sigma(\theta)] \cdot s') \quad (13.105)$$

where the velocity ratio

$$\frac{V_{\text{ref}}(10)}{V_{\text{ref}}(z_{\text{win}})} = \left(\frac{10}{z_{\text{win}}} \right)^{\alpha} \quad (13.106)$$

Thus, if we assign a pressure coefficient $+0.5\Delta c_{p,12}^{E+}$ to opening 1 and $-0.5\Delta c_{p,12}^{E+}$ to opening 2, then this will provide the necessary pressure difference to give the flow in Equation 13.98 in a network context.

Note: the pressure coefficient $\Delta c_{p,12}^{E+}$ refers to the difference in pressure between the two openings and is defined in terms of the wind speed at window height. If this is to be combined with a background pressure coefficient for the façade it is important to ensure the two are defined using the same reference velocity.

13.1.12.3 Testing/Validation/Data Source(s)

The SS model was developed using wind tunnel pressure and flow rate data acquired by CPP Wind Engineering & Air Quality Consultants, who carried out two series of tests: (a) Closed Box tests, with a sealed building, to obtain pressure and velocity data and (b) Ventilation tests, with one or two apertures open, to obtain flow rate data. See Linden et al. (2013) for full details.

Each experimental configuration consisted of a cuboidal building with or without a set of blocks representing nearby buildings.

- Building: either 2-story, with WB = 47.5 cm, DB = 19.3 cm, HB = 9.9 cm, or 4-story, with HB = 19.8 cm. The model has a nominal scale of 1:70 (based on earlier tests).
- Environment: building either isolated or at center of a 3 x 3 array of equal-sized blocks, which were of same aspect ratio and either low (2-story height) or high (4-story height), and with either narrow spacing (approximately 0.5WB between blocks) or wide spacing (approximately WB), giving a total of 5 different environments.
- Approach flow: suburban boundary layer, approximately 10 m/s at 1 m height. The model was mounted on a turntable allowing any desired wind direction to be used. Increments of 11.25° and 22.5° were used for the Closed Box and Ventilation runs, respectively.
- Room and openings: the building envelope contained a second-floor room of dimensions WRM = 45.9 cm, DRM = 17.7 cm and HRM = 5.0 cm. A total of 15 opening positions were available, distributed around the room. These were sealed for the Closed Box tests but opened in various combinations for the Ventilation runs.
- Sensors: 56 pressure transducers, arranged around the opening positions, including 32 at mid-opening height, recorded static pressure, while hot film sensors at 6 different positions recorded flow speed near the surface. For Ventilation runs the decay in concentration of a tracer was measured at two locations inside the room.

The data used to develop the model consisted of 6 scenarios: 3 building/environment cases,

- 2-story isolated building
- 4-story isolated building
- 2-story building with low, widely-spaced blocks

Figure 13.12: Local velocity as function of wind angle for wind tunnel data analyzed. On the 2-story graph ‘WP85’ refers to Warren and Parkins (1985), whose measurement location is most closely matched by the “Center” curve.

Figure 13.13: Wind tunnel data, averaged over all cases, plotted with curve to fit data.

combined with 2 choices of opening position on the South (long) façade, namely wide separation ($s' = 0.75$) and medium separation ($s' = 0.32$).

13.1.13 Occupant Ventilation Control

The AirflowNetwork:OccupantVentilationControl object enhances the AirflowNetwork model and provides more practical and advanced controls for window opening and closing operations, based on Marais & Teichmann (2014). This control includes minimum open and closed time control, indoor thermal comfort control, and opening and closing probability controls.

13.1.13.1 Procedures of occupant ventilation control

It should be pointed that the open elapsed time and closed elapsed time are not independent. In other words, when one of the elapsed times value is greater than 0, then other elapsed time value must be equal to 0. The model is either tracking a window as open, in which case the open elapsed time grows, or as closed, in which case the closed elapsed time grows.

The calculation procedures are presented in the following steps:

Step 1: Open elapsed time check

The model checks the open elapsed time first. When the open elapsed time is greater than 0 and less than the minimum opening time, a window will remain open. Otherwise, the model goes to Step 2.

$$\text{Open elapsed time} > \text{minimum open time} \quad (13.107)$$

Step 2: Closed elapsed time check

This step checks the closed elapsed time. When the closed elapsed time is greater than 0 and less than the minimum closed time, a window will remain closed. Otherwise, the model goes to Step 3.

$$\text{Closed elapsed time} > \text{minimum closed time} \quad (13.108)$$

Step 3: Elapsed time only?

When either the open elapsed time or the closed elapsed time is long enough (greater than the minimum time) and no other checks are needed, the model returns to the other ventilation control defined in the Ventilation Control Mode field in AirflowNetwork:MultiZone:Zone or AirflowNetwork:MultiZone:Surface. If other checks are needed, the following steps will be performed.

Step 4: Thermal comfort temperature calculation

The thermal comfort check requires the thermal comfort temperature and the comfort band. The comfort temperature of T_{comf} is calculated as a function of the outdoor dry-bulb temperature T_{out} . The comfort temperature calculation may be based on two curves and a boundary temperature point.

$$T_{comf} = \begin{cases} \text{LowTempCurve}, & \min T_{out} < x \leq \text{BoundaryPoint} \\ \text{HighTempCurve}, & \text{BoundaryPoint} \leq x < \max T_{out} \end{cases} \quad (13.109)$$

Step 5: Thermal band calculation

The comfort band is calculated as a function of the design personal dissatisfaction PPD.

$$\theta = -0.0028(100 - \text{PPD})^2 + 0.3419(100 - \text{PPD}) - 6.6275 \quad (13.110)$$

This equation is valid for PPD 0% to 35%

Step 6: Upper boundary check of thermal comfort

After calculation of the comfort temperature and band, the thermal comfort check will be performed using the zone air operative temperature T_g . The check consists of upper and lower boundary checks.

The upper boundary check checks window opening status and uses the following logic:

$$T_g > (T_{comf} + \theta) \quad (13.111)$$

If the above logic check is true, the opening probability check will be performed. The detailed description is given in the opening probability section.

If the above logic check is false, no action is needed.

If the opening probability check is true and upper boundary check is satisfied, a window will be opened, regardless of open/closed status at the previous time step. If the opening probability check is false and upper boundary check is satisfied, a window will remain at the status from the previous time step.

$$T_g > (T_{comf} + \theta) \quad \& \quad \text{OpeningProbability} \quad (13.112)$$

Step 7: Lower boundary check of thermal comfort

The lower boundary check will follow the upper boundary check to check the window closing status, using the following logic.

$$T_g < (T_{comf} - \theta) \quad (13.113)$$

If the above logic check is true, the closing probability check will be performed. The detailed description is given in the closing probability section.

If the above logic check is false, no action is needed.

If the closing probability check is true and lower boundary check is satisfied, a window will be closed, regardless of open/closed status at the previous time step. If the closing probability check is false and lower boundary check is satisfied, a window will remain at the status from the previous time step.

$$T_g < (T_{comf} - \theta) \quad \& \quad \text{ClosingProbability} \quad (13.114)$$

The output variables from the model are open status, opening probability status, and closing probability status. The detailed description of opening status is given in the Airflow Network Outputs section in the Input Output Reference.

Note: The upper and lower boundary checks are not independent. In other words, when one of boundary check is satisfied, the other check will be dissatisfied.

13.1.13.2 Procedures of opening probability control

Opening probability control provides an optional random number check. The control logic of opening probability is described in the following steps.

Step 1: Closed elapsed time check

This check requires that closed elapsed time is longer than the minimum closing time.

Closed time > minimum closed time

If the time duration is not long enough, the output is false so that a window remains closed.

If the time duration is long enough, an occupancy check is performed.

Step 2: Occupancy check

If a zone is not occupied and the occupancy check is requested, the output is false. If the zone is occupied, the next step is to check the setpoints using zone air temperature at the previous time step as a reference.

Step 3: Setpoint check

There are 5 temperature control types. The following types are available:

- No control: Bypass
- Single heating setpoint: If $T_{zon} > \text{setpoint}$, go to next step. Otherwise, return false.
- Single cooling setpoint: If $T_{zon} < \text{setpoint}$, go to next step. Otherwise, return false.
- Single heating and cooling setpoint: no action by returning false
- Dual heating and setpoints: If heating setpoint < T_{zon} < Cooling setpoint, go to next step. Otherwise, return false.

Step 4: Select bypass or opening probability check

A choice is provided at this stage so that the opening probability check may be performed or bypassed. If bypassed, the output will be true to open a window. If performed, probability will be determined from a schedule.

Step 5: Perform opening probability check

The opening probability (OP) value is determined from a schedule.

OP = Schedule value or specific function

If the probability value is greater than a random number, the output is true.

OP > random number (random number is between 0 and 1)

Otherwise, the result will be false.

13.1.13.3 Procedures of closing probability control

The control logic of closing probability is described as follows.

Step 1: Open elapsed time check

This check requires that open elapsed time is longer than the minimum opening time.

Open time > minimum open time

If the time duration is not long enough, the output is false and the window remains open. Otherwise, Step 2 will be performed.

Step 2: Select by-pass or closing probability check

A choice is provided at this step so that the closing probability check may be performed or bypassed. If bypassed, the output will be true to close a window. If performed, the closing probability will be calculated. The closing probability (CP) value is given from a schedule.

CP = Schedule value or specific function

If the closing probability check is performed and the closing probability is greater than a random number, the output is true.

CP > random number (random number is between 0 and 1)
 Otherwise, the result will be false.

13.1.14 Pressure Control

Pressure control is achieved by varying either zone exhaust fan flow rate in a controlled zone or relief air flow rate in an AirLoop. It requires an AirLoop with an OA mixer to reach the pressure setpoint by adjusting a relief air flow, or an OA mixer and an exhaust fan in a controlled zone to reach the pressure setpoint by adjusting an exhaust fan flow rate. The calculation logic is shown below:

1. The AirflowNetwork model will run twice with zero and maximum flow rates for either the controlled zone exhaust fan or relief air flow rate. The controlled zone pressures are the return values.

In general, the zero flow rate of either exhaust fan or relief node will generate the maximum zone pressure, while the maximum flow rate of either exhaust fan or relief node will produce the minimum zone pressure.

2. If the setpoint pressure is between the maximum zone pressure caused by zero exhaust fan or relief node flow rate and the minimum zone pressure caused by maximum exhaust fan flow rate or outdoor air flow rate, then the AirflowNetwork model will use root solver to find a solution with calculated zone exhaust fan flow rate or relief node flow rate. Otherwise, the pressure setpoint will not be met.

3. If both maximum and minimum pressures are higher than the setpoint, the maximum exhaust or outdoor flow rate will be forced.

4. If both maximum and minimum pressures are lower than the setpoint, then zero flow rate will be forced.

13.2 RoomAir Models

The group of models described in this section is used to account for non-uniform room air temperatures that may occur within the interior air volume of a zone. These models are accessed using the RoomAirModelType input object. RoomAir modeling was added to EnergyPlus starting with Version 1.2. Although there are many types of analyses (comfort, indoor air quality, etc) that might benefit from localized modeling of how room air varies across space, most of the room air models in EnergyPlus only address the distribution of *temperature* within the zone. This allows surface heat transfer and air system heat balance calculations to be made taking into account natural thermal stratification of air and different types of intentional air distribution designs such as under-floor and side-wall displacement ventilation that purport to extract room air at higher-than-mean temperatures. The exception is the RoomAirflowNetwork model, which integrates the AirflowNetwork model and applies the nodal airflow model within zones. Note that EnergyPlus does **not** have completely general methods of modeling room air that are applicable to every conceivable type of airflow that might occur in a zone. Such models (e.g. RANS-CFD) are too computationally expensive to use with EnergyPlus for the foreseeable future. The models that are available in EnergyPlus offer only limited modeling capabilities for select room airflow configurations. Also note that because the complete mixing model for room air has long been the standard in building energy simulation, there is not currently a consensus on how to best model non-uniform air temperatures in buildings. Therefore, it is up to the user to have a good understanding of when, where, and how to apply the room air models available in EnergyPlus. The rest of this section provides some guidance in the

way of examples and further discussion of the models available in EnergyPlus.

EnergyPlus offers the different types of air models listed in the table below along with the input objects associated with the use of that model.

Table 13.2: Summary of room air models available in EnergyPlus

Air model name	Applicability	Input Objects Required
Well-Mixed	All zones	None, default
User Defined	Any zone where the user has prior knowledge of the temperature pattern	‘RoomAirModelType’, ‘RoomAir:TemperaturePattern:UserDefined’, ‘RoomAir:TemperaturePattern: xx’
One-Node Displacement Ventilation (Mundt)	displacement ventilation in typical office-type zones	‘RoomAirModelType’, ‘RoomAirSettings:OneNodeDisplacementVentilation’, ‘RoomAir:Node’
Three-Node Displacement Ventilation (UCSD)	displacement ventilation	‘RoomAirModelType’, ‘RoomAirSettings:ThreeNodeDisplacementVentilation’
Under-Floor Air Distribution Interior Model (UCSD)	Interior zones served by a UFAD system	‘RoomAirModelType’, ‘RoomAirSettings:UnderFloorAirDistributionInterior’
Under-Floor Air Distribution Exterior Model (UCSD)	Exterior zones served by a UFAD system	‘RoomAirModelType’, ‘RoomAirSettings:UnderFloorAirDistributionExterior’
UCSD Cross Ventilation	cross ventilation	‘RoomAirModelType’, ‘RoomAirSettings:CrossVentilation’
RoomAirflowNetwork	Room air model using AirflowNetwork	‘RoomAirModelType’, ‘RoomAirSettings:AirflowNetwork’ ‘RoomAirflowNetwork:Node’, ‘RoomAirflowNetwork:Node:AdjacentSurfaceList’, ‘RoomAirflowNetwork:Node:InternalGains’, ‘RoomAirflowNetwork:Node:InternalGains’, ‘AirflowNetwork:IntraZone:Node’, ‘AirflowNetwork:IntraZone:Linkage’

The room air models are coupled to the heat balance routines using the framework described by Griffith and Chen (2004). Their framework was modified to include features needed for a comprehensive program for annual energy modeling rather than one for hourly load calculations. The formulation is largely shifted from being based on the setpoint temperature to one based on the current mean air temperature. This is necessary to allow for floating temperatures and dual setpoint control where there may be times that the mean zone temperatures are inside the dead band. The

coupling framework was also extended to allow for exhaust air flows (e.g. bathroom exhaust fans) in addition to air system return flows.

The inside face temperature calculation is modified by rewriting the zone air temperature, T_a , with an additional subscript, i , for the surface index ($T_{a_j} \rightarrow T_{a_{i,j}}$ or $T_a \rightarrow T_{a_i}$). The inside face heat balance is solved for its surface temperature using,

$$T_{s_{i,j}} = \frac{T_{so_{i,j}} Y_{i,o} + \sum_{k=1}^{nz} T_{so_{i,j-k}} Y_{i,k} - \sum_{k=1}^{nz} T_{s_{i,j-k}} Z_{i,k} + \sum_{k=1}^{nq} \Phi_{i,k} q''_{ki,j-k} + T_{a_{i,j}} h_{c_{i,j}} + q''_{LWS} + q''_{LWX} + q''_{SW} + q''_{sol}}{Z_{i,o} + h_{c_{i,j}}} \quad (13.115)$$

where:

T_s is the inside face temperature

i is the subscript indicates individual surfaces

j is the subscript indicates current time step

k is the subscript indicates time history steps

T_{so} is the outside face temperature

Y_i are the cross CTF coefficients

Z_i are the inside CTF coefficients

φ_i are the flux CTF coefficients

q''_{ki} is the conduction heat flux through the surface

h_{c_i} is the surface convection heat transfer coefficient

T_a is the near-surface air temperature

q''_{LWS} is the longwave radiation heat flux from equipment in zone

q''_{LWX} is the net long wavelength radiation flux exchange between zone surfaces

q''_{SW} is the net short wavelength radiation flux to surface from lights

q''_{sol} is the absorbed direct and diffuse solar (short wavelength) radiation.

13.2.1 User Defined RoomAir Temperatures

The input object RoomAir:TemperaturePattern:UserDefined provides a capability for users to define the sort of air temperature pattern he or she expects in the zone. With these models, the pattern is generally set beforehand and does not respond to conditions that evolve during the simulation. (Exception: the pattern available through the RoomAir:TemperaturePattern:TwoGradient object will switch between two different pre-defined vertical gradients depending on the current value of certain temperatures or thermal loads.)

The user-defined patterns obtain the mean air temperature, T_{MAT} , from the heat balance domain and then produce modified values for:

- T_{ai} is the adjacent air temperature which is then used in the calculation of inside face surface temperature during the heat balance calculations.
- $T_{leaving}$ is the temperature of air leaving the zone and entering the air system returns.
- $T_{exhaust}$ is the temperature of air leaving the zone and entering the exhaust.
- T_{stat} is the temperature of air “sensed” at the thermostat (not currently used in air system control because air system flows use load-based control).

The user defined room air models used indirect coupling so that the patterns provide values for, or ways to calculate, how specific temperatures differ from T_{MAT} . The various ΔT values determined from the model are applied to T_{MAT} as follows:

$$T_{ai} = \Delta T_{ai} + T_{MAT} \quad (13.116)$$

(where “ i ’s” represents each surface in the zone that is affected by the model)

$$T_{leaving} = \Delta T_{return} + T_{MAT} \quad (13.117)$$

$$T_{exhaust} = \Delta T_{exhaust} + T_{MAT} \quad (13.118)$$

$$T_{stat} = \Delta T_{stat} + T_{MAT} \quad (13.119)$$

The patterns defined by the object ‘RoomAir:TemperaturePattern:SurfaceMapping’ are fairly straightforward. The user directly inputs values for ΔT_{ai} for each surface. The pattern “maps” specific surfaces, identified by name, to ΔT_{ai} values. This provides completely general control (but in practice may be cumbersome to use). The other patterns focus on temperature changes in the vertical direction. Surfaces do not need to be identified, but all the surfaces with the same height will be assigned the same ΔT_{ai} values.

The patterns defined by the object ‘RoomAir:TemperaturePattern:NondimensionalHeight’ apply a temperature profile based on a non-dimensionalized height, Z . The height of each surface is defined to be the z-coordinate of the surface’s centroid relative to the average z-coordinate of the floor surfaces. The zone ceiling height is used as the length scale to non-dimensionalize each surface’s height so that,

$$Z_i = (z_{i,centroid} - z_{floorAvg}) / Ceiling\ Height \quad (13.120)$$

(where “ i ’s” represents each surface in the zone that is affected by the model)

The values for Z_i are constrained to be between 0.01 and 0.99 because the value is meant to describe the air layer near the surface (say approximate 0.1 m from the surface) rather than the surface itself.

The user-defined profile is treated as a look up table or piecewise linear model. The values for ΔT_{ai} are determined by searching the Z values in the user-defined profile and performing linear interpolation on the associated ΔT_a values.

The patterns defined by the object ‘RoomAir:TemperaturePattern:ConstantGradient’ apply a constant temperature gradient in the vertical direction. The model assumes that T_{MAT} occurs at the mid-plane so that $Z_{T_{MAT}} = 0.5$ (by definition). The surface Z_i values are compared to $Z_{T_{MAT}}$ and then scaled with zone ceiling height to obtain values for the change in height (in units of meters), Δz . The user defined gradient, $grad$, (units of °C/m) is then used to determine ΔT_{ai} values using:

$$\Delta T_{ai} = \Delta z * grad \quad (13.121)$$

The patterns defined by the object ‘RoomAir:TemperaturePattern:TwoGradient’ are very similar to the constant gradient pattern above but the value of $grad$ used at any given time is selected by interpolating between two user-defined values for $grad$. Five options are available, three based on

temperatures and two based on thermal loads – see the Input Output Reference. The user provides upper and lower bounding values. If the current value of the “sensing” variable lies between the upper and lower bounds, then *grad* is determined using linear interpolation. If the designated value is above the upper bound then the upper value for *grad* is used (no extrapolation). Similarly, if the designated value is below the lower bound, then the lower value for *grad* is used. Note that “upper” and “lower” indicate the temperature and heat rate bounds and that the values for *grad* do not have to follow in the same way; the *grad* value for the lower bound could be higher than the *grad* value for the upper bound (providing a something of a reverse control scheme). Rather than directly using ΔT values from the user, the temperatures for the return air, exhaust and thermostat are determined based on user-entered heights (in units of meters from the floor) and applying the current value for *grad*.

13.2.2 One-Node Displacement Ventilation RoomAir Model

The input object RoomAirSettings:OneNodeDisplacementVentilation provides a simple model for displacement ventilation. Mundt (1996) points out that a floor air heat balance provides a simple and reasonably accurate method of modeling the temperature near the floor surface. The slope of a linear temperature gradient can then be obtained by adding a second upper air temperature value that comes from the usual overall air system cooling load heat balance. The figure below diagrams the temperature distribution versus height being calculated by the model. Mundt’s floor air heat balance is extended to include convection heat gain from equipment and by ventilation or infiltration that may be introduced near the floor in order to maintain all the terms in the air heat balance of the Heat Balance Model. This yields the following heat balance for a floor air node,

$$\rho c_p \dot{V} (T_{AirFloor} - T_{Supply}) = h_{cFloor} A_{Floor} (T_{Floor} - T_{AirFloor}) + Q_{ConvSourceFloor} + Q_{InfilFloor} \quad (13.122)$$

where:

ρ is the air density

c_p is the air specific heat at constant pressure

\dot{V} is the air system flow rate

T_{supply} is the air system’s supply air drybulb temperature

h_{cFloor} is the convection heat transfer coefficient for the floor

A_{floor} is the surface area of the floor

T_{floor} is the surface temperature of the floor

$Q_{convSourceFloor}$ is the convection from internal sources near the floor (< 0.2 m)

$Q_{InfilFloor}$ is the heat gain (or loss) from infiltration or ventilation near the floor.

“Floor splits” are the fraction of total convective or infiltration loads that are dispersed so as to add heat to the air located near the floor. The user prescribes values for floor splits as input. No guidance is known to be available to use in recommending floor splits, but the user could for example account for equipment known to be near the floor, such as tower computer cases, or supplementary ventilation designed to enter along the floor. The equation above can be solved directly for $T_{AirFloor}$ and is used in the form of the equation below,

$$T_{AirFloor} = \frac{\rho c_p \dot{V} T_{Supply} + \sum h_{cFloor} A_{Floor} T_{Floor} + \dot{Q}_{ConvSourceFloor} + \dot{Q}_{InfilFloor}}{\rho c_p \dot{V} + \sum h_{cFloor} A_{Floor}} \quad (13.123)$$

The upper air node temperature is obtained by solving the overall air heat balance for the entire thermal zone for the temperature of the air leaving the zone and going into the air system return, $T_{leaving}$.

$$T_{Leaving} = \frac{-\dot{Q}_{sys}}{pc_p\dot{V}} + T_{Supply} \quad (13.124)$$

where \dot{Q}_{sys} is the air system heat load with negative values indicating a positive cooling load. Values for \dot{Q}_{sys} are computed by the load calculation routines and passed to the air model. The vertical temperature gradient or slope, dT/dz , is obtained from,

$$\frac{dT}{dz} = \frac{T_{Leaving} - T_{AirFloor}}{H_{return}} \quad (13.125)$$

where H_{return} is the distance between the air system return and the floor air node assumed to be 0.1 m from the floor and z is the vertical distance.

The constant slope allows obtaining temperatures at any vertical location using,

$$T_{a_i} = T_{leaving} - \frac{dT}{dz}(z_{leaving} - z_i) \quad (13.126)$$

So for example the temperatures near the ceiling can easily be determined. Accounting for the location of the thermostat inside the zone (e.g. 1.1 m) is accomplished by returning the temperature for the appropriate height to the appropriate air node used for control. If the walls are subdivided in the vertical direction as shown in the figure above, then the air model can provide individual values for each surface based on the height and slope. However, no additional heat balances are necessarily made (in the air domain) at these points as all the surface convection is passed to the model in the totaled value for \dot{Q}_{sys} .

13.2.3 Three-Node Displacement Ventilation RoomAir Model

13.2.3.1 Overview

The input object RoomAirSettings:ThreeNodeDisplacementVentilation provides a simple model for heat transfer and vertical temperature profile prediction in displacement ventilation. The fully-mixed room air approximation that is currently used in most whole building analysis tools is extended to a three node approach, with the purpose of obtaining a first order precision model for vertical temperature profiles in displacement ventilation systems. The use of three nodes allows for greatly improved prediction of thermal comfort and overall building energy performance in low energy cooling strategies that make use of unmixed stratified ventilation flows.

The UCSD Displacement Ventilation Model is one of the non-uniform zone models provided through the Room Air Manager in EnergyPlus. The intent is to provide a selection of useful non-uniform zone air models to enable the evaluation of air-conditioning techniques that use stratified or partially stratified room air. Such techniques include displacement ventilation (DV) and underfloor air distribution (UFAD) systems. The methodology can also include, in principle, natural displacement ventilation and also wind-driven cross-ventilation (CV).

Figure 13.14: Height versus temperature schematic for Mundt model

13.2.3.2 Displacement Ventilation

A DV system is a complete contrast to a conventional forced air system. In a conventional system conditioned air is delivered at ceiling level and the intent is to create a fully mixed space with uniform conditions. In a DV system conditioned air is delivered at floor level and low velocity in order to minimize mixing and to establish a vertical temperature gradient. The incoming air “displaces” the air above it which, in turn, is exhausted through ceiling level vents. In DV a noticeable interface occurs between the occupied zone of the room and a mixed hot layer near the ceiling of the room (Dominique & Guitton, 1997). Maintaining the lower boundary of this warm layer above the occupied zone is one of the many unique challenges of displacement ventilation design. Often DV systems use 100% outside air. The vertical displacement air movement means that convective heat gains introduced near the ceiling will be removed without affecting the occupied region of the room. Also a fraction of the heat gains that occur in the occupied zones rise as plumes into the upper part of the space, thereby reducing the cooling load. Similarly the fresh air will be used more effectively than with a fully mixed system: the fresh air won’t be “wasted” in the upper, unoccupied region of the room. Finally, the vertical temperature gradient means that the average room temperature can be higher for a DV conditioned room than with a conventionally conditioned room: the occupants feel the lower temperature in the lower region of the room and are unaffected by the higher temperature near the ceiling. However, whenever the outside air temperature is above $\approx 19^{\circ}\text{C}$ this advantage is mostly lost: the internal loads must be removed from the space independently of the airflow pattern (during the warmer hours buildings tend to be almost closed to the outside, operating in closed loop). The inflow temperature advantage is then only useful for the minimum outside air that must always be provided (in most cases this remaining advantage is negligible).

DV systems have limitations. In order to avoid chilling the occupants the supply air temperature used for DV is considerably higher than that used in conventional forced-air systems. This can lead to problems in removing both sensible and latent loads. Exterior spaces may have conditions that are not conducive to establishing a vertical temperature gradient. DV systems seem to be best suited to interior spaces with only moderate loads.

13.2.3.3 Non-uniform zone models

Several types of models have been proposed as suitable for inclusion in building energy simulation (BES) programs. These models must be simple enough not to impose an undue computational burden on a BES program, yet provide enough predictive capability to produce useful comparisons between conventional and stratified zone operation strategies. ASHRAE RP-1222 (Chen & Griffith 2002) divides the candidate models into two categories: *nodal* and *zonal*. Nodal models describe the zone air as a network of nodes connected by flow paths; each node couples convectively to one or more surfaces. Zonal models are coarse-grained finite volume models. ASHRAE RP-1222 provides a short history (and examples) of each type of model. In terms of nodal models for displacement ventilation we mention the Mundt model (Mundt 1996), since it is implemented in EnergyPlus, and the Rees-Haves model (Rees & Haves 2001) since it is a well developed nodal-type model and is implemented in the RP-1222 toolkit. The Rees-Haves model, while successful in predicting the flow and temperature field for geometries similar to those used in its development, can suffer from lack of flexibility and clarity in the modeling approximations. When dealing with diverse geometries it is not clear that the flow coefficients used in the model are applicable or why they can be used since plumes, the fundamental driving mechanisms of the displacement flow, are not explicitly modeled.

This is the main difference between the DV models implemented in theRP-1222 toolkit and the model that is described here.

The UCSD DV model is closer to a nodal model than to a zonal model. However, it is best to classify it in a separate category: plume equation based multi-layer models (Linden *et al.* 1990, Morton *et al.* 1956). These models assume that the dominant mechanism is plume-driven flow from discrete internal sources and that other effects (such as buoyancy driven flow at walls or windows) may be neglected. Alternatively, these heat sources also produce plumes that can be included in the model. The result is a zone divided vertically into two or more well separated regions – each region characterized by a single temperature or temperature profile. This characterization allows the physics of the heat gains and the ventilation flow to be represented in a realistic manner, without the introduction of *ad hoc* assumptions.

13.2.3.4 Model Description

13.2.3.5 Single Plume Two Layer Model

The simplest form of the plume equation based models is the case of a single plume in an adiabatic box with constant supply air flow. For this configuration two layers form in the room: a lower layer with similar density and temperature as the inflow air and a mixed upper layer with the same density / temperature as the outflow air. The main assumption of this model, successfully validated against scaled model experiments (Linden *et al.* 1990), is that the interface between the two layers occurs at the height (h) where the vertical buoyancy driven plume flow rate is the same as the inflow rate. For a point source of buoyancy in a non-stratified environment (a plume) the airflow rate increases with vertical distance from the source according to:

$$\dot{V} = C \cdot B^{1/3} z^{5/3} \quad (13.127)$$

where:

\dot{V} = plume volume flux [m³/s]

B = buoyancy flux [m⁴/s³]

z = vertical distance above source [m]

$$C = \frac{6}{5} \alpha \left(\frac{9}{10} \alpha \right)^{1/3} \pi^{2/3} \quad (13.128)$$

α = plume entrainment constant; a value of 0.127 is used, suitable for top-hat profiles for density and velocity across the plumes.

For an ideal gas:

$$\Delta\rho/\rho = \Delta T/T \quad (13.129)$$

resulting in the following relation between heat input rate and buoyancy flux:

$$B = \frac{g\dot{Q}}{\rho C_p T} \quad (13.130)$$

where

ρ = density of air [kg/m³]

T = air temperature [K]

g = acceleration of gravity [m/s²]

\dot{Q} = heat input rate [W]

C_p = specific heat capacity of air [J/kgK]

Since the plume volume flow rate increases with height with exponent 5/3, for any room inflow rate (F , (m³/s)) there will always be a height (h , (m)) where the plume driven flow rate matches the inflow rate. This height is obtained by setting (1.1) equal to F and solving for $z = h$:

$$h = F^{3/5} / (C^{3/5} B^{1/5}) \quad (13.131)$$

Substituting in and introducing air properties at 20°C gives:

$$h = 24.55 \cdot F^{3/5} / \dot{Q}^{1/5} \quad (13.132)$$

13.2.3.6 Multiple Plumes and Wall Heat Transfer

Of course, it would be rare for a real world case to consist of a single point-source plume originating on the floor, unaffected by heat gains from walls and windows. For multiple plumes of equal strength a straight-forward extension of the single is possible. N plumes of unequal strength result in the formation of n vertical layers. This case is much more complex but if we are satisfied with a first order precision model the equal strength model can be used by averaging the plume strengths (Carrilho da Graça, 2003). Even in a case where all plumes are of equal strength, nearby plumes may coalesce. Plumes that are less than 0.5 meters apart at their source will coalesce within 2 meters (Kaye & Linden, 2004).

As the complexity of the physical systems modeled increases some limitations must be imposed. In particular, the biggest challenge remains the interaction between wall driven boundary layers (positively and negatively buoyant) and displacement flows. For this reason, the model that is developed below is not applicable when:

1. Downward moving buoyancy driven airflow rate is of the same order of magnitude as plume driven flow (these airflow currents are typically generated on lateral surfaces or in the ceiling whenever these surfaces are much cooler than the room air).
2. Upward moving wall or floor generated buoyancy flux in the lower layer is of the same order of magnitude as plume driven flow.

Although these limitations are significant it is important to note that even in the presence of dominant convection from the floor surface, a buoyancy, two layer flow can be established whenever the plume buoyancy flux is more than 1/7 of the horizontal flux (Hunt *et al.* 2002). A two layer structure can also originate when the only heat source is a heated portion of the room floor, as long as the heated area does not exceed 15% of the room floor (Holford *et al.* 2002).

For the case of multiple non-coalescing plumes (n), with equal strength, the total vertical airflow for a given height is:

$$\dot{V} = CnB^{1/3}z^{5/3} \quad (13.133)$$

resulting in a mixed layer height of:

$$h = \frac{24.55F^{3/5}}{n^{3/5}\dot{Q}^{1/5}} \quad (13.134)$$

13.2.3.7 Implementation

The model predicts three temperatures that characterize the three main levels in the stratification of the room:

1. A floor level temperature T_{floor} to account for the heat transfer from the floor into the supply air.
2. An occupied subzone temperature T_{oc} representing the temperature of the occupied region.
3. An upper level temperature T_{mx} representing the temperature of the upper, mixed region and the outflow temperature.

We assume that the model for multiple, equal strength plumes (equations and will be adequate for our calculations. The supply air flow rate \dot{V} is obtained by summing all the air flows entering the zone: supply air, infiltration, ventilation, and inter-zone flow. The heat gain \dot{Q} is estimated by summing all the convective internal gains located in the occupied subzone – task lights, people, equipment – and dividing this power equally among the n plumes. With these assumptions we can describe the implementation.

The UCSD DV model is controlled by the subroutine *ManageUCSDDVModel* which is called from the *RoomAirModelManager*. The *RoomAirModelManager* selects which zone model will be used for each zone.

The calculation is done in subroutine *CalcUCSDDV*. First we calculate the convective heat gain going into the upper and lower regions.

$$\dot{Q}_{ocz} = \dot{Q}_{oc,conv} + \dot{Q}_{tl,conv} + \dot{Q}_{eleq,conv} + \dot{Q}_{gaseq,conv} + \dot{Q}_{otheq,conv} + \dot{Q}_{hw,conv} + \dot{Q}_{stmeq,conv} + \dot{Q}_{bb,conv} \quad (13.135)$$

$$\dot{Q}_{mxz} = \dot{Q}_{gl,conv} + \dot{Q}_{ltp} + \dot{Q}_{htrad,conv} \quad (13.136)$$

$$\dot{Q}_{tot,conv} = \dot{Q}_{ocz} + \dot{Q}_{mxz} \quad (13.137)$$

Next we sum up the inlet air flows in the form of MCP (mass flow rate times the air specific heat capacity) and MCPT (mass flow rate times C_p times air temperature).

$$MCP_{zone} = MCP_i + MCP_{vent} + MCP_{mix} \quad (13.138)$$

$$MCP_{sys} = \sum_{inlets} \dot{m}_i C_{p,i} \quad (13.139)$$

$$MCP_{tot} = MCP_{zone} + MCP_{sys} \quad (13.140)$$

$$MCPT_{zone} = MCPT_i + MCPT_{vent} + MCPT_{mix} \quad (13.141)$$

$$MCPT_{sys} = \sum_{inlets} \dot{m}_i C_{p,i} T_i \quad (13.142)$$

$$MCPT_{tot} = MCPT_{zone} + MCPT_{sys} \quad (13.143)$$

The number of plumes per occupant $N_{plumesperspers}$ is a user input. The total number of plumes in the zone is:

$$N_{plumes} = N_{occ} \cdot N_{plumespersperson} \quad (13.144)$$

The gains fraction Fr_{gains} is a user input via a schedule. It is the fraction of the convective gains in the occupied subzone that remain in that subzone. Using this we calculate the total power in the plumes and the power per plume.

$$\dot{Q}_{plumes} = (1 - Fr_{gains}) \cdot \dot{Q}_{tot,conv} \quad (13.145)$$

$$\dot{Q}_{perplume} = \dot{Q}_{plumes} / N_{plumes} \quad (13.146)$$

We now make an initial estimate of the height fraction Fr_{hb} (height of the boundary layer divided by the total zone height).

$$Fr_{hb} = (24.55 / H_{ceil}) \left(\frac{0.000833 \cdot MCP_{tot}}{N_{plumes} \cdot \dot{Q}_{perplume}^{1/3}} \right)^{3/5} \quad (13.147)$$

where $0.000833 = 1/(\rho_{air} \cdot c_{p,air})$ converts MCP_{tot} to a volumetric flow rate. Next we iterate over the following 3 steps.

13.2.3.8 Iterative procedure

1. Call subroutine $HcUCSDDV$ to calculate a convective heat transfer coefficient for each surface in the zone, an effective air temperature for each surface, and HA_{mx} , HAT_{mx} , HA_{oc} , HAT_{oc} , HA_{fl} , and HAT_{fl} . Here HA is $\sum_{surfaces} h_{c,i} \cdot A_i$ for a region and HAT is $\sum_{surfaces} h_{c,i} \cdot A_i \cdot T_i$ for a region. The sum is over all the surfaces bounding the region; $h_{c,i}$ is the convective heat transfer coefficient for surface i, A_i is the area of surface i, and T_i is the surface temperature of surface i.
2. Recalculate Fr_{hb} using the Equation 13.147.
3. Calculate the three subzone temperatures: T_{fl} , T_{oc} and T_{mx} .

The h_c 's calculated in step 1 depend on the subzone temperatures and the boundary layer height. In turn the subzone temperatures depend on the HA and HAT 's calculated in step 1. Hence the need for iteration

Next we describe Steps 1 and 3 in more detail.

13.2.3.9 Step 1

Subroutine *HcUCSDDV* is quite straightforward. It loops through all the surfaces in each zone and decides whether the surface is located in the upper, mixed subzone or the lower, occupied subzone, or if the surface is in both subzones. If entirely in one subzone the subzone temperature is stored in the surface effective temperature variable *SurfTempEffBulkAir(SurfNum)* and h_c for the surface is calculated by a call to subroutine *CalcDetailedHcInForDVMModel*. This routine uses the “detailed” natural convection coefficient calculation that depends on surface tilt and $\Delta T^{1/3}$. This calculation is appropriate for situations with low air velocity.

For surfaces that bound 2 subzones, the subroutine calculates h_c for each subzone and then averages them, weighting by the amount of surface in each subzone.

During the surface loop, once the h_c for a surface is calculated, the appropriate subzone HA and HAT sums are incremented. If a surface is in 2 subzones the HA and HAT for each subzone are incremented based on the area of the surface in each subzone.

13.2.3.10 Step 3

The calculation of subzone temperatures follows the method used in the ***ZoneTempPredictor-Corrector*** module and described in the section **Basis for the System and Zone Integration**. Namely a third order finite difference expansion of the temperature time derivative is used in updating the subzone temperatures. Otherwise the subzone temperatures are obtained straightforwardly by solving an energy balance equation for each subzone.

$$T_{fl} = (C_{air,fl} \cdot (3 \cdot T_{-1,fl} - (3/2) \cdot T_{-2,fl} + (1/3) \cdot T_{-3,fl}) + HAT_{fl} + MCPT_{tot} + 0.6 \cdot T_{oc} \cdot MCP_{tot}) / ((11/6) \cdot C_{air,fl} + HA_{fl} + 1.6 \cdot MCP_{tot}) \quad (13.148)$$

$$T_{oc} = (C_{air,oc} \cdot (3 \cdot T_{-1,oc} - (3/2) \cdot T_{-2,oc} + (1/3) \cdot T_{-3,oc}) + \dot{Q}_{ocz} \cdot Fr_{gains} + HAT_{oc} + 1.6 \cdot T_{fl} \cdot MCP_{tot}) / ((11/6) \cdot C_{air,oc} + HA_{oc} + 1.6 \cdot MCP_{tot}) \quad (13.149)$$

$$T_{mx} = (C_{air,mx} \cdot (3 \cdot T_{-1,mx} - (3/2) \cdot T_{-2,mx} + (1/3) \cdot T_{-3,mx}) + \dot{Q}_{ocz} \cdot (1 - Fr_{gains}) + \dot{Q}_{mzx} + HAT_{mx} + T_{oc} \cdot MCP_{tot}) / ((11/6) \cdot C_{air,mx} + HA_{mx} + MCP_{tot}) \quad (13.150)$$

Here $C_{air,fl}$, $C_{air,oc}$, and $C_{air,mx}$ are the heat capacities of the air volume in each subzone. $C_{air,mx}$ is calculated by:

$$R_{air,mx} = V_{mx} \cdot (\Delta z_{mx} / z_{ceil}) \cdot \rho_{air,mx} \cdot c_{p,air,mx} \cdot Mul_{cap} / (\Delta t_z \cdot 3600) \quad (13.151)$$

$$C_{air,mx} = R_{air,mx} \cdot \Delta t_z / \Delta t_{sys} \quad (13.152)$$

The other subzone air heat capacities are calculated in the same manner.

13.2.3.11 Mixed calculation

The above iterative procedure assumed that displacement ventilation was taking place: i.e., conditions were favorable temperature stratification in the zone. Now that this calculation is complete

and the subzone temperatures and depths calculated, we check to see if this assumption was justified. If not, zone conditions must be recalculated assuming a well-mixed zone.

If $T_{mx} < T_{oc}$ or $MCP_{tot} \leq 0$ or $H_{fr} \cdot H_{ceil} < H_{fl,top} + \Delta z_{occ,min}$ then the following mixed calculation will replace the displacement ventilation calculation.

Note: $\Delta z_{occ,min}$ is the minimum thickness of occupied subzone. It is set to 0.2 meters. $H_{fl,top}$ is the height of the top of the floor subzone. It is defined to be 0.2 meters; that is, the floor subzone is always 0.2 meters thick and T_{fl} is the temperature at 0.1 meter above the floor surface.

The mixed calculation iteratively calculates surface convection coefficients and room temperature just like the displacement ventilation calculation described above. In the mixed case however, only one zone temperature T_{avg} is calculated. The 3 subzone temperatures are then set equal to T_{avg} .

First, Fr_{hb} is set equal to zero.

Then the code iterates over these steps.

1. Calculate T_{avg} using:

$$T_{avg} = (C_{air,z} \cdot (3 \cdot T_{-1,z} - (3/2) \cdot T_{-2,z} + (1/3) \cdot T_{-3,z}) + \dot{Q}_{tot,conv} + HAT_{oc} + HAT_{mx} + HAT_{fl} + MCP_{tot}) / ((11/6) \cdot C_{air,z} + HA_{oc} + HA_{mx} + HA_{fl} + MCP_{tot}) \quad (13.153)$$

$$T_{mx} = T_{avg} \quad (13.154)$$

$$T_{oc} = T_{avg} \quad (13.155)$$

$$T_{fl} = T_{avg} \quad (13.156)$$

2. Call $HcUCSDDV$ to calculate the h_c 's.

3. Repeat step 1

13.2.3.12 Final calculations

The displacement ventilation calculation finishes by calculating some report variables. Using Equation 13.147, setting the boundary height to 1.5 meters and solving for the flow, we calculate a minimum flow fraction:

$$\dot{V}_{min} = (1.5/24.55)^{5/3} \cdot N_{plumes} \cdot \dot{Q}_{perplume}^{1/3} \quad (13.157)$$

$$Fr_{min flow} = .000833 \cdot MCP_{tot} / \dot{V}_{min} \quad (13.158)$$

We define heights:

$$H_{trans} = Fr_{hb} \cdot H_{ceil} \quad (13.159)$$

$$H_{mxavg} = (H_{ceil} + H_{trans})/2 \quad (13.160)$$

$$H_{ocavg} = (H_{fltop} + H_{trans})/2 \quad (13.161)$$

$$H_{flavg} = H_{fltop}/2 \quad (13.162)$$

Using the user defined comfort height we calculate the comfort temperature.

If mixing:

$$T_{comf} = T_{avg} \quad (13.163)$$

If displacement ventilation:

If $H_{comf} < H_{flavg}$:

$$T_{comf} = T_{fl} \quad (13.164)$$

Else if $H_{comf} \geq H_{flavg}$ and $H_{comf} < H_{ocavg}$:

$$T_{comf} = (T_{fl}(H_{ocavg} - H_{comf}) + T_{mx}(H_{comf} - H_{flavg})/(H_{ocavg} - H_{flavg}) \quad (13.165)$$

Else if $H_{comf} \geq H_{ocavg}$ and $H_{comf} < H_{mxavg}$:

$$T_{comf} = (T_{oc}(H_{mxavg} - H_{comf}) + T_{mx}(H_{comf} - H_{ocavg})/(H_{mxavg} - H_{ocavg}) \quad (13.166)$$

Else if $H_{comf} \geq H_{mxavg}$ and $H_{comf} < H_{ceil}$:

$$T_{comf} = T_{mx} \quad (13.167)$$

Using the user defined thermostat height we calculate the temperature at the thermostat.

If mixing:

$$T_{stat} = T_{avg} \quad (13.168)$$

If displacement ventilation:

If $H_{stat} < H_{flavg}$:

$$T_{stat} = T_{fl} \quad (13.169)$$

Else if $H_{stat} \geq H_{flavg}$ and $H_{stat} < H_{ocavg}$:

$$T_{stat} = (T_{fl}(H_{ocavg} - H_{stat}) + T_{mx}(H_{stat} - H_{flavg})/(H_{ocavg} - H_{flavg}) \quad (13.170)$$

Else if $H_{stat} \geq H_{ocavg}$ and $H_{stat} < H_{mxavg}$:

$$T_{stat} = (T_{oc}(H_{mxavg} - H_{stat}) + T_{mx}(H_{stat} - H_{ocavg})/(H_{mxavg} - H_{ocavg}) \quad (13.171)$$

Else if $H_{stat} \geq H_{mxavg}$ and $H_{stat} < H_{ceil}$:

$$T_{stat} = T_{mx} \quad (13.172)$$

The average temperature gradient is:

If $H_{mxavg} - H_{flavg} > 0.1$:

$$GradT_{avg} = (T_{mx} - T_{fl})/(H_{mxavg} - H_{flavg}) \quad (13.173)$$

else $GradT_{avg} = -9.999$

The maximum temperature gradient is:

If $H_{ocavg} - H_{flavg} > 0.1$:

$$GradT_{\max,1} = (T_{oc} - T_{fl}) / (H_{ocavg} - H_{flavg}) \quad (13.174)$$

else $GradT_{\max,1} = -9.999$

If $H_{mxavg} - H_{ocavg} > 0.1$:

$$GradT_{\max,2} = (T_{mx} - T_{oc}) / (H_{mxavg} - H_{ocavg}) \quad (13.175)$$

else $GradT_{\max,2} = -9.999$ and

$$GradT_{\max} = \max(GradT_{\max,1}, GradT_{\max,2}) \quad (13.176)$$

For reporting purposes, if the zone is deemed to be mixed, the displacement ventilation report variables are set to flag values.

If $T_{mx} < T_{oc}$ or $MCP_{tot} \leq 0$ or $H_{fr} \cdot H_{ceil} < H_{fl,top} + \Delta z_{occ,min}$ or $T_{mx} - T_{oc} < \Delta T_{CritRep}$

$$GradT_{avg} = -9.999 \quad (13.177)$$

$$GradT_{\max} = -9.999 \quad (13.178)$$

$$FR_{\min,flow} = -1.0 \quad (13.179)$$

$$H_{trans} = -9.999 \quad (13.180)$$

Finally, the zone node temperature is set to T_{mx} .

13.2.4 Under-Floor Air Distribution Interior Zone Model

13.2.4.1 Overview

The input object RoomAirSettings:UnderFloorAirDistributionInterior provides a simple model for heat transfer and nonuniform vertical temperature profile for interior zones of a UFAD system. These zones are expected to be dominated by internal loads, a portion of which (such as occupants and workstations) will act to generate plumes. The plumes act to potentially create room air stratification, depending on the type & number of diffusers, the amount and type of load, and the system flowrate. In order to better model this situation the fully-mixed room air approximation that is currently used in most whole building analysis tools is extended to a two node approach, with the purpose of obtaining a first order precision model for vertical temperature profiles for the interior zones of UFAD systems. The use of 2 nodes allows for greatly improved prediction of thermal comfort and overall building energy performance for the increasingly popular UFAD systems.

The UCSD UFAD Interior Zone Model is one of the non-uniform zone models provided through the Room Air Manager in EnergyPlus. The intent is to provide a selection of useful non-uniform zone air models to enable the evaluation of air-conditioning techniques that use stratified or partially stratified room air. Such techniques include displacement ventilation (DV) and underfloor air distribution (UFAD) systems. The methodology can also include natural displacement ventilation and also wind-driven cross-ventilation (CV).

13.2.4.2 Underfloor air distribution systems

UFAD systems represent, in terms of room air stratification, an intermediate condition between a well-mixed zone and displacement ventilation. Air is supplied through an underfloor plenum at low pressure through diffusers in the raised floor. The diffusers can be of various types: e.g., swirl, variable-area, displacement, and produce more or less mixing in the zone. UFAD systems are promoted as saving energy due to: higher supply air temperature; low static pressure; cooler conditions in the occupied subzone than in the upper subzone; and sweeping of some portion of the convective load (from ceiling lights, for instance) into the return air without interaction with the occupied region of the zone.

Modeling a UFAD system is quite complex and involves considerably more than just a non-uniform zone model. The zones' coupling to the supply and return plenums must be modeled accurately (particularly radiative transfer from a warm ceiling to a cool floor and on into the supply plenum by conduction). The supply plenum must be accurately modeled, giving a good estimate of the supply air temperature and conduction heat transfer between supply & return plenums through the slab. The HVAC system must be modeled including return air bypass and various types of fan powered terminal units.

The UCSD UFAD interior zone model is similar to the UCSD DV model. The most obvious difference is that the UFAD model has no separate near-floor subzone. Like the UCSD DV model it is a plume equation based multi-layer model (2 layers in this case). The zone is modeled as being divided into 2 well separated subzones which we denote as “occupied” and “upper”. Each subzone is treated as having a single temperature. The boundary between the 2 subzones moves up & down each time step as a function of zone loads and supply air flow rate. Thus at each HVAC time step, the height of the boundary above the floor must be calculated, portions of surfaces assigned to each subzone, and a separate convective heat balance performed on each subzone.

13.2.4.3 Model Description

The UFAD interior zone model is based upon non-dimensional analysis of the system and using the non-dimensional description to make a comparison between full-scale UCB test chamber data & small-scale UCSD salt tank measurements.

In order to do the non-dimensional comparisons, we need to define two dimensionless parameters. One is Γ , and the other is ϕ . Lin & Linden (Lin & Linden, 2005) showed that in a UFAD system, the buoyancy flux of the heat source (B) and the momentum flux of the cooling jets (M) are the controlling parameters on the stratification. Since $[B] = L^4 T^{-3}$ and $[M] = L^4 T^{-2}$, we can have a length scale as $M^{3/4}/B^{1/2}$.

Definition of Γ for the single-plume single-diffuser basic model

We observed, in our small-scale experiments, that the total room height does not affect the interface position, or the height of the occupied zone. In other words, H might not be the critical length scale for the stratification. Therefore, we started to use \sqrt{A} as the reference length. Then Γ is defined as:

$$\Gamma = \frac{M^{3/4}}{B^{1/2} A^{1/2}} = \frac{(Q^2/A)^{3/4}}{B^{1/2} A^{1/2}} = \frac{Q^{3/2}}{A^{5/4} B^{1/2}} \quad (13.181)$$

Definition for multi-diffuser and multi-source cases

We only considered single-diffuser, single-source cases in above analysis. Suppose there are n equal diffusers and m equal heat sources in a UFAD room. We shall divide the number of diffusers

up into a number of separate heat sources so that each subsection with $n' = n/m$ diffusers per heat source will have the same stratification as other subsections. Further, the air flow and the heat load into the subsection Q' and B' will be $Q' = Q/m$ $B' = B/m$ respectively, where Q' and B' are the total air flow and the total heat load for the entire UFAD space. Then the momentum flux each diffuser per heat source carries is $M_d = (\frac{1}{n'}Q')^2/A$. Equation 13.181 will be modified as:

$$\Gamma = \frac{(n'M_d)^{3/4}}{B'^{1/2}\sqrt{n'A}} = \frac{Q'^{3/2}}{(n'A)^{5/4}B'^{1/2}} = \frac{Q^{3/2}}{m(n'A)^{5/4}B^{1/2}} \quad (13.182)$$

Full-scale cases

Because B is the buoyancy flux of the heat sources and M is the momentum flux of the cooling jets, in a real full-scale room, we shall consider the total room net heat load (plume heat input, minus the room losses) and the total net flow rate coming from the diffusers (input room air flow, minus the room leakage). Further, if the diffuser is swirl type, the vertical momentum flux should be used.

$$\Gamma = \frac{(Q \cos \theta)^{3/2}}{m(n'A)^{5/4}(0.0281W)^{1/2}} \quad (13.183)$$

where Q is the net flow rate coming out from all diffusers (m^3/s); W is the total net heat load (kW); A is the effective area of each diffuser (m^2); n' is the number of diffusers per heat source; θ is the angle between the diffuser slots and the vertical direction and m is the number of heat sources.

Definition of ϕ

In our theoretical model, two-layer stratification forms at steady state, provided that each diffuser carries the same momentum flux, and each heat source has the same heat load. We could define a dimensionless parameter ϕ , which indicates the strength of stratification.

Small-scale cases

In our salt-water tank experiments, fluid density r is measured. Define that:

$$\phi = \frac{\rho_u - \rho_l}{\rho_u - \rho_o} \quad (13.184)$$

where ρ_u and ρ_l are the fluid density of the upper layer and lower layer, separately; and ρ_o is the source density at the diffusers.

Therefore, $\rho_l = \rho_o$ gives $\phi = 1$, which means the largest stratification (displacement ventilation case); $\rho_l = \rho_u$ leads to $\phi = 0$, in which case there is no stratification (mixed ventilation case).

Full-scale cases

Similarly, we can define ϕ for full-scale cases by using temperature.

$$\phi = \frac{T_r - T_{oz}}{T_r - T_s} \quad (13.185)$$

where T_r , T_{oz} , and T_s are the return air temperature, the occupied zone temperature and the supply temperature, respectively (K). Again $\phi = 1$ occurs in displacement ventilation; while $\phi = 0$ happens in mixed ventilation.

Comparisons between full-scale UCB data and small-scale UCSD data

The figures (Figure 13.15. Data comparisons in the non-dimensional (a) regular Γ - ϕ plot and Figure 13.16. (b) log-log Γ - ϕ plot.) show the comparisons between UCB's data and the UCSD

Figure 13.15: Data comparisons in the non-dimensional (a) regular Γ - ϕ plot

Figure 13.16: (b) log-log Γ - ϕ plot.}

salt tank data in the Γ - ϕ plot. As seen in the figures, the full-scale and small-scale data are on the same trend curve. This provides the evidence that the salt-tank experiments have included most characteristics of a UFAD system. Note that big Γ (>20) of UCB's experiments all have large DDR (from 1.19 to 2.18). The largest DDR (2.18) even gives a negative $(T_r - T_{oz})/(T_r - T_s)$, which is NOT shown in the figures.)

We could work out the occupied zone temperature by using the least-square fitting line suggested in Figure 13.16. Hence the interface height is needed to determine a entire two-layer stratification. Figure 13.17 shows the dimensionless interface height ($h/\sqrt{n'A}$) of the UCSD small-scale experiments plotted against Γ . Note that for the experiments with elevated heat source, the interface heights have been modified by $h' = h - \frac{1}{2}h_s$ where h_s is the vertical position of the elevated heat source. All data then are located along a line in Figure 13.17. Since the salt-tank experiments are concluded to represent important characteristics of a full-scale UFAD room, this figure provides some guidelines for estimate the interface position in a real UFAD room.

Figure 13.17: Non-dimensional interface height of small-scale experiments.

Formulas for EnergyPlus based on the dimensionless parameter Γ

If we have input including the supply temperature T_s (K); the number of diffusers n ; the number of heat sources m ; the vertical position of the heat sources h_s (m); the heat load W (kW); the effective area of a diffuser A (m^2); and the total supply air flow rate Q (m^3/s) then the output

will be;

$$T_r = \frac{0.0281W}{Qg} T_s + T_s \quad (13.186)$$

$$T_{oz} = T_r - 1.6\Gamma^{-0.76}(T_r - T_s) \quad (13.187)$$

$$h = \sqrt{\frac{n}{m}} A(7.43\ln(\Gamma) - 1.35) + \frac{1}{2}h_s \quad (13.188)$$

where T_r is the return temperature (K); T_{oz} is the occupied subzone temperature (K); h is the interface height (m); and Γ is defined above.

13.2.4.4 Implementation

The implementation closely follows the procedure described in the displacement ventilation zone model. The model predicts two temperatures that characterize the two main levels in the stratification of the room:

1. An occupied subzone temperature T_{oc} representing the temperature of the occupied region;
2. An upper level temperature T_{mx} representing the temperature of the upper, mixed region and the outflow temperature.

We will use Equation 13.188 to calculate the interface height and do a heat balance calculation on each subzone. Γ is given by Equation 13.183. The supply air flow rate \dot{V} is obtained by summing all the air flows entering the zone: supply air, infiltration, ventilation, and inter-zone flow. The heat gain \dot{Q} is estimated by summing all the convective internal gains located in the occupied subzone – task lights, people, equipment – and dividing this power equally among the n plumes. With these assumptions we can describe the implementation.

The UCSD UFI model is controlled by the subroutine *ManageUCSDUFModels* which is called from the *RoomAirModelManager*. The *RoomAirModelManager* selects which zone model will be used for each zone.

The calculation is done in subroutine *CalcUCSDUI*. First we calculate the convective heat gain going into the upper and lower regions.

$$\begin{aligned} \dot{Q}_{ocz} = & \dot{Q}_{oc,conv} + \dot{Q}_{tl,conv} + \dot{Q}_{eleq,conv} + \dot{Q}_{gaseq,conv} + \dot{Q}_{otheq,conv} + \dot{Q}_{hw,conv} + \dot{Q}_{stmeq,conv} \\ & + \dot{Q}_{bb,conv} + \dot{Q}_{waterheater,conv} + \dot{Q}_{fuelcell,conv} \end{aligned} \quad (13.189)$$

$$\dot{Q}_{mxz} = \dot{Q}_{gl,conv} + \dot{Q}_{ltp} + \dot{Q}_{htrad,conv} \quad (13.190)$$

$$\dot{Q}_{tot,conv} = \dot{Q}_{ocz} + \dot{Q}_{mxz} \quad (13.191)$$

Next we sum up the inlet air flows in the form of MCP (mass flow rate times the air specific heat capacity) and MCPT (mass flow rate times C_p times air temperature).

$$MCP_{zone} = MCP_i + MCP_{vent} + MCP_{mix} \quad (13.192)$$

$$MCP_{sys} = \sum_{inlets} \dot{m}_i C_{p,i} \quad (13.193)$$

$$\dot{m}_{systot} = \sum_{inlets} \dot{m}_i \quad (13.194)$$

$$MCP_{tot} = MCP_{zone} + MCP_{sys} \quad (13.195)$$

$$MCPT_{zone} = MCPT_i + MCPT_{vent} + MCPT_{mix} \quad (13.196)$$

$$MCPT_{sys} = \sum_{inlets} \dot{m}_i C_{p,i} T_i \quad (13.197)$$

$$MCPT_{tot} = MCPT_{zone} + MCPT_{sys} \quad (13.198)$$

The number of plumes per occupant $N_{plumesperspers}$ is a user input. The total number of plumes in the zone is:

$$N_{plumes} = N_{occ} \cdot N_{plumespersperson} \quad (13.199)$$

Using this we calculate the total power in the plumes and the power per plume.

$$\dot{Q}_{plumes} = \dot{Q}_{ocz} \quad (13.200)$$

$$\dot{Q}_{perplume} = \dot{Q}_{plumes} / N_{plumes} \quad (13.201)$$

The number of diffusers per plumes is also a user input. To obtain the number of diffusers in the zone:

$$N_{diffusers} = N_{plumes} \cdot N_{diffusersperplume} \quad (13.202)$$

The area A_{diff} is also a user input. For swirl diffusers and for displacement diffusers this area is used as input. For the variable area diffusers, though, we calculate the area. We assume 400 ft/min velocity at the diffuser and a design flow rate per diffuser is 150 cfm (.0708 m³/s). The design area of the diffuser is 150 ft³/min / 400 ft/min = .575 ft² = .035 m². Then the variable area each time step is

$$A_{diff} = \dot{m}_{systot} / (.0708 \cdot N_{diffusers}) \quad (13.203)$$

We now calculate the height fraction Fr_{hb} (height of boundary layer divided by the total zone height).

$$\Gamma = \frac{(\dot{m}_{systot} \cdot \cos(\theta_{throw}))^{3/2}}{N_{plumes} (N_{diffusersperplume} \cdot A_{diff})^{5/4} (0.0281 \cdot 0.001 \cdot \dot{Q}_{plumes})^{1/2}} \quad (13.204)$$

$$Fr_{hb} = \frac{(N_{diffusersperplume} \cdot A_{diff})^{1/2} (7.43 \ln(\Gamma) - 1.35 + 0.5H_s)}{H_{ceil}} \quad (13.205)$$

where θ_{throw} is a user input: the angle between the diffuser slots and vertical; and H_s is the source height above the floor (m).

Next we iterate over the following 2 steps.

13.2.4.5 Iterative procedure

1. Call subroutine *HcUCSDUF* to calculate a convective heat transfer coefficient for each surface in the zone, an effective air temperature for each surface, and HA_{mx} , HAT_{mx} , HA_{oc} , HAT_{oc} . Here HA is $\sum_{surfaces} h_{c,i} \cdot A_i$ for a region and HAT is $\sum_{surfaces} h_{c,i} \cdot A_i \cdot T_i$ for a region. The sum is over all the surfaces bounding the region; $h_{c,i}$ is the convective heat transfer coefficient for surface i , A_i is the area of surface i , and T_i is the surface temperature of surface i .
2. Calculate the two subzone temperatures: T_{oc} and T_{mx} .

The h_c 's calculated in step 1 depend on the subzone temperatures. In turn the subzone temperatures depend on the HA and HAT 's calculated in step 1. Hence the need for iteration.

Next we describe Steps 1 and 2 in more detail.

13.2.4.6 Step 1

Subroutine *HcUCSDUF* is quite straightforward. It loops through all the surfaces in each zone and decides whether the surface is located in the upper, mixed subzone or the lower, occupied subzone, or if the surface is in both subzones. If entirely in one subzone the subzone temperature is stored in the surface effective temperature variable *SurfTempEffBulkAir(SurfNum)* and h_c for the surface is calculated by a call to subroutine *CalcDetailedHcInForDVModel*. This routine uses the “detailed” natural convection coefficient calculation that depends on surface tilt and $\Delta T^{1/3}$. This calculation is appropriate for situations with low air velocity.

For surfaces that bound 2 subzones, the subroutine calculates h_c for each subzone and then averages them, weighting by the amount of surface in each subzone.

During the surface loop, once the h_c for a surface is calculated, the appropriate subzone HA and HAT sums are incremented. If a surface is in 2 subzones the HA and HAT for each subzone are incremented based on the area of the surface in each subzone.

13.2.4.7 Step 2

The calculation of subzone temperatures follows the method used in the **ZoneTempPredictor-Corrector** module and described in the section **Basis for the System and Zone Integration**. Namely a third order finite difference expansion of the temperature time derivative is used in updating the subzone temperatures. Otherwise the subzone temperatures are obtained straightforwardly by solving an energy balance equation for each subzone.

$$\begin{aligned} T_{oc} &= \frac{(C_{air,oc} \cdot (3 \cdot T_{-1,oc} - (3/2) \cdot T_{-2,oc} + (1/3) \cdot T_{-3,oc}) + \dot{Q}_{ocz} \cdot Fr_{gains} + HAT_{oc} + MCP_{tot})}{((11/6) \cdot C_{air,oc} + HA_{oc} + MCP_{tot})} \\ T_{mx} &= \frac{(C_{air,mx} \cdot (3 \cdot T_{-1,mx} - (3/2) \cdot T_{-2,mx} + (1/3) \cdot T_{-3,mx}) + \dot{Q}_{ocz} \cdot (1 - Fr_{gains}) + \dot{Q}_{mxz} + HAT_{mx} + T_{oc} \cdot MCP_{tot})}{((11/6) \cdot C_{air,mx} + HA_{mx} + MCP_{tot})} \end{aligned} \quad (13.206)$$

Here $C_{air,oc}$ and $C_{air,mx}$ are the heat capacities of the air volume in each subzone. $C_{air,mx}$ is calculated by:

$$R_{air,mx} = V_{mx} \cdot (\Delta z_{mx} / z_{ceil}) \cdot \rho_{air,mx} \cdot c_{p,air,mx} \cdot Mul_{cap} / (\Delta t_z \cdot 3600) \quad (13.207)$$

$$c_{air,mx} = R_{air,mx} \cdot \Delta t_z / \Delta t_{sys} \quad (13.208)$$

The gains fraction Fr_{gains} is a user input via a schedule. It is the fraction of the convective gains in the occupied subzone that remain in that subzone.

The other subzone air heat capacities are calculated in the same manner.

13.2.4.8 Mixed calculation

The above iterative procedure assumed that the UFAD nonuniform zone model was appropriate: i.e., conditions were favorable temperature stratification in the zone. Now that this calculation is complete and the subzone temperatures and depths calculated, we check to see if this assumption was justified. If not, zone conditions must be recalculated assuming a well-mixed zone.

If $T_{mx} < T_{oc}$ or $MCP_{tot} \leq 0$ or $H_{fr} \cdot H_{ceil} < \Delta z_{occ,min}$, then the following mixed calculation will replace the UFAD interior zone calculation.

Note: $\Delta z_{occ,min}$ is the minimum thickness of occupied subzone. It is set to 0.2 meters.

The mixed calculation iteratively calculates surface convection coefficients and room temperature just like the displacement ventilation calculation described above. In the mixed case however, only one zone temperature T_{avg} is calculated. The 3 subzone temperatures are then set equal to T_{avg} .

First, Fr_{hb} is set equal to zero.

Then the code iterates over these steps.

Calculate T_{avg} using:

$$T_{avg} = (C_{air,z} \cdot (3 \cdot T_{-1,z} - (3/2) \cdot T_{-2,z} + (1/3) \cdot T_{-3,z}) + \dot{Q}_{tot,conv} + HAT_{oc} + HAT_{mx} + MCPT_{tot}) / ((11/6) \cdot C_{air,z} + HA_{oc} + HA_{mx} + MCP_{tot}) \quad (13.209)$$

$$T_{mx} = T_{avg} \quad (13.210)$$

$$T_{oc} = T_{avg} \quad (13.211)$$

Call $HcUCSDUF$ to calculate the h_c 's.

Repeat step 1

13.2.4.9 Final calculations

The UFAD interior zone calculation finishes by calculating some report variables.

We define heights:

$$H_{trans} = Fr_{hb} \cdot H_{ceil} \quad (13.212)$$

$$H_{mxavg} = (H_{ceil} + H_{trans}) / 2 \quad (13.213)$$

$$H_{ocavg} = H_{trans} / 2 \quad (13.214)$$

Using the user defined comfort height we calculate the comfort temperature.

If mixing:

$$T_{comf} = T_{avg} \quad (13.215)$$

If UFAD:

If $H_{comf} < H_{ocavg}$:

$$T_{comf} = T_{occ} \quad (13.216)$$

Else if $H_{comf} \geq H_{ocavg}$ and $H_{comf} < H_{mxavg}$:

$$T_{comf} = (T_{oc}(H_{mxavg} - H_{comf}) + T_{mx}(H_{comf} - H_{ocavg})) / (H_{mxavg} - H_{ocavg}) \quad (13.217)$$

Else if $H_{comf} \geq H_{mxavg}$ and $H_{comf} < H_{ceil}$:

$$T_{comf} < T_{mx} \quad (13.218)$$

Using the user defined thermostat height we calculate the temperature at the thermostat.

If mixing:

$$T_{stat} < T_{avg} \quad (13.219)$$

If UFAD:

If $H_{stat} < H_{ocavg}$:

$$T_{stat} = T_{occ} \quad (13.220)$$

Else if $H_{stat} \geq H_{ocavg}$ and $H_{stat} < H_{mxavg}$:

$$T_{stat} = (T_{oc}(H_{mxavg} - H_{stat}) + T_{mx}(H_{stat} - H_{ocavg})) / (H_{mxavg} - H_{ocavg}) \quad (13.221)$$

Else if $H_{stat} \geq H_{mxavg}$ and $H_{stat} < H_{ceil}$:

$$T_{stat} = T_{mx} \quad (13.222)$$

The average temperature gradient is:

If $H_{mxavg} - H_{ocavg} > 0.1$:

$$GradT_{avg} = (T_{mx} - T_{occ}) / (H_{mxavg} - H_{ocavg}) \quad (13.223)$$

else $GradT_{avg} = 0.0$.

Finally, the zone node temperature is set to T_{mx} .

Other variables that are reported out are Γ and ϕ .

$$\phi = (T_{mx} - T_{occ}) / (T_{mx} - T_{sup}) \quad (13.224)$$

where T_{sup} is the zone supply air temperature.

13.2.5 Under-Floor Air Distribution Exterior Zone Model

13.2.5.1 Overview

The input object `RoomAirSettings:UnderFloorAirDistributionExterior` provides a simple model for heat transfer and a nonuniform vertical temperature profile for exterior zones of a UFAD system. These zones are expected to be dominated by internal loads, a portion of which (such as occupants and workstations) will act to generate plumes, and by window solar and conduction heat gains. The solar radiation penetrating the room is not expected to generate plumes. However, a window plume is likely to be generated in sunny conditions, particularly if an interior blind is deployed. Thus the exterior UFAD zone will have potentially have plumes from people and equipment and plumes arising from the windows. The plumes act to potentially create room air stratification, depending on the type & number of diffusers, the amount and type of load, and the system flowrate. In order to better model this situation the fully-mixed room air approximation that is currently used in most whole building analysis tools is extended to a two node approach, with the purpose of obtaining a first order precision model for vertical temperature profiles for the exterior zones of UFAD systems. The use of 2 nodes allows for greatly improved prediction of thermal comfort and overall building energy performance for the increasingly popular UFAD systems.

The UCSD UFAD Exterior Zone Model is one of the non-uniform zone models provided through the Room Air Manager in EnergyPlus. The intent is to provide a selection of useful non-uniform zone air models to enable the evaluation of air-conditioning techniques that use stratified or partially stratified room air. Such techniques include displacement ventilation (DV) and underfloor air distribution (UFAD) systems. The methodology can also include natural displacement ventilation and also wind-driven cross-ventilation (CV).

13.2.5.2 Underfloor air distribution systems

UFAD systems represent, in terms of room air stratification, an intermediate condition between a well-mixed zone and displacement ventilation. Air is supplied through an underfloor plenum at low pressure through diffusers in the raised floor. The diffusers can be of various types: e.g., swirl, variable-area, displacement, and produce more or less mixing in the zone. UFAD systems are promoted as saving energy due to: higher supply air temperature; low static pressure; cooler conditions in the occupied subzone than in the upper subzone; and sweeping of some portion of the convective load (from ceiling lights, for instance) into the return air without interaction with the occupied region of the zone.

Modeling a UFAD system is quite complex and involves considerably more than just a non-uniform zone model. The zones' coupling to the supply and return plenums must be modeled accurately (particularly radiative transfer from a warm ceiling to a cool floor and on into the supply plenum by conduction). The supply plenum must be accurately modeled, giving a good estimate of the supply air temperature and conduction heat transfer between supply & return plenums through the slab. The HVAC system must be modeled including return air bypass and various types of fan powered terminal units.

The UCSD UFAD exterior zone model is similar to the UCSD interior zone model. The most obvious difference is that the exterior UFAD has 2 different types of plume sources: people & equipment and windows. Like the UCSD UFAD interior model it is a plume equation based multi-layer model (2 layers in this case). The zone is modeled as being divided into 2 well separated subzones which we denote as "occupied" and "upper". Each subzone is treated as having a single

temperature. The boundary between the 2 subzones moves up & down each time step as a function of zone loads and supply air flow rate. Thus at each HVAC time step, the height of the boundary above the floor must be calculated, portions of surfaces assigned to each subzone, and a separate convective heat balance performed on each subzone.

13.2.5.3 Model Description

As in the interior zone case, we define 2 dimensionless parameters: Γ and ϕ . The definitions of the 2 parameters are the same as in the previous section (Equations 13.181, 13.182, 13.183, 13.184, and 13.185). As in the previous case, the experimental data can be plotted versus Γ and lines fitted to the data give the following formulas for occupied subzone temperature and interface height.

$$T_{oz} = T_r - 1.4\Gamma^{-0.6}(T_r - T_s) \quad (13.225)$$

$$h = \sqrt{\frac{n}{m}}A(11.03\ln(\Gamma) - 10.73) + \frac{1}{2}h_s \quad (13.226)$$

where T_{oz} is the occupied subzone temperature (K); T_r is the return temperature (K); Γ is the dimensionless height parameter defined above; T_s is the supply temperature (K); h is the interface height (m); n is the number of diffusers; m is the number of heat sources; A is the effective area of a diffuser (m^2); and h_s is the vertical position of the heat sources (m). The formula for T_r is the same as in the previous section.

13.2.5.4 Implementation

The implementation closely follows the procedure described in the UFAD interior zone model. The model predicts two temperatures that characterize the two main levels in the stratification of the room:

1. An occupied subzone temperature T_{oc} representing the temperature of the occupied region;
2. An upper level temperature T_{mx} representing the temperature of the upper, mixed region and the outflow temperature.

We will use Equation 13.226 to calculate the interface height and do a heat balance calculation on each subzone. Γ is given by Equation 13.183. The supply air flow rate \dot{V} is obtained by summing all the air flows entering the zone: supply air, infiltration, ventilation, and inter-zone flow. The heat gain \dot{Q} is estimated by summing all the convective internal gains located in the occupied subzone – task lights, people, equipment – and adding to this the convective gain coming from the window surface. With these assumptions we can describe the implementation.

The UCSD UFE model is controlled by the subroutine *ManageUCSDUFModels* which is called from the *RoomAirModelManager*. The *RoomAirModelManager* selects which zone model will be used for each zone.

The calculation is done in subroutine *CalcUCSDUEI*. First we calculate the convective heat gain going into the upper and lower regions.

$$\begin{aligned} \dot{Q}_{ocz} = & \dot{Q}_{oc,conv} + \dot{Q}_{tl,conv} + \dot{Q}_{eleq,conv} + \dot{Q}_{gaseq,conv} + \dot{Q}_{otheq,conv} + \dot{Q}_{hw,conv} + \dot{Q}_{stmeq,conv} \\ & + \dot{Q}_{bb,conv} + \dot{Q}_{waterheater,conv} + \dot{Q}_{fuelcell,conv} \end{aligned} \quad (13.227)$$

$$\dot{Q}_{mxz} = \dot{Q}_{gl,conv} + \dot{Q}_{ltp} + \dot{Q}_{htrad,conv} \quad (13.228)$$

$$\dot{Q}_{tot,conv} = \dot{Q}_{ocz} + \dot{Q}_{mxz} \quad (13.229)$$

Next we sum up the inlet air flows in the form of MCP (mass flow rate times the air specific heat capacity) and MCPT (mass flow rate times C_p times air temperature).

$$MCP_{zone} = MCP_i + MCP_{vent} + MCP_{mix} \quad (13.230)$$

$$MCP_{sys} = \sum_{inlets} \dot{m}_i C_{p,i} \quad (13.231)$$

$$\dot{m}_{systot} = \sum_{inlets} \dot{m}_i \quad (13.232)$$

$$MCP_{tot} = MCP_{zone} + MCP_{sys} \quad (13.233)$$

$$MCPT_{zone} = MCPT_i + MCPT_{vent} + MCPT_{mix} \quad (13.234)$$

$$MCPT_{sys} = \sum_{inlets} \dot{m}_i C_{p,i} T_i \quad (13.235)$$

$$MCPT_{tot} = MCPT_{zone} + MCPT_{sys} \quad (13.236)$$

For exterior zone model, we assume one plume: $N_{plumes} = 1$. The number of diffusers in the zone $N_{diffusers}$ is a user input.

The area A_{diff} is also a user input. For swirl diffusers, linear bar grilles, and displacement diffusers this area is used as input. For the variable area diffusers, though, we calculate the area. We assume 400 ft/min velocity at the diffuser and a design flow rate per diffuser is 150 cfm (.0708 m³/s). The design area of the diffuser is 150 ft³/min / 400 ft/min = .575 ft² = .035 m². Then the variable area each time step is:

$$A_{diff} = \dot{m}_{systot} / (.0708 \cdot N_{diffusers}) \quad (13.237)$$

We now make an initial estimate of the convective gain from the windows.

$$\dot{Q}_{win,conv} = \sum_{i=1, n_{win}} h_{c,i} A_{win,i} T_{winsurf,i} - h_{c,i} A_{win,i} T_{mat} \quad (13.238)$$

Then:

$$\dot{Q}_{plumes} = \dot{Q}_{ocz} + \dot{Q}_{win,conv} \quad (13.239)$$

We now calculate the height fraction Fr_{hb} (height of boundary layer divided by the total zone height).

$$\Gamma = \frac{(\dot{m}_{systot} \cdot \cos(\theta_{throw}))^{3/2}}{(N_{diffusers} \cdot A_{diff})^{5/4} (0.0281 \cdot 0.001 \cdot \dot{Q}_{plumes})^{1/2}} \quad (13.240)$$

$$Fr_{hb} = \frac{(N_{diffusers} \cdot A_{diff})^{1/2} (11.03 \ln(\Gamma) - 10.73 + 0.5 H_s)}{H_{ceil}} \quad (13.241)$$

where θ_{throw} is a user input: the angle between the diffuser slots and vertical; and H_s is the source height above the floor (m).

Next we iterate over the following 2 steps.

13.2.5.5 Iterative procedure

1. Call subroutine *HcUCSDUF* to calculate a convective heat transfer coefficient for each surface in the zone, an effective air temperature for each surface, and HA_{mx} , HAT_{mx} , HA_{oc} , HAT_{oc} , $HA_{mx,win}$, $HAT_{mx,win}$, $HA_{oc,win}$, and $HAT_{oc,win}$. Here HA is $\sum_{surfaces} h_{c,i} \cdot A_i$ for a region and HAT is $\sum_{surfaces} h_{c,i} \cdot A_i \cdot T_i$ for a region. The sum is over all the surfaces bounding the region; $h_{c,i}$ is the convective heat transfer coefficient for surface i , A_i is the area of surface i , and T_i is the surface temperature of surface i . Variables with the *win* subscript are summed over window surfaces only. Then the convective gain from the window is recalculated using Equation 13.242 and the power in the plume is recalculated: $\dot{Q}_{plumes} = \dot{Q}_{ocz} + \dot{Q}_{win,conv}$.
2. Calculate the two subzone temperatures: T_{oc} and T_{mx} .

$$\dot{Q}_{win,conv} = HAT_{mx,win} + HAT_{oc,win} - HA_{mx,win} T_{mx} - HA_{oc,win} T_{oc} \quad (13.242)$$

The h_c 's calculated in step 1 depend on the subzone temperatures. In turn the subzone temperatures depend on the HA and HAT 's calculated in step 1. Hence the need for iteration.

Next we describe Steps 1 and 3 in more detail.

13.2.5.6 Step 1

Subroutine *HcUCSDUF* is quite straightforward. It loops through all the surfaces in each zone and decides whether the surface is located in the upper, mixed subzone or the lower, occupied subzone, or if the surface is in both subzones. If entirely in one subzone the subzone temperature is stored in the surface effective temperature variable *SurfTempEffBulkAir(SurfNum)* and h_c for the surface is calculated by a call to subroutine *CalcDetailedHcInForDVMModel*. This routine uses the “detailed” natural convection coefficient calculation that depends on surface tilt and $\Delta T^{1/3}$. This calculation is appropriate for situations with low air velocity.

For surfaces that bound 2 subzones, the subroutine calculates h_c for each subzone and then averages them, weighting by the amount of surface in each subzone.

During the surface loop, once the h_c for a surface is calculated, the appropriate subzone HA and HAT sums are incremented. If a surface is in 2 subzones the HA and HAT for each subzone are incremented based on the area of the surface in each subzone. The subroutine calculates a separate HA and HAT for the windows for use in calculating the window convective gain.

13.2.5.7 Step 2

The calculation of subzone temperatures follows the method used in the **ZoneTempPredictor-Corrector** module and described in the section **Basis for the System and Zone Integration**. Namely a third order finite difference expansion of the temperature time derivative is used in updating the subzone temperatures. Otherwise the subzone temperatures are obtained straightforwardly by solving an energy balance equation for each subzone.

$$\begin{aligned} T_{oc} &= \frac{(C_{air,oc} \cdot (3 \cdot T_{-1,oc} - (3/2) \cdot T_{-2,oc} + (1/3) \cdot T_{-3,oc}) + \dot{Q}_{ocz} \cdot Fr_{gains} + HAT_{oc} + MCPT_{tot})}{((11/6) \cdot C_{air,oc} + HA_{oc} + MCP_{tot})} \\ T_{mx} &= \frac{(C_{air,mx} \cdot (3 \cdot T_{-1,mx} - (3/2) \cdot T_{-2,mx} + (1/3) \cdot T_{-3,mx}) + \dot{Q}_{ocz} \cdot (1 - Fr_{gains}) + \dot{Q}_{mxz} + HAT_{mx} + T_{oc} \cdot MCP_{tot})}{((11/6) \cdot C_{air,mx} + HA_{mx} + MCP_{tot})} \end{aligned} \quad (13.243)$$

Here $C_{air,oc}$ and $C_{air,mx}$ are the heat capacities of the air volume in each subzone. $C_{air,mx}$ is calculated by:

$$R_{air,mx} = V_{mx} \cdot (\Delta z_{mx} / z_{ceil}) \cdot \rho_{air,mx} \cdot c_{p,air,mx} \cdot Mul_{cap} / (\Delta t_z \cdot 3600) \quad (13.244)$$

$$c_{air,mx} = R_{air,mx} \cdot \Delta t_z / \Delta t_{sys} \quad (13.245)$$

The gains fraction Fr_{gains} is a user input via a schedule. It is the fraction of the convective gains in the occupied subzone that remain in that subzone.

The other subzone air heat capacities are calculated in the same manner.

13.2.5.8 Mixed calculation

The above iterative procedure assumed that the UFAD zone model was applicable: i.e., conditions were favorable temperature stratification in the zone. Now that this calculation is complete and the subzone temperatures and depths calculated, we check to see if this assumption was justified. If not, zone conditions must be recalculated assuming a well-mixed zone.

If $T_{mx} < T_{oc}$ or $MCP_{tot} \leq 0$ or $H_{fr} \cdot H_{ceil} < \Delta z_{occ,min}$, then the following mixed calculation will replace the UFAD exterior zone calculation.

Note: $\Delta z_{occ,min}$ is the minimum thickness of occupied subzone. It is set to 0.2 meters.

The mixed calculation iteratively calculates surface convection coefficients and room temperature just like the displacement ventilation calculation described above. In the mixed case however, only one zone temperature T_{avg} is calculated. The 2 subzone temperatures are then set equal to T_{avg} .

First, Fr_{hb} is set equal to zero.

Then the code iterates over these steps.

Calculate T_{avg} using:

$$\begin{aligned} T_{avg} &= (C_{air,z} \cdot (3 \cdot T_{-1,z} - (3/2) \cdot T_{-2,z} + (1/3) \cdot T_{-3,z}) \\ &\quad + \dot{Q}_{tot,conv} + HAT_{oc} + HAT_{mx} MCP_{tot}) / ((11/6) \cdot C_{air,z} + HA_{oc} + HA_{mx} + MCP_{tot}) \end{aligned} \quad (13.246)$$

$$T_{mx} = T_{avg} \quad (13.247)$$

$$T_{oc} = T_{avg} \quad (13.248)$$

Call *HcUCSDUF* to calculate the h_c 's.

Repeat step 1.

13.2.5.9 Final calculations

The UFAD exterior zone calculation finishes by calculating some report variables.

We define heights:

$$H_{trans} = Fr_{hb} \cdot H_{ceil} \quad (13.249)$$

$$H_{mxavg} = (H_{ceil} + H_{trans}) / 2 \quad (13.250)$$

$$H_{ocavg} = H_{trans} / 2 \quad (13.251)$$

Using the user defined comfort height we calculate the comfort temperature.

If mixing:

$$T_{comf} = T_{avg} \quad (13.252)$$

If UFAD:

If $H_{comf} < H_{ocavg}$:

$$T_{comf} = T_{occ} \quad (13.253)$$

Else if $H_{comf} \geq H_{ocavg}$ and $H_{comf} < H_{mxavg}$:

$$T_{comf} = (T_{oc}(H_{mxavg} - H_{comf}) + T_{mx}(H_{comf} - H_{ocavg})) / (H_{mxavg} - H_{ocavg}) \quad (13.254)$$

Else if $H_{comf} \geq H_{mxavg}$ and $H_{comf} < H_{ceil}$:

$$T_{comf} < T_{mx} \quad (13.255)$$

Using the user defined thermostat height, we calculate the temperature at the thermostat.

If mixing:

$$T_{stat} = T_{avg} \quad (13.256)$$

If UFAD:

If $H_{stat} < H_{ocavg}$:

$$T_{stat} = T_{occ} \quad (13.257)$$

Else if $H_{stat} \geq H_{ocavg}$ and $H_{stat} < H_{mxavg}$:

$$T_{stat} = (T_{oc}(H_{mxavg} - H_{stat}) + T_{mx}(H_{stat} - H_{ocavg})) / (H_{mxavg} - H_{ocavg}) \quad (13.258)$$

Else if $H_{stat} \geq H_{mxavg}$ and $H_{stat} < H_{ceil}$:

$$T_{stat} = T_{mx} \quad (13.259)$$

The average temperature gradient is:

If $H_{mxavg} - H_{occavg} > 0.1$:

$$GradT_{avg} = (T_{mx} - T_{occ}) / (H_{mxavg} - H_{occavg}) \quad (13.260)$$

else $GradT_{avg} = 0.0$.

Finally, the zone node temperature is set to T_{mx} .

Other variables that are reported out are Γ and ϕ .

$$\phi = (T_{mx} - T_{occ}) / (T_{mx} - T_{sup}) \quad (13.261)$$

where T_{sup} is the zone supply air temperature.

13.2.6 Cross Ventilation Room Air Model

13.2.6.1 Overview

The input object RoomAirSettings:CrossVentilation provides a simple model, developed by UCSD, for heat transfer and vertical temperature profile prediction in cross ventilated rooms. This model was developed using scaling analysis, experimental correlations, computational fluid dynamics, and approximate solutions of the Navier-Stokes equations. The model distinguishes two regions in the room, the main jet region and the recirculations, and predicts characteristic airflow velocities and average air temperatures. The model consists of a set of analytical expressions that clearly display the first order effects of room geometry and inflow characteristics on Cross Ventilation airflow and heat transfer.

13.2.6.2 Cross-Ventilation

The CV model is developed from analysis of the flow structure inside a cross-ventilated room, which naturally divides into distinct jet and recirculation flow regions. The flows are calculated for different room and opening geometries using CFD. Correlations with room and aperture parameters are then deduced for a characteristic temperature and velocity in the jet and recirculation regions.

The SS 2-opening model is developed from analysis of wind tunnel data for pressure and ventilation rates, correlating the flow rate with the pressure difference between the two openings, with contributions from both the mean and unsteady components. The local velocity estimate is also based on wind tunnel data, and gives the velocity as a function of wind angle.

13.2.6.3 Approach

With the widespread availability of air conditioning, natural ventilation became a rare feature in commercial buildings in the US. The recent resurgence of the use of natural ventilation relies on systems whose performance can be predicted and controlled, often working in conjunction with mechanical ventilation and cooling systems in hybrid ventilation configurations. In this contemporary approach natural ventilation deals with thermal and air renewal requirements in the cold and mild season and often plays a limited role in the warm season (due to the need to control indoor velocities and noise levels). Whereas traditional natural ventilation systems often use large openings (1-4m²), both recent and expected future examples tend to use smaller openings (0.2-1m²), often in multiple opening configurations that allow for efficient heat removal with controlled indoor velocities.

The modeling approach used is based on simplified solutions of the Navier Stokes equations that are integrated into scaling formulae that predict relevant flow quantities (characteristic velocities and temperatures) in distinct regions of the flow. The scaling expressions that will be developed use the principle of flow similarity: for a given room geometry and flow regime (either laminar or turbulent), the flow pattern is constant. In the present case, where the goal is to predict internal velocities using as input the inflow velocity (that can be estimated by the airflow rate predicted by the AirflowNetwork model), the principle can be stated as:

$$(\text{Velocity in a given position in the room}) = (\text{Inflow velocity}) \times (\text{Constant})$$

The constant is non-dimensional and depends on the position or room zone where the prediction is being made. For a given geometry the constant can be measured experimentally or inferred from a detailed CFD simulation. It is expected that the constant may depend on non-dimensional room geometry parameters that can be inferred from a careful analysis of the flow. The proposed CV model uses a set of CFD simulations, in conjunction with simplified solutions of the Navier Stokes equations, to obtain the constants and their dependence on room geometry features.

The updated CV model proposed in this document was developed using inlet areas A_{in} and room cross-section areas A_{RM} in the following range:

$$0.5\% < A_{in}/A_{RM} < 5\%$$

whereas the existing model used:

$$3.2\% < A_{in}/A_{RM} < 21\%$$

The room lengths for which these models are expected to be applied range between the smallest room size of 4m and the maximum achievable CV room flushing length of 15-18m.

Figure 13.18: Development of an axisymmetric jet from airflow through a window.

Air flows into the room through an inflow window in the form of an approximately axisymmetric jet, with characteristic diameter $L = A_{in}^{1/2}$, that is confined by the room surfaces (see Figure 13.19). The initial portion of the jet (up to six diameters) is called the potential core and is characterized

by shear layer development along the perimeter of the jet. After this phase the jet transitions into a self similar profile whose centerline velocity decays as $1/x'$, where $x' = x/D$ (Awbi, 2003).

For the relevant room length range the geometries used in the two models result in:

New model: $6 < x' < 60$

Existing model: $2 < x' < 18$

The smaller openings used in the new model result in significantly more space for jet development along the room length. In all but the shortest rooms the jet will enter the fully developed stage characterized by a $1/x'$ centerline velocity decay rate. For this reason, the updated model uses the average jet velocity profile as opposed to shear layer momentum transfer.

13.2.6.4 Components of the flow

Figure 13.18 shows the schematic development of a free axisymmetric jet in an unconfined environment, and Figure 13.19 depicts the confinement effects. The air entrained by the jet is detrained at the outlet, creating two recirculation zones that do not exist in a free jet.

The recirculation flow is similar to the flow in a lid driven cavity, where here the driving force is the confined jet flow. Turbulent lid driven cavity flows have been shown to have self-similar velocity profiles, as shown in Figure 13.20.

The model is based on the hypothesis that the flow is composed of:

A – Lid driven cavity flows (in the recirculation regions).

B – A confined axisymmetric jet flow.

Figure 13.19: Top view of a cross ventilated room. The air entrained by the jet is detrained at the outlet, typically creating two recirculation zones.

The goal of the model is to obtain the value and functional form of the constant term shown in the scaling laws for the characteristic average velocities in the two flow regions: jet and recirculation

Figure 13.20: Top view of one half of a cross ventilated room. The flow is approximately composed of a confined jet and two lid driven cavity flows (one on each side).

regions.

To estimate the average jet velocity we integrate along the depth of the room (including both the core region and the $1/x'$ velocity decay region) to derive an average maximum jet velocity, $V_{J,m}$:

$$V_{J,m} = U_{in} \sqrt{A_{in}} \left\{ 6 + 6.3 \ln \left(D^* / 6 \sqrt{A_{in}} \right) \right\} / D^* \quad (13.262)$$

(To allow for wind angle effects the room depth D has been replaced by D^* - see a later section.) The lid-driven cavity flow profile that characterizes the recirculation region has a maximum velocity that is approximately one half of the driving velocity, which in this case is due to the jet. For this reason we define the separation between the two regions along the virtual surface where the jet reaches 50% of its maximum, centerline, velocity.

The analysis of the flow revealed that the room containment effect leads to higher velocities for cases that combine a large inflow opening with a small room cross-section area. In order to account for this effect we propose to use the following non-dimensional scaling parameter:

$$C_{RM} = (A_{in}/A_{RM})^{1/2} \quad (13.263)$$

The expression used for the scaling of the average jet velocity is then:

$$U_J = C_1 C_{RM} V_{J,m} \quad (13.264)$$

or

$$U_J = C_1 \frac{Q_{in}}{\sqrt{A_{in} A_{RM}}} (V_{J,m}/U_{in}) \quad (13.265)$$

where the constant C_1 will be obtained from the results of a set of CFD simulations shown in the next section.

In addition to the jet velocity the characteristic recirculation flow velocity U_R is also an interesting parameter that, according to the self-similar flow profile hypothesis shown in Figure 13.20, should scale with a similar expression to the one shown above for the jet (although with a different correlation constant, C_2). The modeling hypothesis can also be tested by evaluating its capability

to predict the maximum recirculation flow rate, which can be predicted by multiplying the average velocity by the room cross-section area:

$$Q_R = C_3 \frac{Q_{in}}{C_{RM}} (V_{J,m}/U_{in}) \quad (13.266)$$

Because of the self-similar velocity profile shape that occurs in the recirculation, the near wall velocity (used to predict forced convection) can be estimated simply by multiplying the characteristic recirculation velocity by two.

The expressions obtained apply in the turbulent regime (because the CFD simulations on which they are based are for that regime). Both velocity correlations presented below have the functional form:

$$V = aX + b \quad (13.267)$$

where a is C_1 , C_2 or C_3 , X is a velocity scale and b is a constant that results from the best fit. The model has a lower limit on the value of X : if X is too small the flow is no longer turbulent. This limit implies that the point $X = 0$ is never achieved, avoiding the unrealistic prediction of $V(0) = b$.

In addition to the velocity and airflow rate predictions described above it is also essential to predict the temperature variations in the two zones of the flow. In most cases these variations will be positive due to the internal sensible heat gains. However, as a result of room surface heat transfer, in some cases the variations may be negative. Analysis of the CFD simulations that are presented in the next section revealed that approximately all the exhaust air comes from the jet regions. For this reason, the heat gains affect the two regions differently:

- Heat gains in the jet region only affect this region (no temperature increase in the recirculation regions).
- Heat gains in the recirculations affect both jet and recirculation regions (because they must be exhausted by the jets).

In order to predict the temperature increase, heat gains were inserted into the recirculation regions for different room geometries in the set of simulations presented in the next section. The volume containing the heat gains extended over the whole depth of the room, from floor to ceiling, and in the lateral direction from halfway between the window edge and the wall all the way to the wall. Applying energy conservation principles to predict the temperature increase in the jet and recirculation region as a function of the sensible heat gains in each region (the sum of internal gains and internal surface heat transfer) we can obtain the average value of temperature increase in each region:

$$\Delta T_J = C_{T,J} \frac{q''_{RM}}{\rho c_p Q_{in}} \quad (13.268)$$

$$\Delta T_R = C_{T,R} \frac{q''_{RM}}{\rho c_p Q_{in}} \quad (13.269)$$

where q''_{RM} is the total internal heat gain for the room, ρ and c_p are the density and specific heat capacity of air, respectively, and $C_{T,J}$, $C_{T,R}$ are constants.

13.2.6.5 Results

Table 13.3 lists the cases used to develop the updated CV model, which predicts the output variables defined in Table 13.4 (see also Figure 13.21). Figures 13.22, 13.23, and 13.24 show plots of the data derived from the CFD simulations of these test cases, and the lines giving the best fit to the data. Table 13.5 summarizes the correlation formulae and constants. Finally, Table 13.6 provides estimates for the error of the correlation in each test case.

Figure 13.21: Jet and recirculation regions in typical vertical cross-section through room (y-z plane). Jet boundary occurs where jet velocity has fallen to 50% of centerline maximum. Remainder of cross-section is treated as recirculation. Volumetric heat sources are

Table 13.4: Definitions of output variables

Output variable	Symbol	Units	Definition
Jet velocity	U_J	m/s	Volume-averaged jet region velocity. The averaging volume is bounded at each x along the room depth by the line in the y - z plane where the jet velocity drops to 50% of its maximum centerline value.
Recirculation zone velocity	U_R	m/s	Area-averaged velocity in the y - z plane with maximum flow. The averaging area is the recirculation part of the room cross-section. Typically the plane of maximum flow occurs at $x \sim 2D/3$ ($D/3$ before the outlet).
Recirculation zone flow rate	Q_R	m^3/s	Total flow rate for the recirculation regions in the plane of maximum flow (see above).
Jet temperature rise	ΔT_J	$^{\circ}\text{C}$	Volume-averaged temperature variations in the jet region, over the same volume used to define the jet velocity average.
Recirculation zone temperature rise	ΔT_R	$^{\circ}\text{C}$	Volume-average temperature variations in the recirculation region. The average is calculated over the cuboidal volume placed in each recirculation containing the volumetric sensible heat gains (see main text).

See also Figure 13.21. Note the x -coordinate is along the room, the y -coordinate is across the room and the z -coordinate is vertical.

13.2.6.6 Wind angle effects

When the incoming wind is not normal to the façade the jet enters the room at an angle, as shown in Figure 13.25.

This oblique geometry has two main effects on the flow and consequent correlation predictions:

- The inflow area is reduced, creating a larger inflow velocity for the same flow rate.
- The room flow path length is increased, from D to D^* , resulting in a larger apparent depth.
- The first effect increases indoor velocities while the second effect decreases the velocities.

13.2.6.7 Multiple apertures

CFD simulations for rooms with more than one inflow aperture show that the model can be applied to these configurations with minimal adjustments. As a result of increased dissipation in the central recirculation region, where two distinct recirculation flows collide (Figure 13.26), the airflow velocities are reduced by 5-10%, as shown in the charts in Figure 13.27.

Heat transfer in recirculating flows

In most cross ventilation flows with recirculations the mixing between recirculation and inflow jet is only partial. Figure 13.28 shows a schematic representation of the heat transfer process (showing a top view of one half of a symmetrical room). The flow is divided into three distinct streams with connected temperature variations:

- The main jet (labeled J in the figure).

Figure 13.25: Schematic of jet resulting from wind at angle ϕ to façade.

- The part of the recirculation flow that exchanges heat with the jet (label R).
- The wall boundary layer part of the recirculation flow (label W).

The light gray arrows show flow direction. The dark gray arrows show heat transfer in the shear layer. The recirculation region coordinate system is shown in the figure, with coordinate r varying between 0 and L .

13.2.6.8 Heat transfer in a shear layer

It is possible to use a formulation with a heat transfer area, a convection heat transfer coefficient and an average shear layer temperature difference to model the heat exchange between jet and recirculation flows:

$$Q_{y=0} = A_{SL} h_{SL} \Delta T_{SL} \quad (13.270)$$

$$A_{SL} = LP \quad (13.271)$$

$$h_{SL} = \frac{\rho C_P F}{C_D A_{IN} 4 \sigma \sqrt{\pi}} \quad (13.272)$$

Locally, the heat transfer process is driven by the variable, local, temperature difference:

$$\rho C_P F \frac{\partial T_J(x)}{\partial x} = - \frac{A_{SL} h_{SL}}{L} (T_J(x) - T_R(x)) = \frac{P}{C_D A_{IN} 4 \sigma \sqrt{\pi}} (T_J(x) - T_R(x)) \quad (13.273)$$

Figure 13.26: Flow regions for a room with 2 inlets and 2 outlets.

Figure 13.28: Top view of the flow structure in case R.

13.2.6.9 Predicting air temperature in the recirculation region of the flow

An accurate representation of system behavior must consider both the local heat transfer in the shear layer (varying along the x direction, driven by the temperature profiles $T_J(x)$ and $T_R(x)$) and the heat transfer in the wall boundary layers (with temperature $T_W(r)$). Both transfers can be modeled using differential equations, resulting in the following system of equations:

$$\begin{aligned} \rho C_p F R \frac{\partial T_W(r)}{\partial r} &= \frac{A_S h_S}{L} (T_S - T_W(r)) \\ \rho C_p F R \frac{\partial T_R(x)}{\partial x} &= \frac{A_{SL} h_{SL}}{L} (T_J(x) - T_R(x)) \\ \rho C_p F \frac{\partial T_J(x)}{\partial x} &= \frac{A_{SL} h_{SL}}{L} (T_R(x) - T_J(x)) \end{aligned} \quad (13.274)$$

The relevant boundary conditions are:

$$T_W(L) = T_R(0), T_W(0) = T_R(L), T_J(0) = T_{IN} \quad (13.275)$$

The first equation in Equation 13.274 models heat transfer in the wall layer. The second models the temperature variation of the portion of the recirculation flow that is in contact with the jet, it differs from the third equation only in a sign (the temperature variation in T_R is symmetric to the variation in T_J) and the flow rate ($F \cdot R$ for the recirculation and F for the main jet). The temperature in the recirculation region is given by:

$$T_W(r) = T_S - (T_S - T_{IN}) \frac{e^{\frac{h_S A_S}{\rho C_P R F L} r} (e^{-\frac{A_{SL} h_{SL} (1+R)}{\rho C_P R F}} - 1)}{e^{-\frac{A_{SL} h_{SL} (1+R)}{\rho C_P R F}} - e^{\frac{h_S A_S}{\rho C_P R F}} (1 + R) + R} \quad (13.276)$$

13.2.6.10 Heat transfer in recirculating flows with internal gains

Whereas surface heat transfer is an important component of room heat transfer, internal gains often dominate the room temperature field. Referring to the previously used subdivision of the room into jet and recirculation regions we can see that gains can occur exclusively in the jet region, exclusively in the recirculation region or in both regions.

13.2.6.11 Heat gains in the jet region

The effect of gains in the jet region on room air temperature distribution is simple to model and, within the first order accuracy goal, can be characterized as follows:

For gains occurring in the jet region (between the inlet and the room outlet) a change in inflow temperature is an adequate, conservative approximation. From energy conservation we conclude that the altered inflow temperature is given by:

$$T_{ING} = T_{IN} + \frac{G_J}{\rho C_P F} \quad (13.277)$$

Gains occurring in the jet region, close to the outlet can be ignored in a first order accuracy model.

Clearly the two approaches described above are only exact when: the gains occur at the inlet and perfectly mix with the inflow jet (for the first case), or whenever the gains occur very close to the outlet (in the second case). In all other situations, the first approach provides a conservative approximation. In the model implementation in EnergyPlus the user will not define the exact location of the heat gains within each region of the flow therefore, heat gains in the jet region, are inserted in two equal parts in two separate points of the jet flow (in the room entrance and before the exit, see points $r = 0$ and $r = L_R$ in Figure 13.28).

13.2.6.12 Heat gains in the recirculation region

When heat gains occur in the recirculation region significant heat accumulation occurs due to the limited heat transfer ability of the shear layer. Due to this limited ability, the recirculation is partially isolated from the main jet flow and higher temperatures are generated in this region whenever heat gains are present. The concept of a global heat transfer coefficient is not applicable.

In the case of a flow in a room with adiabatic surfaces and heat gains in the recirculation region the indoor air temperatures can be predicted using the solution to the following system of equations:

$$\begin{aligned} \rho C_p F R (T_R(0) - T_R(L)) &= G_R \\ \rho C_p F R \frac{\partial T_R(x)}{\partial x} &= \frac{A_{SL} h_{SL}}{L} (T_J(x) - T_R(x)) \\ \rho C_p F \frac{\partial T_J(x)}{\partial x} &= \frac{A_{SL} h_{SL}}{L} (T_R(x) - T_J(x)) \end{aligned} \quad (13.278)$$

This system of equations differs from the system shown in Equation 13.274 in several ways. Because there is no wall heat transfer there is no need to split the recirculation flow in two parts (R and W). The temperature increase in the recirculation flow is simply defined by the internal gains (first equation in Equation 13.278). The second and third equations in Equation 13.278 model shear layer heat transfer and are similar in the two cases (Equation 13.274 and Equation 13.278).

The recirculation flow temperature at $x = 0$ is given by:

$$T_R(0) = T_{IN} + \left(\frac{1}{e^{\frac{A_{SL} h_{SL} (1+R)}{\rho C_P F R}} - 1} + 1 \right) \frac{G_R (1+R)}{\rho C_P F R} \quad (13.279)$$

The temperature in the recirculation is inversely proportional to the recirculation flow ratio (R) and the shear layer area (measured by the product: $A_{SL} h_{SL}$). As both of these parameters increase this expression becomes similar to Equation 13.277. The recirculation flow temperature at $x = L$ is given by:

$$T_R(L) = T_R(0) + \Delta T_R \quad (13.280)$$

The temperature variations in the recirculation flow is given by:

$$\Delta T_R = \frac{G_R}{\rho C_P F R} \quad (13.281)$$

13.2.6.13 Combined effects of surface heat transfer and internal gains in the recirculation region

In this case, the following system of equations must be solved:

$$\begin{aligned} \rho C_p F R \frac{\partial T_W(r)}{\partial r} &= -\frac{A_S h_S}{L} (T_S - T_W(r)) - \frac{G_R}{L_R} \\ \rho C_p F R \frac{\partial T_R(x)}{\partial x} &= \frac{A_{SL} h_{SL}}{L} (T_J(x) - T_R(x)) \\ \rho C_p F \frac{\partial T_J(x)}{\partial x} &= \frac{A_{SL} h_{SL}}{L} (T_R(x) - T_J(x)) \end{aligned} \quad (13.282)$$

With the boundary conditions: $T_W(L) = T_R(0)$, $T_W(0) = T_R(L)$, $T_J(0) = T_{IN}$

For simplicity the heat gains are considered to be evenly distributed along the recirculation path. The temperature variation in the recirculation region is given by:

$$T_W(r) = T_S + \frac{G_R}{A_S h_S} - \frac{e^{\frac{h_S A_S}{\rho C_P R F} \frac{r}{L_R}} (e^{-\frac{A_{SL} h_{SL} (1+R)}{\rho C_P R F}} - 1) (G_R + A_S h_S (T_S + T_{IN}))}{e^{-\frac{A_{SL} h_{SL} (1+R)}{\rho C_P R F}} + R - e^{\frac{h_S A_S}{\rho C_P R F}} (1+R)} \quad (13.283)$$

Table 13.7: List of variables for CV model

Symbol	Units	Description
a	-	Slope of correlation line of best fit
A_{in}	m ²	Inlet area
A_{RM}	m ²	Room cross-sectional area
b	-	Intercept of correlation line of best fit
c_p	J/kg/K	Specific heat capacity of air
C_{RM}	-	Confinement scaling factor, $(A_{in}/A_{RM})^{1/2}$
C_1	-	Correlation constant for jet velocity
C_2	-	Correlation constant for recirculation velocity

Table 13.7: List of variables for CV model

Symbol	Units	Description
C_3	-	Correlation constant for recirculation flow rate
D	m	Room depth, distance between inlet and outlet facades
D^*	m	Effective room depth adjusted for wind angle
H	m	Room height
q_{RM}''	W	Total heat input from internal heat sources
Q_{in}	m^3/s	Inlet flow rate, $A_{in}U_{in}$
Q_R	m^3/s	Maximum recirculation region flow rate
U_{in}	m/s	Inlet velocity, average over inlet area
U_m	m/s	Maximum centerline velocity of jet
U_o	m/s	Uniform inlet velocity of jet
U_J	m/s	Volume-averaged jet velocity
U_R	m/s	Average recirculation region velocity over plane of maximum flow
V	m/s	Velocity scale
$V_{J,m}$	m/s	Average of U_m over room depth
W	m	Room width
x	m	Coordinate along room depth, $0 \leq x \leq D$
x'	-	Non-dimensional x-coordinate, x/D
X	m/s	Velocity correlation parameter
Y	m	Lateral coordinate across room width
Z	m	Vertical coordinate
ΔT_J	$^{\circ}C$	Average jet temperature variation
ΔT_R	$^{\circ}C$	Average recirculation region temperature variation
r	kg/m^3	Density of air
ϕ	$^{\circ}$	Wind direction relative to façade normal

13.2.7 RoomAirflowNetwork Model

13.2.7.1 Overview

The RoomAirflowNetwork integrates the RoomAir model with the AirflowNetwork model. The model allows multiple Room Air nodes to be associated with AirflowNetwork intra zone nodes. The AirflowNetwork intra zone linkages provide links among the intra zone nodes and users may specify airflow components among these links. The AirflowNetwork model calculates airflows of the links. The incoming airflows are part of the zone heat and moisture balances of intra zone nodes. The

model also allows users to specify a node to be connected to surfaces to have convective heat transfer and/or moisture transfer between surfaces and the node, portion of internal gains and supply air and return air fractions from zone equipment and AirLoop terminals.

The input object RoomAirSettings:AirflowNetwork lists multiple RoomAirflowNetwork nodes in a zone. The input object of RoomAirflowNetwork:Node defines a list of connections assigned to a particular RoomAirflowNetwork node so that the connections will be used as components of node heat and moisture balance equations. In addition, the input objects AirflowNetwork:IntraZone:Node and AirflowNetwork:IntraZone:Linkage specify airflow nodes, linkages, and associated flow components, so that the AirflowNetwork model is used to calculate intrazone linkage airflows, which will be a part of loads for the RoomAir node balances.

13.2.7.2 Model description

The model calculates each component of the governing equations first. Then heat and moisture balance equations are solved to get the node temperature and humidity ratio at the current time step.

Governing equations for each RoomAirflowNetwork node are described below:

Energy balance equation

$$F_i C_{z,i} \frac{dT_{z,i}}{dt} = \sum_{j=1}^{N_{i,g}} F_{gain,j} \dot{Q}_{i,j} + \sum_{j=1}^{N_{i,sur}} h_{i,j} A_j (T_{s,j} - T_{z,i}) + \sum_{j=1}^{N_{i,AFN}} \dot{m}_{AFN_{i,j}} C_p (T_{z,j} - T_{z,i}) + \sum_{j=1}^{N_{i,HVAC}} F_{HVAC,j} \dot{m}_{sup,i,j} C_p (T_{sup,j} - T_{z,i}) \quad (13.284)$$

where:

F_i = Fraction of zone air volume for the ith node, defined in the Fraction of Zone Air Volume field of the RoomAir:Node:Airflownetwork

$C_{z,i}$ = Volumetric heat capacity for the ith node: $\rho_{air,i} V C_p C_T$

$\rho_{air,i}$ = Dry air density at the ith zone node

C_p = zone dry air specific heat

C_T = sensible heat capacity multiplier (Detailed description is provided below)

V = Zone air volume

$T_{z,i}$ = Air temperature at the ith zone RoomAir node

$N_{i,g}$ = The number of internal gains for the ith node, defined in the RoomAir:Node:Airflownetwork:InternalC object

$F_{gain,j}$ = Fraction of internal gain from jth internal gain object defined in the RoomAir:Node:Airflownetwork object

$\dot{Q}_{i,j}$ = The amount of internal sensible gain at the jth internal gain object and ith node.

$\sum_{j=1}^{N_{i,g}} F_{gain,j} \dot{Q}_{i,j}$ = The total amount of internal sensible gains assigned to the ith node

$N_{i,sur}$ = The number of adjacent surface with convective heat transfer for the ith node, defined in the RoomAir:Node:Airflownetwork:AdjacentSurfaceList object

$h_{i,j}$ = Heat transfer coefficient between the jth adjacent surface and ith node

A_j = Area of the jth adjacent surface

$T_{s,j}$ = Inside temperature at the j th adjacent surface

$\sum_{j=1}^{N_{i,sur}} h_{i,j} A_j (T_{s,j} - T_{z,i})$ = The total amount of convective gains from adjacent surfaces attached to the i th node

$N_{i,AFN}$ = The number of RoomAir:Node:Airflownetwork objects connected to the i th node. The links are defined in AirflowNetwork:IntraZone:Linkage objects.

$\dot{m}_{AFN,i,j}$ = Mass flow rate from the j th node to the i th node. The flow rates are calculated in the AirflowNetwork model. It should be pointed out that the outgoing flows from the i th node will not be used in the present energy and moisture balance calculations, because they are a part of energy and moisture balances.

$T_{z,j}$ = Air temperature at the j th zone RoomAir node

$\sum_{j=1}^{N_{i,g}} \dot{m}_{AFN,i,j} C_p (T_{z,j} - T_{z,i})$ = The total amount of heat transfer driven by intra zonal flows

$N_{i,HVAC}$ = The number of RoomAir:Node:Airflownetwork:HVACEquipment objects which provide supply air to the i th node.

$F_{HVAC,j}$ = Fraction of output or supply air to the i th node from j th HVAC equipment defined in RoomAir:Node:Airflownetwork:HVACEquipment objects

$\dot{m}_{sup,i,j}$ = The supply mass flow rate from the j th HVAC equipment

$T_{sup,j}$ = Supply air temperature at the j th HVAC equipment

$\sum_{j=1}^{N_{i,HVAC}} F_{HVAC,j} \dot{m}_{sup,i,j} (T_{sup,j} - T_{z,i})$ = The total amount of heat transfer from HVAC equipment to the i th node

Moisture balance equation

$$F_i M_{z,i} \frac{dW_{z,i}}{dt} = \sum_{j=1}^{N_{i,g}} F_{gain,j} \dot{Q}_{i,j} + \sum_{j=1}^{N_{i,sur}} h_{M,j} A_j (W_{s,j} - W_{z,i}) + \sum_{j=1}^{N_{i,AFN}} \dot{m}_{AFN,i,j} (W_{z,j} - W_{z,i}) + \sum_{j=1}^{N_{i,HVAC}} F_{HVAC,j} \dot{m}_{sup,i,j} (W_{sup,j} - W_{z,i}) \quad (13.285)$$

where:

F_i = Fraction of zone air volume for the i th node, defined in the Fraction of Zone Air Volume of the RoomAir:Node:Airflownetwork

$M_{z,i}$ = Mass for the i th node: $\rho_{air,i} V_{Cp} C_T$

$\rho_{air,i}$ = Dry air density at the i th zone RoomAir node

V = Zone air volume

$W_{z,i}$ = Air humidity ratio at the i th zone RoomAir node

$N_{i,g}$ = The number of internal gains for the i th node, defined in the RoomAir:Node:Airflownetwork:InternalGains object

$F_{gain,j}$ = Fraction of internal gain from j th internal gain object defined in the RoomAir:Node:Airflownetwork object

$\dot{Q}_{i,j}$ = The amount of internal latent gain at the j th internal gain object and i th node.

$\sum_{j=1}^{N_{i,g}} F_{gain,j} \dot{Q}_{i,j}$ = The total amount of internal latent gains attached to the i th node

$N_{i,sur}$ = The number of adjacent surface with convective heat transfer for the i th node, defined in the RoomAir:Node:Airflownetwork:AdjacentSurfaceList object

$h_{M,j}$ = Mass transfer coefficient between the j th adjacent surface and i th node

A_j = Area of the j th adjacent surface

$W_{s,j}$ = Inside humidity ratio at the j th adjacent surface

$\sum_{j=1}^{N_{i,sur}} h_{M,j} A_j (W_{s,j} - W_{z,i})$ = The total amount of convective moisture gains from adjacent surfaces attached to the i th node

$N_{i,AFN}$ = The number of RoomAir:Node:Airflownetwork objects connected to the i th node. The links are defined in AirflowNetwork:IntraZone:Linkage objects.

$\dot{m}_{AFN,i,j}$ = Mass flow rate from the j th node to the i th node. The flow rates are calculated in the AirflowNetwork model. It should be pointed out that the outgoing flow from the i th node will not be used in the present calculation, because they are a part of energy balance.

$W_{z,j}$ = Air humidity ratio at the j th zone RoomAir node

$\sum_{j=1}^{N_{i,AFN}} \dot{m}_{AFN,i,j} (W_{z,j} - W_{z,i})$ = The total amount of moisture transfer driven by intra zonal flows

$N_{i,HVAC}$ = The number of RoomAir:Node:Airflownetwork:HVACEquipment objects which provide supply air to the i th node.

$F_{HVAC,j}$ = Fraction of output or supply air to the i th node from j th HVAC equipment defined in RoomAir:Node:Airflownetwork:HVACEquipment objects

$\dot{m}_{sup,i,j}$ = The supply mass flow rate from the j th HVAC equipment

$W_{sup,j}$ = Supply air humidity ratio at the j th HVAC equipment

$\sum_{j=1}^{N_{i,HVAC}} F_{HVAC,j} \dot{m}_{sup,i,j} (W_{sup,j} - W_{z,i})$ = The total amount of moisture transfer from HVAC equipment to the i th node

13.2.7.3 Calculation procedures

The AirflowNetwork model is called first to calculate intrazone linkage air flows based on node temperatures and humidity ratios at the previous time step. The linkage loads are summarized based on each node with all incoming airflow, while any outgoing airflows from the node of the interest are excluded in the node energy and moisture balances. When the RoomAirModelAirflowNetwork module is called, it summarizes internal gains at each node based on specification provided in the RoomAirflowNetwork:Node:InternalGains object, convective heat transfer from adjacent walls specified in the RoomAirflowNetwork:Node:AdjacentSurfaceList object. These load components are used in the predictor to predict system loads based on thermostat setpoint and supply fraction in the controlled zone node. In the corrector, the supply air conditions defined in the RoomAirflowNetwork:Node:HVACEquipment object are added. After all load components are assembled together, the node energy and moisture balance equations are solved. The node temperature and humidity ratio are calculated at the current time step.

13.3 Hybrid Model

13.3.1 Overview

The hybrid modeling integrates physics-based and data-driven modeling methods which combines forward and inverse physics-based modeling taking advantage of easily measurable zone air temperature, humidity ratio, or CO₂ concentration data to solve hard-to-measure zone parameters including internal thermal mass, air infiltration rate, or zone people count. It aims to enhance the current energy retrofit practices not only offering more user-friendly energy modeling environments but also providing more accurate estimates of energy savings at the same time. Parameters such as interior thermal mass, air infiltration rates, and people count are required in physics-based models, and they have significant impacts as they are driving factors for the dynamic performance of buildings. An accurate estimate of interior thermal mass has been a difficult problem because the building usually has various amounts of furniture and changeable partitions. The air infiltration rate changes in time and dynamically interacts with indoor and outdoor climatic conditions. However the accurate estimation of the data is almost impossible to collect without a fan pressurized test, which can not be easily done by typical energy modelers (Gowri et al. 2009). The high uncertainty of occupants' presence and behavior have significant impacts on building energy modeling (Clevenger & Haymaker, 2001). However, people count is usually hard to measure in reality, which result in simplification of occupancy schedule assumptions in energy modeling. The hybrid model introduces an approach estimate the zone level interior thermal masss, air infiltration rate, and people count with measured zone air parameters in EnergyPlus.

Solving building energy and environmental problems inversely using measured data gets more attention as more data are easily and freely available. (Yinping Zhang et al. 2015). Measurements are to supplement to reduce discrepancies or to identify model parameters, nevertheless the majority of efforts go into the derivation of the dynamic inverse modeling. Inverse modeling is a discipline that applies mathematical techniques to combine measurements and models. Inverse modeling can provide solutions when direct measurements of model parameters are not widely available, rendering the use of numerical techniques. Temperature, humidity, and CO₂ concentration data are easily available nowadays and are used for controls of indoor environments due to a wider use of low-cost thermostats with data loggers, which bring opportunities to inversely solve other hard-to-measure

parameters.

The new hybrid modeling approach uses the inverse modeling method to improve the accuracy of the building energy simulation for existing buildings, which adds measured data to solve uncertain model parameters. The hybrid modeling approach builds upon the virtue of the physics-based model taking advantage of measured data. The approach uses measured zone air temperature, humidity ratio, or CO₂ concentration to solve highly uncertain parameters such as internal thermal mass, infiltration airflow rate, and people count with the reformulated zone heat, moisture, or CO₂ balance equations. Figure 13.29 shows the relationship among the measurements and unknown parameters.

Figure 13.29: Relationship among measurements and unknown parameters

Figure 13.30 illustrates a conceptual diagram that easily express the concept of the hybrid modeling approach with measured air temperature.

Figure 13.30: Hybrid model conceptual diagram

13.3.2 Zone Balance Algorithms

The hybrid model algorithms are built upon the physics-based zone air balance equations reformulated to solve a partially inverse problem. The hybrid model approach inverts the physics-based

Table 13.8: Nomenclature for the Hybrid Model

Q_{int}	Internal heat gain
h_s	Convective heat transfer coefficient
A_s	Zone surface area
T_s	Zone surface temperature
T_z	Zone air temperature
T_{iz}	Interzone air temperature
T_o	Outdoor air temperature
T_{sup}	Air system supply air temperature
q_{inf}	Infiltration air flow rate
\dot{m}_{iz}	Interzone air mass flow rate
\dot{m}_{sys}	Air system mass flow rate
V	Zone volume
ρ_{air}	Air density
C_z	Heat capacity of zone air and internal thermal mass
C_p	Zone air specific heat
C_T	Heat capacity multiplier

energy model, reformulating the heat, moisture, and CO₂ balance algorithms with measured zone air temperature, humidity ratio, and CO₂ concentration data (traditionally results/output of the physics-based model) to solve highly unknown parameters.

EnergyPlus provides algorithms of 3rd order backward difference and analytical solution to solve the zone air energy balance equation. The 3rd order finite difference approximation provides stability without requiring a prohibitively small time step, the method still has truncation errors and requires a fixed time step length for the previous three simulation time steps. Therefore, different time step lengths for the previous three simulation time steps may make the temperature coefficients invalid. The analytical solution algorithm is an integration approach that provides a possible way to obtain solutions without truncation errors and independent of time step length and only requires the zone air temperature for one previous time step. The hybrid modeling approach uses the analytical solution for internal thermal mass inverse calculation and the 3rd order backward difference for infiltration inverse calculation. The basis for the zone air system integration is to formulate energy balances for the zone air as shown in following equations and solve the resulting ordinary differential equations.

13.3.2.1 Zone air heat balance algorithm

The sum of zone loads and the provided air system energy equals the change in energy stored in the zone. Typically the zone capacitance, C_z includes the zone air only when formulating energy balances for the zone air. The internal thermal mass, including furniture, books, and changeable partitions, is assumed to be in thermal equilibrium with the zone air, thus it is added in the zone heat capacitance, C_z . The infiltration airflow rate, \dot{m}_{inf} changes for different conditions depending on outdoor temperature, wind speed, and HVAC system operations. The energy provided from

systems to the zone is represented as Q_{sys} .

$$C_z \frac{dT_z}{dt} = \Sigma Q_i + \Sigma [h_i A_i (T_{si} - T_z)] + \Sigma [\dot{m}_i C_p (T_{zi} - T_z)] + \dot{m}_{inf} C_p (T_o - T_z) + Q_{sys} \quad (13.286)$$

$$C_z = V \rho_{air} C_p C_T \quad (13.287)$$

Where:

ρ_{air} : Zone air density [kg/m^3],

V_z : Zone air volume [m^3],

C_p : Zone air specific heat [$kJ/kg \cdot K$],

T_z : Zone air temperature at the current time step [K],

T_{zi} : Nearby zone air temperature at the current time step [K],

T_o : Outdoor air temperature at the current time step [K],

T_{sys} : System supply air temperature at the current time step [K],

t : Current time,

ΣQ_{in} : Sum of internal sensible heat gain ,

$\Sigma h_i A_i (T_{si} - T_z)$: Convective heat transfer from the zone surfaces [kW],

$\Sigma \dot{m}_{zi} C_p (T_{zi} - T_z)$: Heat transfer due to interzone air mixing [kW],

$\dot{m}_{inf} (T_o - T_z)$: Heat transfer due to infiltration of outside air [kW],

$\dot{m}_{sys} (T_{sys} - T_z)$: Heat transfer due to air supplied by HVAC system [kW],

13.3.2.2 Zone air moisture balance algorithm

The moisture balance equation is in the following form. The sum of zone moisture loads and the provided air system moisture content equals the change in moisture content stored in the zone.

$$\begin{aligned} \rho_{air} V_z C_w \frac{dW_z}{dt} = & \Sigma k g_{mass_{sched}} + \Sigma A_i h_i r h o_{air} (W_{si} - W_z) + \Sigma \dot{m}_{zi} C_p (W_{zi} - W_z) \\ & + \dot{m}_{inf} (W_o - W_z) + \dot{m}_{sys} (W_{sys} - W_z) \end{aligned} \quad (13.288)$$

Where:

- ρ_{air} : Zone air density [kg/m^3],
- V_z : Zone air volume [m^3],
- C_w : Zone air humidity capacity multiplier,
- W_z : Zone air humidity ratio [$kg_w/kg_{dry-air}$],
- W_{zi} : Nearby zone air humidity ratio [$kg_w/kg_{dry-air}$],
- W_o : Outdoor air humidity ratio [$kg_w/kg_{dry-air}$],
- W_{sys} : System supply air humidity ratio [$kg_w/kg_{dry-air}$],
- t : Current time,
- $\Sigma kg_{mass_{sched}}$: sum of scheduled internal moisture load [kg/s],
- $\Sigma \dot{m}_{zi}(W_{zi} - W_z)$: Moisture transfer due to interzone air mixing [kg/s],
- $\dot{m}_{inf}(W_o - W_z)$: Moisture transfer due to infiltration [kg/s],
- $\dot{m}_{sys}(W_{sys} - W_z)$: Moisture transfer due to HVAC supply air [kg/s],

13.3.2.3 Zone air CO₂ balance algorithm

Similarly, there is a CO₂ balance equation in the following form. The sum of zone CO₂ loads and the provided air system CO₂ content equals the change in CO₂ content stored in the zone.

$$\rho_{air} V_z C_{CO_2} \frac{dC_z}{dt} = \Sigma kg_{mass_{sched}} \times 10^6 + \Sigma \dot{m}_{zi}(C_{zi} - C_z) + \dot{m}_{inf}(C_o - C_z) + \dot{m}_{sys}(C_{sys} - C_z) \quad (13.289)$$

Where:

- ρ_{air} : Zone air density [kg/m^3],
- V_z : Zone air volume [m^3],
- C_{CO_2} : Zone carbon dioxide capacity multiplier [dimensionless],
- C_z : Zone air carbon dioxide concentration at the current time step [ppm],
- C_{zi} : Nearby zone air carbon dioxide concentration [ppm],
- C_o : Carbon dioxide concentration in outdoor air [ppm],
- C_{sys} : Carbon dioxide concentration in the system supply airstream [ppm],
- t : Current time,
- $\Sigma kg_{mass_{sched}}$: Sum of scheduled internal carbon dioxide loads [kg/s],
- $\Sigma \dot{m}_{zi}(C_{zi} - C_z)$: Carbon dioxide transfer due to interzone air mixing [$ppm \cdot kg/s$],
- $\dot{m}_{inf}(C_o - C_z)$: Carbon dioxide transfer due to infiltration and ventilation of outdoor air [$ppm \cdot kg/s$],
- $\dot{m}_{sys}(C_{sys} - C_z)$: Carbon dioxide transfer due to system supply [$ppm \cdot kg/s$],

13.3.3 Internal thermal mass hybrid modeling method

There are two approaches to model internal thermal mass in EnergyPlus. One approach is to use the internal mass objects to define construction specifications of internal furnishing materials, and the other is to use the temperature capacitance multipliers. The multiplier increases zone air capacity as it represents the effective storage capacity of the zone interior thermal mass. Figure 13.31 illustrates two approaches of representing interior thermal mass in EnergyPlus.

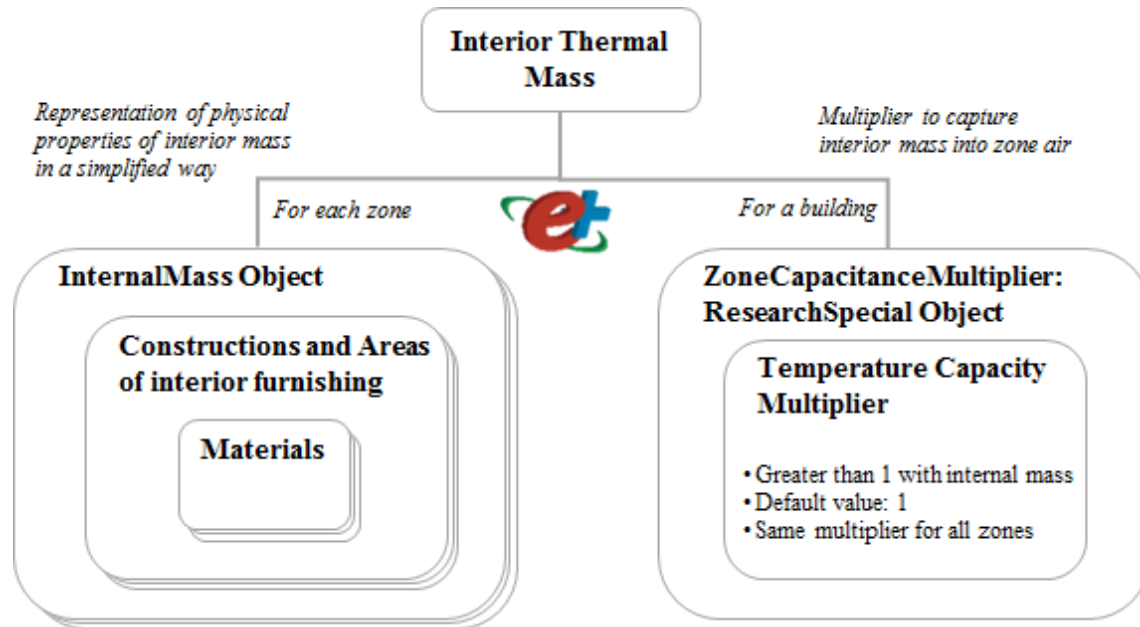

Figure 13.31: Two approaches of representing interior thermal mass in EnergyPlus

13.3.3.1 Interior mass objects in EnergyPlus modeling

The EnergyPlus object, “InternalMass”, is used to specify the construction materials and area of interior mass within the space, which are important to heat transfer calculations. Internal mass objects participate in the zone air heat balance and the longwave radiant exchange. The geometry of the internal mass construction is greatly simplified due to the difficulty of measurement. They do not directly interact with the solar heat gain because internal mass objects do not have a specific location in space. Internal mass objects can represent multiple pieces of interior mass (furniture, partitions) with different constructions. Internal mass exchanges energy through its both surfaces with the zone by convection.

13.3.3.2 Zone capacitance multiplier

There is an object, “ZoneCapacitanceMultiplier:ResearchSpecial”, an advanced feature to specify the effective storage capacity of a zone. The capacitance multiplier of 1.0 by default indicates the capacitance comes from only the air in the zone. This multiplier can be increased if the zone air capacitance needs to be increased for stability of the simulation or to allow modeling higher or lower levels of damping behavior over time. This multiplier is used in the zone predictor-correction

algorithm to adjust the zone air thermal capacity. The current EnergyPlus assumes the same constant capacitance multiplier for all zones. Although it allows users modifying this multiplier, it is not easy to determine the accurate value and not common for a typical use.

The use of the internal mass multiplier, the zone temperature capacitance multiplier only corrects the zone air heat capacity reflecting heat stored in the internal mass. Assumptions are not different from the approach used in InternalMass object, which ignores the geometrical construction of the internal mass, and do not contribute to the heat transfer across surfaces and the solar heat gain through windows. The approach in this hybrid modeling method derives the interior mass by solving the zone temperature capacity multiplier. The derivation is based on the inverse modeling method replacing the input of interior thermal mass with the measured zone air temperature. The zone air temperature is the only additional requirement for the proposed approach.

13.3.3.3 Inverse algorithm for zone capacitance multiplier

The interior thermal mass including furniture, books, and changeable partitions, is assumed to be in thermal equilibrium with the zone air, thus it is added in the zone heat capacitance, C_z . The interior thermal mass is assumed to be in equilibrium with the zone air. The interior mass in the current EnergyPlus model uses a capacitance multiplier, C_T indicating the capacitance as part of the air in the volume of the specified zone. The default value is given as 1.0 corresponding to the total capacitance for the zone's volume of air at current zone conditions. The hybrid model to derive internal thermal mass uses the capacitance multiplier that indicates the capacitance added to the zone air. The added internal thermal mass capacitance will be represented in the multiplier, which the value would be greater than 1.0. The formulation starts with the heat balance on the zone air. The following equation calculates the time-series zone air temperature, T_z , reformulating the above equation using the analytical solution method.

$$\begin{aligned}
 T_z^t = & \left[T_z^{t-\delta t} - \frac{\Sigma Q_i + \Sigma(h_i A_i T_{si}) + \Sigma(\dot{m}_i C_p T_{zi}) + \dot{m}_{inf} C_p T_o + \dot{m}_{sys} C_p T_{sup}^t}{\Sigma(h_i A_i) + \Sigma(\dot{m}_i C_p) + \dot{m}_{inf} C_p + \dot{m}_{sys} C_p} \right] \\
 & \times e^{-\frac{\Sigma(h_i A_i) + \Sigma(\dot{m}_i C_p \dot{m}_{inf} C_p) + \dot{m}_{sys} C_p}{C_z^t} \delta t} \\
 & + \frac{\Sigma Q_i + \Sigma(h_i A_i T_{si}) + \Sigma(\dot{m}_i C_p T_{zi}) + \dot{m}_{inf} C_p T_o + \dot{m}_{sys} C_p T_{sup}^t}{\Sigma(h_i A_i) + \Sigma(\dot{m}_i C_p) + \dot{m}_{inf} C_p + \dot{m}_{sys} C_p}
 \end{aligned} \tag{13.290}$$

The hybrid modeling approach derives the internal mass by solving the heat capacity of zone air and internal thermal mass, C_z . The equation below shows the inverse heat balance algorithm that replacing the zone air temperature, T_z with the measured zone air temperature. The current timestep measured temperature, T_z^t and the previous timestep measured temperature, $T_z^{t-\delta t}$ are given from inputs, then the zone air heat capacity, C_z^t for each timestep is expressed as following.

$$C_z^t = - \frac{[\Sigma(h_i A_i) + \Sigma(\dot{m}_i C_p \dot{m}_{inf} C_p) + \dot{m}_{sys} C_p] \delta t}{\ln \left[\frac{T_z^t - \frac{\Sigma Q_i + \Sigma(h_i A_i T_{si}) + \Sigma(\dot{m}_i C_p T_{zi}) + \dot{m}_{inf} C_p T_o + \dot{m}_{sys} C_p T_{sup}^t}{\Sigma(h_i A_i) + \Sigma(\dot{m}_i C_p) + \dot{m}_{inf} C_p + \dot{m}_{sys} C_p}}{T_z^{t-\delta t} - \frac{\Sigma Q_i + \Sigma(h_i A_i T_{si}) + \Sigma(\dot{m}_i C_p T_{zi}) + \dot{m}_{inf} C_p T_o + \dot{m}_{sys} C_p T_{sup}^t}{\Sigma(h_i A_i) + \Sigma(\dot{m}_i C_p) + \dot{m}_{inf} C_p + \dot{m}_{sys} C_p}} \right]} \tag{13.291}$$

There are different conditions in deriving the interior thermal mass depending on the air system operation. The initial process assumes that calculation is conducted when HVAC systems are off. If HVAC systems are turned off during unoccupied hours, the zone heat capacity can be determined without additional inputs of the supply air temperature for the above condition. The condition when

the air system is off, $Q_{sys} = 0$, this induces $T_{sup}^t = T_z^t$. Zone air capacitance with internal mass, C_z remains constant, not changing with the given time series. When the air system is operating, Q_{sys} is not zero. This requires input values of the supply air temperature as denoted as T_{sup}^t and supply air volume. These are additional inputs when estimating interior thermal mass under the condition when HVAC system is operating. When the air system is operating, $C_z \frac{dT_z}{dt}$ becomes zero or almost zero. The zone temperature is maintained at the set-point temperature, thus the temperature difference between T_z^t and $T_z^{t-\delta t}$ is zero. For those hours zone temperatures are maintained at the set-point temperature, the interior thermal mass, C_z^t is not calculated.

Zone air heat capacity needs to be derived from the stabilized internal zone air temperature data that fully captures the stored heat in the air and internal thermal mass. It is recommended the measured zone temperature needs to be at least one week of data for more reliable result. Zone heat capacity is an important component for buildings as it stabilizes interior temperatures, thus at least one week of the measured interior temperature can capture the stored heat in the interior thermal mass. The temperature capacity multiplier i.e., internal mass multiplier, C_T^t is calculated for each time step using the equation below.

$$C_T^t = \frac{C_z^t}{V \rho_{air} C_p} \quad (13.292)$$

The default value is 1.0. Ideally the zone heat capacity shall remain constant for the same condition of the interior environment in the zone heat balance equation. An underlying assumption is that the zone heat capacity is treated as constant for the equilibrium of the inversed heat balance model. However the measured temperatures are not the same as the simulated zone air temperatures which is the result of the energy simulation in Equations 13.291 and 13.292. This causes the internal mass multiplier, C_T^t , the result from the inverse model is not constant during the course of the simulation period. The hybrid model will determine a time span when $|T_z^t - T_z^{t-\delta t}| > 0.05^\circ C$ that C_z^t remains more constant. Internal mass multiplier calculations are only done when the zone air temperature difference between timesteps meets the condition. This filter is needed for more reliable inverse calculation to avoid the anomaly conditions due to the use of the inverse model.

13.3.4 Infiltration hybrid modeling method

13.3.4.1 Infiltration airflow modeling

Infiltration is an uncontrolled outside air into a building depending on the air-tightness of the building envelope and indoor / outdoor climate conditions. A large percentage of the total energy loss of a building can occur through envelope leakage, resulting in excessive heating and cooling loads. Infiltration is represented as the volumetric flow rate of outside air into a building. Infiltration inputs in energy modeling rarely reflect the actual building operating conditions, as the infiltration airflow rate is dynamic and difficult to measure. It is generally understood that the infiltration rate of a building is a function of its age, its construction quality, and weather conditions. Wind speed and temperature at the zone height are driving factors which cause the pressure difference between the outside and the inside of the building.

The infiltration modeling is relatively simplified in the energy simulation because of the lack of knowledge about the sizes and distribution of cracks in the building envelope, the permeability of the envelope, the air flow to the building, and the pressure distribution in and around the building. EnergyPlus allows a simple approach to model the infiltration for users. This requires to

define a design flow rate and coefficients for temperature and wind velocity using the ZoneInfiltration:DesignFlowRate object. EnergyPlus calculates airflow rates by adjusting for the indoor-outdoor temperature differences and the outdoor wind speed using the following equation.

$$\text{Infiltration} = \text{Infiltration}_{\text{design}} F_{\text{schedule}} [A + B|T_z - T_o| + C(\text{WindSpeed}) + D(\text{WindSpeed}^2)] \quad (13.293)$$

Where A is the constant term coefficient, B is the temperature term coefficient, C is the velocity term coefficient, D is the velocity squared coefficient, and F_{schedule} is a user-defined schedule value between 0 and 1.

The simplified infiltration model using a constant infiltration flow rate is designed to capture the average effect over the year and in different locations. The simple infiltration approach has an empirical correlation that modifies the infiltration as a function of wind speed and temperature difference across the envelope. The difficulty in using this approach the determination of valid coefficients for each building type in each location. These coefficients vary and provide very different results that cause great uncertainty. This is not easy to identify correct ones for typical modeling practices. The current EnergyPlus simplified infiltration modeling method uses a fixed infiltration rate that can represent the average impact over a year. This may not be realistic for accurate energy modeling when capturing hourly dynamics. More complicated flow network simulations are necessary for detailed modeling. Other infiltration related EnergyPlus models that add details and complexities are the “Effective Leakage Area” model (Jokisalo et al. 2009) using the ZoneInfiltration:EffectiveLeakageArea object and “Flow Coefficient” model (Walker & Wilson 1998), using the ZoneInfiltration:FlowCoefficient object.

13.3.4.2 Infiltration inverse modeling

It is not easy to estimate as the infiltration is caused by various sources of unknown leakages. The development of the hybrid model fills the gap when estimating the infiltration that reflects all complexities of design flow rate, coefficients, and climate conditions by only requiring easily attainable zone air temperature, humidity ratio, or CO₂ concentration data. The development of the infiltration hybrid modeling algorithm is consistent with the EnergyPlus source code. The approach derives the infiltration mass flow rate, \dot{m}_{inf} by reformulating the zone air heat, moisture, or CO₂ balance equations. The 3rd order backward difference method is used for the inverse model development for the infiltration hybrid modeling. The inverse model using the analytical solution cannot be realized in a mathematical form. The time-series zone air temperature, T_z using the 3rd order method is shown in the following equation.

$$T_z^t = \frac{\left(\Sigma Q_i + \Sigma(h_i A_i T_{si}) + \Sigma(\dot{m}_i C_p T_{zi}) + \dot{m}_{inf} C_p T_o \right.}{\frac{11}{6} \frac{C_z}{\delta t} + \Sigma(h_i A_i) + \Sigma(\dot{m}_i C_p) + \dot{m}_{inf} C_p + \dot{m}_{sys} C_p} \left. + \dot{m}_{sys} C_p T_{sup}^t - \frac{C_z}{\delta t} \left(-3T_z^{t-\delta t} + \frac{3}{2}T_z^{t-2\delta t} - \frac{1}{3}T_z^{t-3\delta t} \right) \right) \quad (13.294)$$

The equation below shows the inverse algorithm for infiltration hybrid modeling method to derive the zone infiltration mass flow rate using the measured zone air temperature.

$$\dot{m}_{inf} = \frac{\left(C_z \frac{\frac{11}{6}T_z^t - 3T_z^{t-\delta t} + \frac{3}{2}T_z^{t-2\delta t} - \frac{1}{3}T_z^{t-3\delta t}}{\delta t} - (\Sigma Q_{in} + \Sigma h_i A_i (T_{si} - T_z) + \Sigma \dot{m}_{zi} C_p (T_{zi} - T_z) + \dot{m}_{sys} C_p (T_{sys} - T_z)) \right)}{C_p (T_o - T_z^t)} \quad (13.295)$$

Similarly, the infiltration air flow rate can be derived with the measured zone air humidity rate:

$$\dot{m}_{inf} = \frac{\left(C_{wz} \frac{\frac{11}{6}W_z^t - 3W_z^{t-\delta t} + \frac{3}{2}W_z^{t-2\delta t} - \frac{1}{3}W_z^{t-3\delta t}}{\delta t} - (\Sigma k g_{mass_{sched}} + \Sigma A_i h_i \rho_{air} (W_{si} - W_z^t) + \Sigma \dot{m}_{zi} (W_{zi} - W_z^t)) \right)}{W_o - W_z^t} \quad (13.296)$$

The infiltration air flow rate can also be derived with the measured zone air CO₂ concentration:

$$\dot{m}_{inf} = \frac{\left(C_{CO_2z} \frac{\frac{11}{6}C_z^t - 3C_z^{t-\delta t} + \frac{3}{2}C_z^{t-2\delta t} - \frac{1}{3}C_z^{t-3\delta t}}{\delta t} - (\Sigma k g_{mass_{sched}} \times 10^6 + \Sigma \dot{m}_{zi} (C_{zi} - C_z) + \dot{m}_{sys} (C_{sys} - C_z)) \right)}{C_o - C_z^t} \quad (13.297)$$

The infiltration air flow rate, q_{inf} is then calculated from the derived infiltration mass flow rate from the following equation.

$$q_{inf} = \frac{\dot{m}_{inf}}{air} \quad (13.298)$$

13.3.5 People count hybrid modeling method

People count is highly unpredictable due to the uncertain people movements and behaviors in buildings. Therefore, simplified occupancy schedules are usually used in real-world building energy modeling and simulation cases. The development of the hybrid model offers a new approach to estimate people count in buildings by leveraging the physics-based zone air heat, moisture, or CO₂ balance equations. Like the inverse modeling for infiltration air flow estimation, the 3rd order backward difference method is used for inversely solving people count. The total sensible heat, moisture, or CO₂ gains from people is solved with the inversed zone balance equations with measured zone air and supply air temperature, humidity ratio, or CO₂ concentration as the inputs. The number of people is then derived by dividing the total sensible, moisture, or CO₂ gains from people by the assumed single person sensible heat, moisture, or CO₂ dissipation amount. This process is shown in the following equations.

- (1). Solve people count with measured zone air temperature.
The sum of internal sensible heat gains is:

$$\Sigma Q_{in} = C_z \frac{\frac{11}{6}T_z^t - 3T_z^{t-\delta t} + \frac{3}{2}T_z^{t-2\delta t} - \frac{1}{3}T_z^{t-3\delta t}}{\delta t} - [\Sigma h_i A_i (T_{si} - T_z) + \Sigma \dot{m}_{zi} C_p (T_{zi} - T_z) + \dot{m}_{inf} C_p (T_o - T_z) + \dot{m}_{sys} C_p (T_{sys} - T_z)] \quad (13.299)$$

The sum of internal sensible heat gains from people is:

$$\Sigma Q_{people} = \Sigma Q_{in} - \Sigma Q_{others} \quad (13.300)$$

Finally, the number of people could be solved:

$$N = \frac{\Sigma Q_{people}}{Q_{single}} \quad (13.301)$$

Where:

$$Q_{single} : \text{Sensible heat rate per person [W]} \quad (13.302)$$

(2). Solve people count with measured zone air humidity ratio.

The sum of internal moisture gains is:

$$\begin{aligned} \Sigma kg_{mass_{sched}} = C_{wz} \frac{\frac{11}{6}W_z^t - 3W_z^{t-\delta t} + \frac{3}{2}W_z^{t-2\delta t} - \frac{1}{3}W_z^{t-3\delta t}}{\delta t} \\ - [\Sigma A_i h_i \rho_{air} (W_{si} - W_z^t) + \Sigma m_{zi} C_p (W_{zi} - W_z^t)] \end{aligned} \quad (13.303)$$

The sum of internal moisture gains from people is:

$$\Sigma kg_{mass_{sched-people}} = \Sigma kg_{mass_{sched}} - \Sigma kg_{mass_{sched-others}} \quad (13.304)$$

Finally, the number of people could be solved:

$$N = \frac{\Sigma kg_{mass_{sched-people}}}{kg_{mass_{single}}} \quad (13.305)$$

Where:

$$kg_{mass_{single}} : \text{Moisture dissipation rate per person [kg/s]} \quad (13.306)$$

(3). Solve people count with measured zone air CO₂ concentration.

The sum of internal CO₂ gains is:

$$\begin{aligned} \Sigma kg_{mass_{sched}} \times 10^6 = C_{CO_2z} \frac{\frac{11}{6}C_z^t - 3C_z^{t-\delta t} + \frac{3}{2}C_z^{t-2\delta t} - \frac{1}{3}C_z^{t-3\delta t}}{\delta t} \\ - [\Sigma m_{zi} (C_{zi} - C_z) \dot{m}_{inf} (C_o - C_z) + \dot{m}_{sys} (C_{sys} - C_z)] \end{aligned} \quad (13.307)$$

The sum of internal CO₂ gains from people is:

$$\Sigma kg_{mass_{sched-people}} = \Sigma kg_{mass_{sched}} - \Sigma kg_{mass_{sched-others}} \quad (13.308)$$

Finally, the number of people could be solved:

$$N = \frac{\Sigma kg_{mass_{sched-people}}}{kg_{mass_{single}}} \quad (13.309)$$

Where:

$$kg_{mass_{single}} : \text{CO}_2 \text{ generation rate per person [m}^3\text{/(s} \cdot \text{W)]} \quad (13.310)$$

Chapter 14

Simulation Models – Encyclopedic Reference

The following descriptions are grouped alphabetically (as much as possible) with some also having additional tags of “Heat Balance”, “HVAC”, and “Plant”. With the integrated solution, these designations signify where the effects of these models have their first impacts. The main sections in this chapter are:

- Air Terminals
- Boilers
- Chillers

14.1 Air System Distribution Terminals

14.1.1 Constant Volume Single Duct Reheat Air Terminal

The input object `AirTerminal:SingleDuct:ConstantVolume:Reheat` provides a model for single duct constant volume systems with reheat that satisfy the cooling load in a zone by changing the inlet air temperature with a reheat coil. The supply air temperature must be low enough to meet the cooling load in the zone having the greatest load. For zones with a smaller cooling load, a reheat coil is used to raise the temperature of the zone inlet air.

This object can be configured with a water, steam, electric or gas reheat coil. Operation is basically the same with all coil types. The coil is controlled to raise the zone supply air temperature (i.e., the Unit Air Outlet Node temperature) to match the zone load. If the coil is undersized, the zone setpoint temperature will not be maintained.

14.1.2 Constant Volume Single Duct No Reheat Air Terminal

The input object `AirTerminal:SingleDuct:ConstantVolume:NoReheat` is used to pass conditioned or treated central supply air directly into a zone without any reheat. This terminal air equipment allows to supply central system air directly to a zone without any zone level control or tempering. The supply air temperature is controlled by the central system to meet the load in a controlled

Figure 14.1: Schematic of AirTerminal:SingleDuct:ConstantVolume:Reheat Unit

zone. This object is configured for use with a constant volume central air system, unitary system or furnace and variable supply air temperature.

This unit allows the program to know what zone this branch of the air system is attached to, and has input fields for availability schedule, air inlet and outlet nodes, an input field for the maximum air flow rate, and other two optional input fields. The air inlet node should be the same as one of the *AirLoopHVAC:ZoneSplitter* or *AirLoopHVAC:SupplyPlenum* component outlet nodes. The air outlet node name should be same as zone air inlet node name and the air distribution unit air outlet node name. The last two optional input fields: *Design Specification Outdoor Air Object Name*, and *Per Person Ventilation Rate Mode* are used to compute the outdoor air requirement of an air terminal unit and the air terminal mass flow rate is set to the value calculated using these two input fields.

Figure 14.2: Schematic of AirTerminal:SingleDuct:ConstantVolume:NoReheat Unit

14.1.3 Variable Air Volume Single Duct Reheat and No Reheat Air Terminals

The VAV Single Duct Reheat and No Reheat terminal units (objects `AirTerminal:SingleDuct:VAV:Reheat` and `AirTerminal:SingleDuct:VAV:NoReheat`) provide models for single duct variable-air-volume (VAV) systems that control zone temperature primarily by varying the quantity of supply air rather than by varying the supply air temperature. The supply air temperature must be low enough to meet the cooling load in the zone having the greatest load when the zone terminal device is wide open. For zones with a smaller cooling load, the terminal device damper reduces the flow to match the zone setpoint.. If the lower flow limit on the terminal device is reached and the load is not matched, the inlet air temperature can be moderated if the terminal device has a reheat coil. In that case both the quantity of air and its temperature entering the zone are varied to meet the load. For air terminals using reheat coils, the maximum flow during reheat may be limited. Limiting the maximum flow during reheat occurs only when cooling is required (when any valid air loop cooling coil is active) and the terminal unit must reheat the air. Optional user inputs may also be used to control the amount of outdoor air entering the zone.

Figure 14.3: Schematic of `AirTerminal:SingleDuct:VAV:NoReheat` Unit

Figure 14.4: Schematic of `AirTerminal:SingleDuct:VAV:Reheat` Unit

The operation of the dampers and the control are described in the section `AirTerminal:SingleDuct:VAV:HeatAndCool:Reheat` and `AirTerminal:SingleDuct:VAV:HeatAndCool:NoReheat`, which follows. The exception is that the

section below describes how the air flow rate is varied for both cooling and heating. For the case of `AirTerminal:SingleDuct:VAV:NoReheat` and `AirTerminal:SingleDuct:VAV:Reheat`, air flow only varies during cooling operation and the air flow rate is set at the minimum value (minimum air flow fraction) when zone heating is required.

14.1.3.1 Minimum Outdoor Air Control

The single duct air terminals may also be used to provide a minimum outdoor air quantity. When the air flow rate required to meet the zone load does not provide sufficient outdoor air, the terminal device damper will open to allow sufficient outdoor air to enter the zone. In this case, the terminal damper is controlled based on the air loop's outdoor air fraction. The outdoor air may be specified as a fixed value per person, per floor area, or per zone. The minimum outdoor air may also be specified as air changes per hour. In addition, these values may be added together to provide a combined minimum outdoor air flow rate or the maximum of each of these values may be used. An outdoor air fraction schedule may also be used to modify the calculation for the minimum amount of outdoor air throughout the simulation (Ref. `DesignSpecification:OutdoorAir`).

14.1.4 Variable Air Volume Heating and Cooling Single Duct Reheat and NoReheat Air Terminal

14.1.4.1 Overview

The VAV Heating and Cooling Single Duct Reheat and No Reheat terminal units (objects `AirTerminal:SingleDuct:VAV:HeatAndCool:Reheat` and `AirTerminal:SingleDuct:VAV:HeatAndCool:NoReheat` provide models for variable-air-volume (VAV) terminal units are widely used in commercial and industrial applications. The VAV terminal units contain actuated dampers that vary the amount of central system air supplied to a zone. These terminal units may also contain a heating coil to trim the supply air temperature when overcooling is possible. The heating coil may also serve as the primary air heating source when the central system contains cooling-only equipment.

The VAV terminal units described here are used primarily with central air handling equipment with cooling and heating capability. The terminal unit dampers modulate in **both** cooling and heating mode to maintain the zone setpoint temperature(s). The central air handling equipment may be either variable air volume or constant volume where a bypass duct is used to shunt excess system air flow back to the inlet of the central air handler as terminal unit dampers modulate to satisfy the zone thermostat (i.e., `AirLoopHVAC:UnitaryHeatCool:VAVChangeoverBypass`).

14.1.4.2 Model Description

The no reheat version of the single duct VAV heat and cool terminal unit contains a single virtual damper assembly and requires minimal inputs. The reheat version contains both a virtual damper assembly and an air reheat coil. Multiple reheat coil types are available:

- 1) `Coil:Heating:Water`
- 2) `Coil:Heating:Electric`
- 3) `Coil:Heating:Fuel`
- 4) `Coil:Heating:Steam`

Both units are simulated to provide an air flow rate sufficient to satisfy the thermostat request. The air flow rate is a function of the terminal unit's inlet air temperature and the load sensed by the thermostat. The output of the models are simply the damper position required to satisfy the zone's thermal load. Other information regarding terminal unit performance may be viewed using node report variables and heating coil report variables.

Figure 14.5: Schematic of AirTerminal:SingleDuct:VAV:HeatAndCool:NoReheat Unit

Figure 14.6: Schematic of AirTerminal:SingleDuct:VAV:HeatAndCool:Reheat Unit

14.1.4.3 Terminal Unit Inputs

Both terminal unit types share several common input fields. A unique terminal unit name must be entered. A system availability schedule is also defined to allow operational control of the terminal unit. The user must then connect the unit to the air distribution system by defining the unit inlet and outlet node names. Design air flow rates are then specified: maximum total air flow rate (autosizable) and minimum air flow fraction.

The reheat version of this terminal unit requires additional information. The name and type of reheat coil and the damper air outlet node name (same as reheat coil inlet node name). Maximum and minimum water flow rates are entered when a water or steam heating coil is used, as well as a control node name for actuating water-side flow rates and a convergence tolerance for iteration control.

14.1.4.4 Simulation and Control

The simulation begins by determining the air mass flow rate required to satisfy the heating/cooling demand.

$$Cp_{zone} = PsyCpAirFnW(\omega_{zone}) \quad (14.1)$$

$$Cp_{inlet} = PsyCpAirFnW(\omega_{inlet}) \quad (14.2)$$

$$DeltaCpT = (Cp_{inlet})(T_{inlet}) - (Cp_{zone})(T_{zone}) \quad (14.3)$$

$$\dot{m} = \min \left(\dot{m}_{max}, \max \left(\dot{m}_{max} \times MinAirFlowFrac \times MinAirFlowTurnDownFrac, \frac{\dot{Q}_{zone}}{DeltaCpT} \right) \right) \quad (14.4)$$

where:

Cp_{zone} = Specific heat of zone air, J/kg-K

Cp_{inlet} = Specific heat of terminal unit inlet air, J/kg-K

ω_{zone} = Zone air humidity ratio, kg/kg

T_{zone} = Zone air dry-bulb temperature, °C

ω_{inlet} = Terminal unit inlet air humidity ratio, kg/kg

T_{inlet} = Terminal unit inlet air dry-bulb temperature, °C

\dot{Q}_{zone} = Zone load, W (positive values denote heating, negative values denote cooling)

\dot{m} = Terminal unit air mass flow rate, kg/s

$PsyCpAirFnW$ = Psychrometric function calculating air specific heat given air humidity ratio

$MinAirFlowFrac$ = User-specified zone minimum air flow fraction

$MinAirFlowTurnDownFrac$ = User-specified zone minimum air flow turndown fraction

\dot{m}_{max} = Terminal unit maximum air mass flow rate, kg/s.

The outdoor air input fields, if entered, are then used to adjust the terminal unit air mass flow rate to ensure the correct amount of outdoor air enters the zone (within the constraints of the terminal unit maximum and minimum flow rate inputs). The amount of outdoor air is calculated per the outdoor air requirements and is adjusted by the fraction of outdoor air entering the air loop outdoor air system.

$$\dot{m} = \max \left(\dot{m}, \frac{\dot{m}_{OA}}{OAFrac} \right) \quad (14.5)$$

where:

\dot{m}_{OA} = zone outdoor air flow rate, kg/s

$OAFrac$ = fraction of outdoor air entering the air loop outside air system.

If the terminal unit is in reheat mode (i.e., the central air loop cooling coil is active, the supply air was overcooled, and the zone thermostat is requesting heating) the maximum air flow rate allowed during reheat mode is adjusted as necessary.

$$\dot{m} = MIN \left(\dot{m}, \dot{m}_{reheat} \right) \quad (14.6)$$

where \dot{m}_{reheat} = maximum air mass flow rate during reheat, kg/s

The damper position is then calculated as:

$$FRAC_{damper} = \frac{\dot{m}}{\dot{m}_{max}} \quad (14.7)$$

and the amount of outdoor air entering the zone is:

$$\dot{V}_{OA} = \dot{m}(OAFrac) \quad (14.8)$$

where:

$FRAC_{damper}$ = Output variable ‘Zone Air Terminal VAV Damper Position’, fraction of maximum flow

\dot{V}_{OA} = Output variable “Zone Air Terminal Outdoor Air Volume Flow Rate” entering the zone, m³/s.

Simulation of the reheat coil occurs next when applicable. The heating demand required to maintain the thermostat heating setpoint temperature and the heating capacity of air flowing through the terminal unit are used to determine the amount of reheat required.

$$\dot{Q}_{reheat} = \dot{Q}_{heatSP} + \dot{m}C_{p,zone}(T_{inlet} - T_{zone}) \quad (14.9)$$

where:

\dot{Q}_{reheat} = Reheat coil load, W (positive values denote heating)

\dot{Q}_{heatSP} = Load to heating setpoint temperature, W (positive values denote heating).

No specific references.

14.1.5 Constant Volume Single Duct Four Pipe Induction Air Terminal

The four pipe induction terminal unit (object name:

AirTerminal:SingleDuct:ConstantVolume:FourPipeInduction) is a hybrid air-hydronic unit that supplies both centrally conditioned air and local hydronic heating/cooling to a zone. Centrally conditioned air is supplied to the terminal unit at high pressure and constant flow. The central (primary) air is discharged into the terminal unit through a nozzle, inducing a fixed flow of zone (secondary) through a hydronic heating/cooling coil. The primary and secondary air streams mix and are discharged to the zone. Hot or cold water flow through the coil is varied to meet the zone heating or cooling requirement.

14.1.5.1 Model

The four pipe induction terminal unit is modeled as a compound component consisting of three sub-components: a hot water coil, a chilled water coil and an air mixer. In terms of EnergyPlus objects these are *Coil:Heating:Water*, *Coil:Cooling:Water*, and *AirLoopHVAC:ZoneSplitter*. The terminal unit is a forward model: its inputs are defined by the state of its inlets: namely its 2 air streams – primary and secondary; and its two water inlets – hot and cold. The outputs of the model are the conditions of the outlet air stream: flow rate, temperature and humidity ratio. The terminal unit data and simulation are encapsulated in the module *HVACSingleDuctInduc*.

14.1.5.2 Inputs and Data

The user describes the terminal unit by inputting the name and type of the heating and cooling coils and the name of the zone mixer. The user must also specify the connectivity of the component by naming the inlet air and water nodes and the air outlet node. Finally maximum and fixed flow rates need to be specified (although these can be autosized): maximum and minimum hot and cold water volumetric flow rates and the total air volumetric flow rate (sum of primary and secondary flow rates). The relative convergence tolerances for the hot and cold water flow rates also need to be input (or allowed to default). Finally the induction ratio needs to be specified: this is defined as the ratio of the secondary air flow rate to the primary air flow rate. The relationship between the flow rates is:

$$\dot{m}_{air,tot} = \dot{m}_{air,pri} + \dot{m}_{air,sec} \quad (14.10)$$

$$\dot{m}_{air,sec} = R_{induc} \cdot \dot{m}_{air,pri} \quad (14.11)$$

so:

$$\dot{m}_{air,pri} = \dot{m}_{air,tot} / (1 + R_{induc}) \quad (14.12)$$

$$\dot{m}_{air,sec} = \dot{m}_{air,tot} \cdot R_{induc} / (1 + R_{induc}) \quad (14.13)$$

where R_{induc} is the user-input induction ratio.

All input data for the four pipe induction terminal units is stored in the array *IndUnit*.

14.1.5.3 Calculation

Given the needed inputs, the output is calculated in subroutine *CalcFourPipeIndUnit*. The temperature, humidity ratio and flow rate of the primary and secondary air streams are taken from the inlet air nodes. The inlet hot and chilled water flow rates are passed in as parameters – temperatures are taken from the inlet water nodes. Then:

The hot water coil is simulated (Call *SimulateWaterCoilComponents*);

The chilled water coil is simulated (Call *SimulateWaterCoilComponents*);

The two air streams are mixed (Call *SimAirMixer*).

Finally the load met by the terminal unit is calculated and passed back to the calling routine:

$$\dot{Q}_{out} = \dot{m}_{tot} \cdot c_{p,air} \cdot (T_{air,out} - T_{air,zone}) \quad (14.14)$$

Note that data is never explicitly passed between the sub-components. This is all handled automatically by the node connections and the data stored on the nodes.

14.1.5.4 Simulation and Control

From the result of the zone simulation, we have the heating/cooling demand on the terminal unit $\dot{Q}_{z,req}$. For a given hot and cold water flow *CalcFourPipeIndUnit* will give us the terminal unit heating/cooling output. We need to vary the hot or cold water flow to make the unit output match the demand. To do this we need to numerically invert *CalcFourPipeIndUnit*: given the output, we want one of the inputs – the hot or cold water flow. The numerical inversion is carried out by calling

subroutine *SolveRegulaFalsi*. This is a general utility routine for finding the zero of a function (the *residual* function) of a single independent variable. In this case, the residual function calculates $(\dot{Q}_{z,req} - \dot{Q}_{out})/\dot{Q}_{z,req}$. *SolveRegulaFalsi* varies either the hot water or cold water mass flow rate to zero the residual.

Decide whether the unit is on or off. The unit is off if: a) it is scheduled off; b) the inlet air mass flow rate is zero; c) the zone thermostat is in the deadband; d) or the zone heating/cooling demand is very small.

If the unit is off, call *CalcFourPipeIndUnit* with the hot and cold water flow rates set to their minimum flows and return.

If the unit is on, check whether active heating or cooling by the hydronic coils is needed. Call *CalcFourPipeIndUnit* with minimum water flows to see what how much cooling (or possibly heating) the unit is doing with primary air only. The output for this case is \dot{Q}_{pri} .

If $\dot{Q}_{z,req} > \dot{Q}_{pri}$, we need active heating. Set the cold water flow rate to the minimum. Check that the terminal unit can meet the load by setting the hot water flow rate to the maximum and calling *CalcFourPipeIndUnit*. If the output is less than the zone demand we are done – all the outputs have been calculated. Otherwise call *SolveRegulaFalsi* to obtain the hot water flow rate that will make the unit output match the zone demand. This ends the unit simulation.

If $\dot{Q}_{z,req} < \dot{Q}_{pri}$, we need active cooling. We set the hot water flow rate to the minimum. We check whether the terminal unit can supply the needed output by setting the cold water flow rate to the maximum and calling *CalcFourPipeIndUnit*. If this maximum cooling output is not able to meet the zone cooling demand we are done. Otherwise call *SolveRegulaFalsi* to obtain the cold water flow rate that will make the unit output match the zone demand. This ends the unit simulation.

Note that the terminal unit output is never explicitly passed to another routine. Instead the output is saved as the outlet conditions on the terminal unit outlet air node. The node data is accessed when the terminal unit output is needed elsewhere in the program (in *SimZoneAirLoopEquipment* for instance).

14.1.6 Fan Powered Induction Series and Parallel Single Duct Reheat Air Terminal

14.1.6.1 Overview

The input objects *AirTerminal:SingleDuct:SeriesPIU:Reheat* and *AirTerminal:SingleDuct:ParallelPIU:Reheat* provide models for fan powered induction terminal units that occur in a variety of configurations. EnergyPlus models 2 types: *series* (sometimes called *constant*) and *parallel* (sometimes called *intermittent*). The series unit provides a constant flow of air to the zone (the fan is always on at a constant flow) with a variable proportion of primary and secondary air. The parallel unit has an intermittent fan: the fan is off at maximum cooling and does not switch on until primary air flow is significantly reduced from the maximum or if reheat is required. Once on it provides a constant flow of secondary air. Both units induce air from the zone or plenum (secondary air) and mix it with centrally conditioned supply air (primary air). Both units are variable volume: the supply air flow rate is varied to match zone conditioning requirement.

14.1.6.2 Model

Both types of PIU are modeled as compound components. The series unit, in sequence from its inlet, consists of an air mixer, a constant volume fan, and a heating coil. In terms of EnergyPlus objects, this is:

1. AirLoopHVAC:ZoneMixer
2. Fan:SystemModel or Fan:ConstantVolume
3. Coil:Heating:Water, Coil:Heating:Electric, Coil:Heating:Fuel or Coil:Heating:Steam

The parallel unit contains a fan (in the secondary air stream, an air mixer, and a heating coil. In terms of EnergyPlus objects, this is:

1. Fan:SystemModel or Fan:ConstantVolume
2. AirLoopHVAC:ZoneMixer
3. Coil:Heating:Water, Coil:Heating:Electric, Coil:Heating:Fuel or Coil:Heating:Steam

Both units are forward models: their inputs are defined by the state of their inlets: namely the air inlet and the hot water inlet. The outputs of the models are the conditions of the outlet air stream: flow rate, temperature and humidity ratio. The PIUs data and simulation are encapsulated in the module *PoweredInductionUnits*. The main simulation routine for the units within the module are *CalcSeriesPIU* and *CalcParallelPIU*.

14.1.6.3 Inputs and Data

The user describes the PIU by inputting the names of the mixer, fan and heating coil sub-components plus the type of the heating coil sub-component. The user must connect the unit to the overall HVAC systems by naming various inlet and outlet nodes: the primary air inlet node, the secondary air inlet node, the unit air outlet node, and the hot water inlet node. One internal node name is needed: the coil air inlet node (same as fan outlet mode for series, mixer outlet node for parallel). Design flow rates need to be specified (although these can be autosized): maximum total air flow rate (series), maximum primary air flow rate, minimum primary air flow fraction, maximum secondary air flow rate (parallel), fan-on flow fraction (parallel), and maximum and minimum hot water flow rates. A convergence tolerance needs to be specified for units with hot water coils. There is an on/off availability schedule that need to be set.

All input data for the powered induction terminal units is stored in the array *PIU*.

14.1.6.4 Calculation

The calculation is performed by simulating the sub-components in the order given above. Most of the code is involved with figuring out what the various flow rates should be before simulating the subcomponents. These calculations are described below.

14.1.6.5 Simulation and Control

Series

From the result of the zone simulation we have the heating/cooling demand on the terminal unit \dot{Q}_{tot} . The subroutine *CalcSeriesPIU* needs to determine the flow rates that will allow the unit to meet this load. The first step is to determine the on/off state of the unit and determine the air flow rates.

- If the unit is scheduled off, the primary and secondary flow rates are set to zero.
- If there is no primary air flow (or less than .001 kg/s), the primary air flow is set to zero and the secondary air flow is set to the constant total air flow input by the user only if there is a heating load.
- If the zone temperature is in the deadband or the zone load is less than 1 watt or the zone needs heating, the primary air flow rate is set to the minimum flow rate specified by the input and the secondary air flow rate is set to the difference between the fixed total air flow rate and the primary air flow rate.
- Otherwise, the zone needs cooling and the unit is active.
 - We determine the fan temperature rise: the secondary air flow is set to the max total air flow, primary air flow to zero, and the mixer and fan are simulated. The fan delta T is the difference between the temperature at the fan's outlet node and inlet node.
 - We calculate the unit air outlet temperature needed to meet the zone cooling load: $T_{out} = T_z + \dot{Q}_{z,req}/(\dot{m}_{air,tot} \cdot c_{p,air,z})$
 - The temperature needed at the outlet of the mixer is then: $T_{mix} = T_{out} - \Delta T_{fan}$
 - We can then set the primary air flow rate.
 - * If $T_{mix} \leq T_{in,pri}$, then $\dot{m}_{pri} = \dot{m}_{pri,max}$
 - * Else if $T_{mix} \geq T_{in,pri}$ and $T_{mix} \geq T_{in,sec}$, then $\dot{m}_{pri} = \dot{m}_{pri,min}$
 - * Otherwise $\dot{m}_{pri} = \dot{m}_{air,tot} \cdot (T_{in,sec} - T_{mix}) / (T_{in,sec} - T_{in,pri})$, subject to the constraints that the flow rate can't be bigger than the max and min allowed.

The air flow rates are now determined and we can fire the air mixer (Call *SimAir-Mixer*) and fan (Call *SimulateFanComponents*) component simulations. Finally we simulate the heating coil:

- for a hot water coil, if the coil is off (no flow, deadband, no load) just fire the coil simulation once (Call *SimulateWaterCoilComponents*). Otherwise call *ControlCompOutput*; *ControlCompOutput* is a general component control routine. In this case it calls *SimulateWaterCoilComponents* repeatedly while varying the hot water flow rate and minimizing

$$(c_{p,air} \cdot \dot{m}_{air,tot} \cdot (T_{out} - T_z) - \dot{Q}_{z,req}) / \dot{Q}_{z,req} \quad (14.15)$$

to within the heating convergence tolerance.

- For gas, electric or steam coils, the required coil output is set to $\dot{Q}_{coil,req} = \dot{Q}_{z,req} - c_{p,air} \cdot \dot{m}_{air,coil}(T_{air,coil,in} - T_z)$. Then the coil simulation is fired (Call *SimulateHeatingCoilComponent* or *SimulateSteamCoilComponents*).

Finally the unit sensible output is calculated:

$$\dot{Q}_{sens,out} = \text{PsyHFnTdbW}(T_{air,out}, W_z) - \text{PsyHFnTdbW}(T_z, W_z) \quad (14.16)$$

where *PsyHFnTdb* is the EnergyPlus function giving enthalpy as a function of temperature and humidity ratio.

Parallel

From the result of the zone simulation we have the heating/cooling demand on the terminal unit \dot{Q}_{tot} . The subroutine *CalcParallelPIU* needs to determine the flow rates that will allow the unit to meet this load. The first step is to determine the on/off state of the unit and determine the air flow rates.

- If the unit is scheduled off, the primary and secondary flow rates are set to zero.
- If there is no primary air flow (or less than .001 kg/s), the primary air flow is set to zero and the secondary air flow is set to the max secondary air flow input by the user only if there is a heating load.
- If the zone temperature is in the deadband or the zone load is less than 1 watt or the zone needs heating, the primary air flow rate is set to the minimum flow rate specified by the input. If there is a heating load or reheat is required, the secondary air flow rate is set to max secondary air flow input by the user.
- Otherwise, the zone needs cooling and the unit is active.
 - We determine the fan temperature rise: the secondary air flow is set to the max secondary air flow, primary air flow to zero, and the fan and mixer are simulated. The fan delta T is defined as the difference between the temperature at the mixer outlet node and the fan inlet node.
 - Assuming that the fan is off, we calculate the primary air flow needed to meet the cooling demand.

$$\dot{m}_{pri} = \dot{Q}_{z,req} / (c_{p,air} \cdot (T_{in,pri} - T_z)) \quad (14.17)$$

The flow rate is constrained to be between the min and max primary air flow rates. If this calculated primary flow rate is greater than the fan-on flow rate, the secondary flow rate is set to zero and we are done. Otherwise, the fan is on and we need to recalculate the primary air flow rate.

$$\dot{m}_{pri} = (\dot{Q}_{z,req} - c_{p,air} \cdot \dot{m}_{sec} \cdot (T_{in,sec} + \Delta T_{fan} - T_z)) / (c_{p,air} \cdot (T_{in,pri} - T_z)) \quad (14.18)$$

The secondary flow rate is set to the user input fixed flow rate if reheat is required or if the primary air flow fraction is at or below the user-specified fan on fraction. The primary air flow rate is constrained to be between the min and max primary flow rated.

The air flow rates are now determined and we can fire the fan (Call *SimulateFanComponents*) and air mixer (Call *SimAirMixer*) component simulations. Finally we simulate the heating coil:

- For a hot water coil, if the coil is off (no flow, deadband, no load) just fire the coil simulation once (Call *SimulateWaterCoilComponents*). Otherwise call *ControlCompOutput*; *ControlCompOutput* is a general component control routine. In this case it calls *SimulateWaterCoilComponents* repeatedly while varying the hot water flow rate and minimizing

$$(c_{p,air} \cdot \dot{m}_{air,tot} \cdot (T_{out} - T_z) - \dot{Q}_{z,req}) / \dot{Q}_{z,req} \quad (14.19)$$

to within the heating convergence tolerance.

- For gas, electric or steam coils, the required coil output is set to $\dot{Q}_{coil,req} = \dot{Q}_{z,req} - c_{p,air} \cdot \dot{m}_{air,coil}(T_{air,coil,in} - T_z)$. Then the coil simulation is fired (Call *SimulateHeatingCoilComponent* or *SimulateSteamCoilComponents*).

Finally the unit sensible output is calculated:

$$\dot{Q}_{sens,out} = \text{PsyHFnTdbW}(T_{air,out}, W_z) - \text{PsyHFnTdbW}(T_z, W_z) \quad (14.20)$$

where *PsyHFnTdb* is the EnergyPlus function giving enthalpy as a function of temperature and humidity ratio.

14.1.7 Variable Air Volume Fan Powered Single Duct Air Terminal

14.1.7.1 Overview

The input object *AirTerminal:SingleDuct:VAV:Reheat:VariableSpeedFan* provides a model for variable speed (VS) fan VAV terminal unit that is a typical VAV reheat unit with the addition of a variable-speed blower fan to assist in moving supply air from the plenum to the conditioned zone. It is typically used with under-floor air distribution systems (UFAD) where the supply air is sent at low static pressure through an under-floor supply plenum. The fan has two maximum flow rate settings: one for cooling and one for heating. The cooling maximum is usually the actual fan maximum while the heating maximum is a lesser flow rate. The fan is upstream of the heating coil (this is a blow-through unit). The heating coil can be hot-water, electric or gas. Cooling control is obtained by varying the supply air flow rate from the cooling maximum to the minimum flow rate. Heating control is established by varying both the heating coil output (or hot water flow rate for hot water coils) and the supply air flow rate. Note that for this unit the minimum supply air flow rate is the flow rate when the fan is off.

14.1.7.2 Model

The VS fan VAV terminal unit is modeled as a compound component consisting of two sub-components: a fan and a heating coil. In terms of EnergyPlus objects the fan is a *Fan:VariableVolume* object and the heating coil is a *Coil:Heating:Water*, *Coil:Heating:Electric* or a *Coil:Heating:Fuel*. The terminal unit is a forward model: its inputs are defined by the state of its inlets: namely its air inlet and its hot water inlet, if it has a hot water coil. The outputs of

the model are the conditions of the outlet air stream: flow rate, temperature and humidity ratio. The terminal unit data and simulation are encapsulated in the module *SingleDuct*. The main simulation routine for the unit within the module is *SimVAVVS*.

14.1.7.3 Inputs and Data

The user describes the terminal unit by inputting the name and type of the heating coil and the name and type of the fan. The user must also specify the connectivity of the component by naming the inlet air node; the air node connecting the fan and heating coil (fan outlet, coil inlet); the unit air outlet node (same as the zone inlet node); and hot water inlet node (if any). Maximum flow rates need to be specified (although these can be autosized): maximum cooling and heating air flow rates and the maximum hot water flow rate (if there is a hot water coil). Minimum flow rates are specified by giving a minimum flow fraction for the air flow and a volumetric flow rate minimum for the hot water. For the units with hot water coils the relative convergence tolerance for the hot water flow rate also needs to be input (or allowed to default).

All input data for the VS fan VAV terminal units is stored in the array *sd_airterminal*.

14.1.7.4 Calculation

Given the needed inputs, the output is calculated in subroutine *CalcVAVVS*. The temperature and humidity of the supply air stream are taken from the inlet air node. The inlet air flow rate and the hot water flow rate are passed in as parameters. If the coil is electric or gas the coil heating power is passed instead of the hot water flow rate. Then

The fan is simulated (call *SimulateFanComponents*). If the fan is off the fan outlet conditions are set to the inlet conditions.

The heating coil is simulated (call *SimulateWaterCoilComponents* if the coil is a hot water coil; call *SimulateHeatingCoilComponents* if the coil is gas or electric).

Finally the sensible load met by the terminal unit is calculated and passed back to the calling routine:

$$\dot{Q}_{out} = \dot{m}_{air} \cdot c_{p,air} \cdot (T_{air,out} - T_{air,zone}) \quad (14.21)$$

Note that data is never explicitly passed between the sub-components. This is all handled automatically by the node connections and the data stored on the nodes.

14.1.7.5 Simulation and Control

From the result of the zone simulation we have the heating/cooling demand on the terminal unit \dot{Q}_{tot} . For the given inlet conditions *CalcVAVVS* will give us the terminal unit heating/cooling output. We need to vary the air or hot water flow rate or the heating coil power (for gas or electric coils) to make the unit output match the demand. To do this we need to numerically invert *CalcVAVVS*: given the output, we want one of the inputs – the air or hot water flow rate or the heating coil power. The numerical inversion is carried out by calling subroutine *SolveRegulaFalsi*. This is a general utility routine for finding the zero of a function (the *residual* function) of a single independent variable. In this case the residual function calculates $(\dot{Q}_{tot} - \dot{Q}_{out})/\dot{Q}_{tot}$. *SolveRegulaFalsi* varies either the air mass flow rate, the hot water mass flow rate or the heating coil power to zero the residual.

The unit is simulated in the following sequence.

Decide whether the unit is on or off. The unit is off if: a) it is scheduled off; b) the inlet air mass flow rate is zero; or c) the zone thermostat is in the deadband

If the unit is off, call *CalcVAVVS* with flow rates set to their minimum flows and return.

If the unit is on, we need to establish the boundaries of 4 conditioning regions: a) active cooling with fan on; b) active heating with fan on; c) active heating with fan off; d) passive cooling with fan off. The heating/cooling demand will fall into one of these regions. Once the correct region is determined, we will know which model input to vary for control and thus how to invert the calculation.

To establish the boundaries of region a) we call *CalcVAVVS* twice: once with the supply air flow rate set to the cooling maximum, once with the cooling air flow rate set to the minimum. In both cases the heating coil output is at the minimum and the fan is on. Call the 2 cooling outputs $\dot{Q}_{cool,max,fanon}$ and $\dot{Q}_{cool,min,fanon}$. Remembering that EnergyPlus convention is that cooling loads are negative, then if $\dot{Q}_{tot} < \dot{Q}_{cool,max,fanon}$ the terminal unit can not meet the demand. Set the air mass flow rate to the cooling maximum and call *CalcVAVV* again. This concludes the simulation. If $\dot{Q}_{cool,max,fanon} < \dot{Q}_{tot} < \dot{Q}_{cool,min,fanon}$ the cooling demand is in the active cooling region. We hold the heating at the minimum, allow the supply air flow to vary between the cooling maximum and the minimum with the fan on, and call *SolveRegulaFalsi* to obtain the supply air flow rate that will produce the unit sensible cooling output that matches the demand. This concludes the simulation.

To establish the boundaries of region b) call *CalcVAVVS* twice: once with the supply air flow rate set to the heating maximum, once with the supply air flow rate set to the minimum. In both calls, if the heating coil is a hot water coil, the hot water flow rate is at the maximum. For electric and gas coils, the heating power is set to the maximum at maximum supply air flow and to zero at the minimum supply air flow. In both calls the fan is set to be on. Call the 2 heating outputs returned from the two calls to *CalcVAVVS* $\dot{Q}_{heat,max,fanon}$ and $\dot{Q}_{heat,min,fanon}$. If $\dot{Q}_{heat,max,fanon} < \dot{Q}_{tot}$ the terminal unit can not meet the load. Set the air flow rate to the heating maximum and the hot water flow rate or heating coil power to the maximum and call *CalcVAVVS* again. This concludes the simulation for this case. If $\dot{Q}_{heat,min,fanon} < \dot{Q}_{tot} < \dot{Q}_{heat,max,fanon}$ the heating demand is in the active heating, fan on region. For a hot water coil we call *SolveRegulaFalsi* with the supply air flow rate as the input that is varied and the hot water flow rate set to the maximum. For electric and gas coils the coil power and the supply air flow rate are both varied together from their minimum to maximum in a call to *SolveRegulaFalsi*. The call to *SolveRegulaFalsi* concludes the simulation for this case.

This region only applies to terminal units with a hot water coil. To establish the boundaries of region c) the fan is set to off, the supply air flow rate is set to minimum flow and *CalcVAVVS* is called twice: once with the hot water flow at maximum and once with the hot water flow at minimum. Call the two heating outputs $\dot{Q}_{heat,max,fanoff}$ and \dot{Q}_{tot} . If \dot{Q}_{tot} is between these values, the supply air flow rate is set to its minimum, the fan is set to off, and in the call to *SolveRegulaFalsi* the hot water flow rate is varied to meet the load. This concludes the simulation for this case.

If the cooling demand does not fall into cases a) – c), the unit is assumed to be in the passive cooling state: heating is off or at the minimum, the fan is off, and the minimum supply air flow is delivered to the zone.

Note that the terminal unit output is never explicitly passed to another routine. Instead the output is saved as the outlet conditions on the terminal unit outlet air node. The node data is accessed when the terminal unit output is needed elsewhere in the program (in *SimZoneAirLoopEquipment* for instance).

14.1.8 Four Pipe Beam Unit (AirTerminal:SingleDuct:ConstantVolume:FourPipeBeam)

The four pipe beam air terminal units (*AirTerminal:SingleDuct:ConstantVolume:FourPipeBeam*) are ceiling-mounted, beam-type units that are provided with primary air from a central system and additional heating or cooling by inducing room air to flow over a hydronic convector. They are called *four pipe* because the units are connected with two pipes for chilled water supply and return and another two pipes for hot water supply and return. A simple empirical model is used to enable using input data derived from manufacturer's catalog data.

14.1.8.1 Model Description

The model assumes that the total conditioning power, \dot{Q}_{Tot} , is the sum of the conditioning provided by the primary air, \dot{Q}_{SA} , and the conditioning provided by the beam convector, \dot{Q}_{Beam} .

$$\dot{Q}_{Tot} = \dot{Q}_{SA} + \dot{Q}_{Beam} \quad (14.22)$$

The primary air contribution is easily determined using:

$$\dot{Q}_{SA} = \dot{m}_{SA} \cdot (c_{p,SA} \cdot T_{SA} - c_{p,Z} \cdot T_Z) \quad (14.23)$$

The convector power \dot{Q}_{Beam} is coupled directly to the zone air heat balance (using a source code term called *NonAirSysOutput*) in a way that provides only sensible heat transfer directly to the zone air node. We therefore assume that the air terminal's convector is always dry during cooling. Many of the terms used in the performance calculations are normalized by the total length of beam in zones, L .

When the unit is operated in cooling mode, the convector power is determined using the rated normalized cooling capacity that is modified by three separate functions.

$$\dot{Q}_{Beam,cool} = \dot{q}_{cool,rated} \cdot f_{\Delta T_{cool,mod}}() \cdot f_{\dot{m}_{SA,cool,mod}}() \cdot f_{\dot{m}_{CW,mod}}() \cdot L \quad (14.24)$$

The modification factor $f_{\Delta T_{cool,mod}}()$ describes how the cooling capacity is adjusted to account for the temperature difference between the zone air and the chilled water entering the convector. This empirical correction factor is intended to account for how heat transfer between the chilled water and induced room air flow depends on the temperature difference, both in terms of surface convection heat transfer and the rate of induced air flow. The function can be described using any of the single-variable curves or a lookup table. The single independent variable is the ratio between the current temperature difference, ΔT_{air-CW} , and the temperature difference used to rate beam performance, $\Delta T_{air-CW,rated}$.

$$f_{\Delta T_{cool,mod}}() = f_{\Delta T_{cool,mod}}\left(\frac{\Delta T_{air-CW}}{\Delta T_{air-CW,rated}}\right) \quad (14.25)$$

$$\Delta T_{air-CW} = T_Z - T_{CW,in} \quad (14.26)$$

The modification factor $f_{\dot{m}_{SA,cool,mod}}()$ describes how the cooling capacity is adjusted to account for the primary air flow rate. This empirical correction factor is intended to account for how varying

primary air flow rates will impact the rate that room air is induced to flow across the convector. The function can be described using any of the single-variable curves or a lookup table. The single independent variable is the ratio between the current normalized primary air flow rate, \dot{m}_{SA} , and the normalized flow rate used to rate beam performance, $\dot{m}_{SA,rated}$. Flow rates are normalized by dividing the total length of all the beam units in the zone. The ratio is calculated using air mass flow rates with the rated flow rate assumed to be for standard temperature and pressure at sea level so that elevation effects appear only in the numerator when the function is evaluated.

$$f_{\dot{m}_{SA,cool,mod}}() = f_{\dot{m}_{SA,cool,mod}}\left(\frac{\dot{m}_{SA}}{\dot{m}_{SA,rated}}\right) \quad (14.27)$$

$$\dot{m}_{SA} = \frac{\dot{M}_{SA}}{L} \quad (14.28)$$

$$\dot{m}_{SA,rated} = \dot{v}_{SA,rated} \cdot \rho_{air,STP} \quad (14.29)$$

The modification factor $f_{\dot{m}_{CW,mod}}()$ describes how the cooling capacity is adjusted to account for the flow rate of chilled water through the convector. This empirical correction factor is intended to account for how varying chilled water flow rates will impact the velocity of fluid inside the pipes and the corresponding impact on the rate of surface convection heat transfer inside the convector. The function can be described using any of the single-variable curves or a lookup table. The single independent variable is the ratio between the current normalized chilled water flow rate, \dot{m}_{CW} , and the normalized chilled water flow rate at the rating point, $\dot{m}_{CW,rated}$.

$$f_{\dot{m}_{CW,mod}}() = f_{\dot{m}_{CW,mod}}\left(\frac{\dot{m}_{CW}}{\dot{m}_{CW,rated}}\right) \quad (14.30)$$

$$\dot{m}_{CW} = \frac{\dot{M}_{CW}}{L} \quad (14.31)$$

$$\dot{m}_{CW,rated} = \dot{v}_{CW,rated} \cdot \rho_{CW} \quad (14.32)$$

The model for when the unit is operated in heating mode is very similar. The convector power is determined using the rated normalized heating capacity that is modified by three separate functions.

$$\dot{Q}_{Beam,heat} = \dot{q}_{heat,rated} \cdot f_{\Delta T_{heat,mod}}() \cdot f_{\dot{m}_{SA,heat,mod}}() \cdot f_{\dot{m}_{HW,mod}}() \cdot L \quad (14.33)$$

The modification factor $f_{\Delta T_{heat,mod}}()$ describes how the heating capacity is adjusted to account for the temperature difference between the hot water and the zone air entering the convector. Notice that for heating the temperature difference is defined different from cooling operation so that positive difference values are the result. This empirical correction factor is intended to account for how heat transfer between the hot water and induced room air flow depends on the temperature difference, both in terms of surface convection heat transfer and induced air flow rates. The function can be described using any of the single-variable curves or a lookup table. The single independent variable is the ratio between the current temperature difference, ΔT_{HW-air} , and the temperature difference used to rate beam performance, $\Delta T_{HW-air,rated}$.

$$f_{\Delta T_{heat,mod}}() = f_{\Delta T_{heat,mod}}\left(\frac{\Delta T_{HW-air}}{\Delta T_{HW-air,rated}}\right) \quad (14.34)$$

$$\Delta T_{HW-air} = T_{HW,in} - T_Z \quad (14.35)$$

The modification factor $f_{\dot{m}_{SA,heat,mod}}()$ describes how the heating capacity is adjusted to account for the primary supply air flow rate. This empirical correction factor is intended to account for how varying primary air flow rates will impact the rate that room air is induced to flow across the convector. The function can be described using any of the single-variable curves or a lookup table. The single independent variable is the same ratio described above for cooling and it is assumed that the unit can be rated using the same primary air flow rate for both heating and cooling operation of the four pipe unit. Flow rates are normalized by dividing the total length of all the beam units in the zone. The ratio is calculated using air mass flow rates with the rated flow rate assumed to be for standard temperature and pressure at sea level so that elevation effects appear only in the numerator when the function is evaluated.

$$f_{\dot{m}_{SA,heat,mod}}() = f_{\dot{m}_{SA,heat,mod}}\left(\frac{\dot{m}_{SA}}{\dot{m}_{SA,rated}}\right) \quad (14.36)$$

The modification factor $f_{\dot{m}_{HW,mod}}()$ describes how the heating capacity is adjusted to account for the flow rate of hot water through the convector. This empirical correction factor is intended to account for how varying hot water flow rates will impact the velocity of fluid inside the pipes and the corresponding impact on the rate of surface convection heat transfer inside the convector. The function can be described using any of the single-variable curves or a lookup table. The single independent variable is the ratio between the current normalized hot water flow rate, \dot{m}_{HW} , and the normalized hot water flow rate at the rating point, $\dot{m}_{HW,rated}$.

$$f_{\dot{m}_{HW,mod}}() = f_{\dot{m}_{HW,mod}}\left(\frac{\dot{m}_{HW}}{\dot{m}_{HW,rated}}\right) \quad (14.37)$$

$$\dot{m}_{HW} = \frac{\dot{M}_{HW}}{L} \quad (14.38)$$

$$\dot{m}_{HW,rated} = \dot{v}_{HW,rated} \cdot \rho_{HW} \quad (14.39)$$

where:

$c_{p,SA}$ is the specific heat of primary air entering through the air terminal unit, in J/kg-K.

$c_{p,Z}$ is the specific heat of zone air, in J/kg-K.

$c_{p,CW}$ is the specific heat of zone air, in J/kg-K.

$f_{\dot{m}_{CW,mod}}()$ is the cooling capacity modification factor function of chilled water flow rate

$f_{\Delta T_{cool,mod}}()$ is the cooling capacity modification factor function of air-water temperature difference

$f_{\dot{m}_{SA,cool,mod}}()$ is the cooling capacity modification factor function of primary air flow rate

$f_{\dot{m}_{HW,mod}}()$ is the heating capacity modification factor function of hot water flow rate

$f_{\Delta T_{heat,mod}}()$ is the heating capacity modification factor function of water - air temperature difference

$f_{\dot{m}_{SA,heat,mod}}()$ is the heating capacity modification factor function of primary air flow rate

L is the total length of all beam units serving the zone, in m

\dot{m}_{CW} is the mass flow rate of chilled water per meter of length, in kg/s-m

$\dot{m}_{CW,rated}$ is the mass flow rate of chilled water per meter of length at rating point, in kg/s-m

\dot{m}_{HW} is the mass flow rate of hot water per meter of length, in kg/s-m

$\dot{m}_{HW,rated}$ is the mass flow rate of hot water per meter of length at rating point, in kg/s-m

\dot{m}_{SA} is the mass flow rate of primary air per meter of length, in kg/s-m

$\dot{m}_{SA,rated}$ is the mass flow rate of primary air per meter of length at rating point, kg/s-m

\dot{M}_{SA} is the mass flow rate of primary air entering the zone through the air terminal unit, in kg/s

\dot{M}_{CW} is the mass flow rate of chilled water, kg/s

\dot{M}_{HW} is the mass flow rate of hot water, kg/s

$\dot{q}_{cool,rated}$ is the rated beam cooling capacity per meter of length, in W/m.

$\dot{q}_{heat,rated}$ is the rated beam heating capacity per meter of length, in W/m.

\dot{Q}_{Beam} is the conditioning power delivered to the zone by the beam convector, in W.

\dot{Q}_{SA} is the conditioning power delivered to the zone by the primary air mass flow, in W.

\dot{Q}_{Tot} is the total (net) conditioning power delivered to zone by the air terminal unit, in W.

$\rho_{air,STP}$ is the density of air at standard conditions (sea level), in kg/m³

ρ_{air} is the density of air at standard conditions adjusted for elevation), in kg/m³

ρ_{CW} is the density of chilled water, in kg/m³

T_{SA} is the drybulb temperature of the (central) primary air entering the air terminal unit, in degrees C.

T_Z is the drybulb temperature of the zone air, in °C.

$T_{CW,in}$ is the temperature of chilled water entering the convector, in °C.

ΔT_{air-CW} is the difference between the zone air temperature and chilled water entering the convector, Δ°C.

ΔT_{HW-air} is the difference between the water and zone air temperature entering the convector, Δ°C.

$\Delta T_{air-CW,rated}$ is the value of ΔT_{air-CW} at rating conditions for cooling performance, Δ°C.

$\Delta T_{HW-air,rated}$ is the value of ΔT_{HW-air} at rating conditions for heating performance, Δ°C.

$\dot{v}_{SA,rated}$ is the volume flow rate of air per meter length at rating point, in m³/s-m.

$\dot{v}_{CW,rated}$ is the volume flow rate of chilled water per meter length at rating point, in m³/s-m.

$\dot{v}_{HW,rated}$ is the volume flow rate of hot water per meter length at rating point, in m³/s-m.

The performance capacity model described above is controlled to modulate water flow through the beam's convector using the non-linear numerical solver in EnergyPlus called Solve root solver. The predicted zone load to setpoint $\dot{Q}_{Zone,Required}$ is adjusted by \dot{Q}_{SA} to determine the required beam load.

$$\dot{Q}_{Beam,Required} = \dot{Q}_{Zone,Required} - \dot{Q}_{SA} \quad (14.40)$$

When $\dot{Q}_{Zone,Required}$ is negative, the beams need to provide cooling and when it is positive the beams need to provide heating. The the solver iterates the water flow rate to find a flow rate that will meet the load.

When cooling, the result for beam capacity (negative for cooling) is used to calculate the leaving temperature of the chilled water using:

$$T_{CW,out} = T_{CW,in} - \frac{\dot{Q}_{Beam}}{\dot{m}_{CW} \cdot c_{p,CW}} \quad (14.41)$$

However, to protect from a non-physical result the leaving chilled water temperature is constrained to be no warmer than a 1.0°C approach temperature compared to the zone air or the primary supply air. If the above result is too warm the leaving temperature and beam cooling

capacity are adjusted using the following equations, and a recurring warning is issued to alert the user that there may be a problem with the cooling performance input data.

$$T_{CW,out} = \max(T_{SA}, T_Z) - 1.0 \quad (14.42)$$

$$\dot{Q}_{Beam} = \dot{m}_{CW} \cdot c_{p,CW} \cdot (T_{CW,in} - T_{CW,out}) \quad (14.43)$$

Similarly when heating, the result for beam capacity (positive for heating) is used to calculate the leaving temperature of the hot water using,

$$T_{HW,out} = T_{HW,in} - \frac{\dot{Q}_{Beam}}{\dot{m}_{HW} \cdot c_{p,HW}} \quad (14.44)$$

To protect from a non-physical result the leaving hot water temperature is constrained to be no cooler than a 1.0°C approach temperature compared to the zone air or the primary supply air. If the above result is too cool the leaving temperature and beam heating capacity are adjusted using the following equations, and a recurring warning is issued to alert the user that there may be a problem with the heating performance input data.

$$T_{HW,out} = \min(T_{SA}, T_Z) + 1.0 \quad (14.45)$$

$$\dot{Q}_{Beam} = \dot{m}_{CW} \cdot c_{p,CW} \cdot (T_{HW,in} - T_{HW,out}) \quad (14.46)$$

14.1.8.2 Four Pipe Beam Sizing

The four pipe beam model has four inputs that can be autosized:

- L is the total length of all beam units serving the zone, in m
- $\dot{V}_{SA,Des}$ is the design primary supply air volume flow rate, in m³/s
- $\dot{V}_{CW,Des}$ is the design chilled water volume flow rate, in m³/s
- $\dot{V}_{HW,Des}$ is the design hot water volume flow rate, in m³/s

Because of the way the model is formulated with defaulted inputs for rated, normalized performance data, we can link the four inputs together to ensure an internally consistent set of sizes. If any one of these four inputs is not autosized (given a fixed value at input) then the other three can be computed using the normalized, rated performance data which are either input or have default values. If the total beam length is input, then the following equations are used:

$$\dot{V}_{SA,Des} = \dot{v}_{SA,rated} \cdot L \quad (14.47)$$

$$\dot{V}_{CW,Des} = \dot{v}_{CW,rated} \cdot L \quad (14.48)$$

$$\dot{V}_{HW,Des} = \dot{v}_{HW,rated} \cdot L \quad (14.49)$$

If the design primary supply air flow rate is input then the beam length can be determined as follows and then water flow rates evaluated as above.

$$L = \frac{\dot{V}_{SA,Des}}{\dot{v}_{SA,rated}} \quad (14.50)$$

If the chilled water flow rate is input, then the beam length can be determined as follows and the other values evaluated as above:

$$L = \frac{\dot{V}_{CW,Des}}{\dot{v}_{CW,rated}} \quad (14.51)$$

If the hot water flow rate is input, then the beam length can be determined as follows and the other values evaluated as above:

$$L = \frac{\dot{V}_{HW,Des}}{\dot{v}_{HW,rated}} \quad (14.52)$$

When all four inputs are autosized, which is the usual case, there is no simple way to anchor the sizes and we need to use the results from the zone and system sizing calculations to determine sizes for the four pipe beam unit. The following design data from the zone and system sizing calculations are used when sizing the four pipe beam:

$\dot{V}_{TU,Z,final,cool}$ is the final zone terminal unit design volume flow rate for cooling, in m^3/s

$\dot{V}_{TU,Z,final,heat}$ is the final zone terminal unit design volume flow rate for heating, in m^3/s

$\dot{V}_{Z,final,OA}$ is the final zone design volume flow rate for minimum outdoor air mechanical ventilation, in m^3/s .

$T_{SA,cool,design}$ is the final design zone terminal unit inlet supply air temperature at cooling peak, in $^{\circ}\text{C}$.

$w_{SA,cool,design}$ is the final design zone terminal unit inlet supply air humidity ratio at cooling peak, in $\text{kg}_{H_2O}/\text{kg}_{dryair}$.

$T_{Z,cool,design}$ is the final design zone air temperature at cooling peak, in $^{\circ}\text{C}$.

$w_{Z,cool,design}$ is the final design zone air humidity ratio at cooling peak, in $\text{kg}_{H_2O}/\text{kg}_{dryair}$.

$\dot{Q}_{Z,cool,design}$ is the final design zone cooling load at cooling peak, in W.

$T_{CW,design}$ is the chilled water plant loop supply side design exit temperature, in $^{\circ}\text{C}$.

$T_{SA,heat,design}$ is the final design zone terminal unit inlet supply air temperature at heating peak, in $^{\circ}\text{C}$.

$w_{SA,heat,design}$ is the final design zone terminal unit inlet supply air humidity ratio at heating peak, in $\text{kg}_{H_2O}/\text{kg}_{dryair}$.

$T_{Z,heat,design}$ is the final design zone air temperature at heating peak, in $^{\circ}\text{C}$.

$w_{Z,heat,design}$ is the final design zone air humidity ratio at heating peak, in $\text{kg}_{H_2O}/\text{kg}_{dryair}$.

$\dot{Q}_{Z,heat,design}$ is the final design zone heating load at heating peak, in W.

$T_{HW,design}$ is the hot water plant loop supply side design exit temperature, in $^{\circ}\text{C}$.

Overhead beam type air terminals induce room air to flow over the convector by the directing primary supply air through special nozzles. Therefore, the cooling and heating capacity of the beam's convector is not separable from the primary flow rate, varying the primary flow rate varies the beam capacity. The design primary flow rate is chosen to be largest value that satisfies three requirements: (1) the ventilation requirement, (2) the design cooling load (if cooling is present), (3) and the design heating load (if heating is present).

The sizing method here uses the non-linear solver inside EnergyPlus, called root solver, to arrive at a set of sizes that meet the design load. The solver is for a single independent variable and although we have four sizes to solve for, we can reduce the problem to finding a suitable design primary supply air flow rate and then the other sizes can be determined from that as shown above. The solver needs as its input a minimum and a maximum “x-value,” which here is the primary supply air flow rate, and then it searches for a solution that minimizes a residual. In general the design primary supply flow rate that meets the load is somewhere between the minimum flow required for ventilation and a maximum flow where the primary supply flow meets all the zone’s design load without any help from the beam’s convector. For example if the supply air is cold, as it would be for latent control, and there is a cooling load then there will be a relatively large air flow rate that meets all the load without any cooling from chilled water circulating through the beam. This larger air flow serves as the upper bound for the solver.

When sizing for the cooling design load, the following design values are set for use in the model calculations:

$$T_{CW,in} = T_{CW,design} \quad (14.53)$$

$$\dot{m}_{HW} = 0.0 \quad (14.54)$$

$$T_Z = T_{Z,cool,design} \quad (14.55)$$

$$T_{SA} = T_{SA,cool,design} \quad (14.56)$$

$$c_{p,Z} = PsyCpAirFnW(w_{Z,cool,design}) \quad (14.57)$$

$$c_{p,SA} = PsyCpAirFnW(w_{SA,cool,design}) \quad (14.58)$$

$$\dot{Q}_{Zone,Required} = -1.0 \cdot \dot{Q}_{Z,cool,design} \quad (14.59)$$

$$\dot{m}_{SA,maxlimit} = \left(\frac{\dot{Q}_{Z,cool,design}}{c_{p,SA} \cdot (T_{Z,cool,design} - T_{SA,cool,design})} \right) \quad (14.60)$$

or if $(T_{Z,cool,design} - T_{SA,cool,design}) < 2.0$ then:

$$\dot{m}_{SA,maxlimit} = \left(\frac{\dot{Q}_{Z,cool,design}}{c_{p,SA} \cdot 2.0} \right) \quad (14.61)$$

$$\dot{m}_{SA,minlimit} = \min(\dot{V}_{Z,final,OA}, \frac{\dot{m}_{SA,maxlimit}}{3.0}, \max(\dot{V}_{TU,Z,final,heat}, \dot{V}_{TU,Z,final,cool})) \quad (14.62)$$

When sizing for the heating design load, the following design values are set for use in the model calculations:

$$T_{HW,in} = T_{HW,design} \quad (14.63)$$

$$\dot{m}_{CW} = 0.0 \quad (14.64)$$

$$T_Z = T_{Z,heat,design} \quad (14.65)$$

$$T_{SA} = T_{SA,heat,design} \quad (14.66)$$

$$c_{p,Z} = PsyCpAirFnW(w_{Z,heat,design}) \quad (14.67)$$

$$c_{p,SA} = PsyCpAirFnW(w_{SA,heat,design}) \quad (14.68)$$

$$\dot{Q}_{Zone,Required} = \dot{Q}_{Z,heat,design} \quad (14.69)$$

$$\dot{m}_{SA,maxlimit} = \left(\frac{\dot{Q}_{Z,heat,design}}{c_{p,SA} \cdot (T_{SA,heat,design} - T_{Z,heat,design})} \right) \quad (14.70)$$

or if $(T_{SA,heat,design} - T_{Z,heat,design}) < 2.0$ then:

$$\dot{m}_{SA,maxlimit} = \left(\frac{\dot{Q}_{Z,heat,design}}{c_{p,SA} \cdot 2.0} \right) \quad (14.71)$$

$$\dot{m}_{SA,minlimit} = 0.0 \quad (14.72)$$

The trial value for design primary supply air flow rate is used to calculate design values for length, chilled water flow, and hot water flow.

$$\dot{V}_{SA,Des} = \left(\frac{\dot{m}_{SA,trial}}{\rho_{air}} \right) \quad (14.73)$$

$$L = \frac{\dot{V}_{SA,Des}}{\dot{v}_{SA,rated}} \quad (14.74)$$

$$\dot{V}_{CW,Des} = \dot{v}_{CW,rated} \cdot L \quad (14.75)$$

$$\dot{V}_{HW,Des} = \dot{v}_{HW,rated} \cdot L \quad (14.76)$$

The residual is calculated by evaluating the entire model to determine the total capacity for a trial flow rate (and corresponding design length and maximum water flow rates) and comparing it to the design load.

$$residuum = \left(\frac{(\dot{Q}_{Zone,Required} - \dot{Q}_{Tot})}{\dot{Q}_{Zone,Required}} \right) \quad (14.77)$$

After the solvers have run and the final sizes for the four pipe beam have been determined, there is one more step taken to make further adjustments in the central sizing data structures for sizing

air system components. The usual methods of sizing the main AirLoopHVAC branch and fans are not able account for the methods used to size the four pipe beam. When the Sizing:System object was set to use *VentilationRequirement*, the air handler will be too small. When the Sizing:System object was set to use *Sensible*, the air handler will be too large. The system sizing calculations have already been completed at the time the four pipe beam air terminals are sized so we need to make some adjustments. The final primary supply air flow rate size is compared to the original final zone sizes for the air terminal unit and the air loop sizes adjusted to make up for the difference. A sizing report item called “AirLoopHVAC Design Supply Air Flow Rate Adjustment [m3/s]” is generated for each four pipe beam that shows the magnitude of the adjustment to data structure values used to size central air systems. Therefore when autosizing air handlers with four pipe beams, it is expected that the outcomes for air system sizes will not agree with the system sizing reporting because of the differences introduced by this adjustment.

14.1.8.3 Developing Model Input From Catalog Data

An example is presented showing how manufacturer’s data can be converted into the input data for the proposed model. The following example is for a Trox active DID632A product with a type “H” nozzle, where the rating point has been chosen based on a 6 foot active length and 140 CFM primary rate with other rating conditions as listed in the catalog data. The EnergyPlus IDF input for this example is show as the example in the in the Input Output reference description of the four pipe beam.

Reference Values - Cooling							Reference Values - Heating							
t_R	75 °F	t_{CWS}	57 °F	t_R	70 °F	t_{HWS}	120 °F							
t_{Pr}	55 °F	\dot{V}_{CW}	1.50 GPM	t_{Pr}	55 °F									
Active Length	Nozzle Type	Primary Air		Cooling			Cooling			Heating			Isothermal Throw ⁶	NC ⁷

Figure 14.7: FourPipeBeam/tableData

Snippet of catalog data for capacity and primary air flow rate dependence (Trox DID632A)

Choosing a 6 foot beam (with Nozzle type H) at 140 CFM as the rating point, we get $3726 \text{ Btu/h} = 1092 \text{ W}$, $6 \text{ ft} = 1.83 \text{ m}$, and $1092/1.83 = 597 \text{ W/m}$ for normalized beam cooling capacity at rating point. The associated primary air flow rate of $140 \text{ ft}^3/\text{min} = 0.066 \text{ m}^3/\text{s}$ and $0.066/1.83 = 0.036 \text{ m}^2/\text{s}$ is the normalized beam primary air flow rate at the rating point. Note that because the flow rate is normalized by beam length, the units are $\text{m}^3/\text{s}/\text{m}$ (which reduces to m^2/s). The rating heating capacity is listed as a “net” heating rate but since this is not well defined in the catalog we go ahead and assume that this represents the beam heating rate where the associated cooling provided by the primary air has already been subtracted. The net heating capacity is $7411 \text{ Btu/h} = 2172 \text{ W}$. This value need to be increased by the primary cooling provided by $55^\circ\text{F} = 12.7^\circ\text{C}$ air entering a zone at $70^\circ\text{F} = 21^\circ\text{C}$. The catalog does not completely define the moist air state of the zone nor the primary air so we assume nominal average moist air density of 1.2 kg/m^3 and a specific heat of 1000.0 J/kg-K so that the primary air cooling rate is $(21 - 12.7) * 0.066 * 1.2 * 1000 = 660 \text{ W}$. The beam heating rate is therefore $2172 + 660 = 2832 \text{ W}$. Then normalizing for beam length $2832/1.83 = 1548 \text{ W/m}$ is the rated beam heating capacity.

The catalog includes two more data points for capacity at different flow rates, one for $100 \text{ ft}^3/\text{min}$ and the other for $180 \text{ ft}^3/\text{min}$. These are processed in the same way as the rating point data and used to create the modification curves that describe performance as a function of primary air flow rate.

14.1.9 Cooled Beam Unit (AirTerminal:SingleDuct:ConstantVolume:CooledBeam)

Cooled beam (frequently called chilled beams) systems are usually hybrid water – air systems. Commonly there is a constant flow, fixed temperature central forced air system for meeting ventilation and latent load requirements. Sometimes this forced air system’s flow rate is varied according to ventilation demand; and of course its supply air temperature could be reset in various ways. Sensible cooling load is met by the cooled beam units; these are ceiling suspended units with cool water circulating through them. Some types of units are “passive” – they cool by radiation and natural convection. Other types of units are “active” and act as supply air terminal units with the supply air inducing room air over the beam cooling elements. These units cool almost entirely by convection. The DOE-2 model (upon which this model is based) is a convection only model – even the “passive” units are assumed to operate 100% convectively. The cooled beam elements act as an alternative to normal ceiling radiant cooling: they are not coupled to the building mass and they operate more in a convective mode, but they can, like radiant cooling, use fairly warm cooling water.

Heating is accomplished separately from the cooled beam system – usually baseboards are used on the building perimeter to meet heating loads.

14.1.9.1 Model

The chilled beam system is modeled as an EnergyPlus terminal unit. In terms of configuration within the overall HVAC system, it resembles a 4 pipe induction terminal unit. The user describes the system as a typical single duct constant volume system (with outside air mixer, fan, heating and cooling coils) on the air loop side, and with cooled beam terminal units on the zone equipment side.

The model is an empirical model developed at the equipment manufacturer Halton Oy. It consists of the following relationships.

The beam cooling output per unit length in W/m is:

$$P_{beam} = A \cdot K \cdot \Delta T \quad (14.78)$$

The coil heat transfer coefficient in W/(m²K) is:

$$K = \alpha \cdot \Delta T^{n1} \cdot v_{\rho}^{n2} \cdot \omega^{n3} \quad (14.79)$$

The room air mass flow rate across coil in kg/(m²s) is:

$$v_{\rho} = (q_{in}/\alpha_0) \cdot \rho_{air} \quad (14.80)$$

The room air volumetric flow rate across coil per unit length in m³/(s-m) is:

$$q_{in} = K_1 \cdot \Delta T^n + K_{in} \cdot q_{pr} \quad (14.81)$$

where:

ΔT is the room air–water temperature difference (average water temperature is used) in °C

ω is the water velocity in m/s

q_{pr} is the supply air flow rate per unit length m³/(s-m).

The other symbols are the model parameters input by the user (see the IO Ref for descriptions).

14.1.9.2 Inputs and Data

The user describes the unit by inputting the name, referencing an availability schedule, and choosing a type (*active* or *passive*). The user must also specify the connectivity of the component by naming the inlet and outlet air and water nodes. The maximum water and fixed air flow rates need to be specified (although these can be autosized). The design inlet and outlet water temperatures are inputs. Generally the inlet water temperature is quite warm (15°C is the default) and the temperature rise is small (design outlet water temperature defaults to 17°C). Two key inputs are the number of beams (in the zone) and the beam length. It is generally wise to let these inputs autosize.

The remaining inputs are parameters specific to the product model. Good defaults are supplied and they should not be changed without information from the manufacturer.

14.1.9.3 Sizing

The Cooled Beam sizing calculations generally follow the procedures used for other terminal units (see *Loop Equipment Sizing*). One difference is that the Cooled Beams use the Cooled Beam inputs *Design Inlet Water Temperature* and *Design Outlet Water Temperature* for the chilled water ΔT rather than the ΔT from Plant Sizing. There are also two inputs unique to the Cooled Beam units that are autosized and will be described here.

The input *Number of individual beam units in the zone* is autosized by dividing the beam system zone design chilled water flow rate (either input by the user or autosized) by a nominal chilled water beam flow rate: 0.07 kg/s.

The input *Length of an individual beam unit* is autosized by using the model equations to calculate the length. The inputs to the equations are:

1. The design load per beam. The design load is calculated from the design water mass flow rate and the design water inlet and outlet temperatures. The design load is divided by the number of beams to obtain the design load per beam.
2. The design air supply air flow per beam – obtained by dividing the design supply air flow by the number of beams.
3. The design water flow per beam (m^3/s) – obtained by dividing the design water flow by the number of beams.
4. The design water velocity – obtained by dividing the design water flow per beam by the cross sectional inside area of a water tube ($\pi D^2/4$, where D is the input *Pipe inside diameter*).
5. Average air to water $\Delta T = T_{z,cool\ peak} - 0.5(T_{w,des\ inlet} + T_{w,des\ outlet})$; where $T_{z,cool\ peak}$ is the zone air temperature at the cooling peak and the $T_{w,des}$'s are the water design inlet and outlet temperatures.

With these inputs the model equations can be solve directly for beam length for passive cooled beams, and iteratively for active cooled beams.

14.1.9.4 Calculation

The subroutine *CalcCoolBeam* uses the model equations to calculate the cooling power $P_{beams,out}$ delivered to the room air and the outlet water temperature given the water flow rate (and the room air temperature and water inlet temperature). Since the model equations are nonlinear they must be solved iteratively. The subroutine does this by varying the outlet water temperature $T_{w,out}$ and calculating the water-side cooling power:

$$P_w = q_{w,beam} \cdot c_{p,w} \cdot (T_{w,out} - T_{w,in}) \quad (14.82)$$

and comparing it to the air-side cooling power:

$$P_{air} = K \cdot A \cdot \Delta T \cdot L_{beam} \quad (14.83)$$

where $q_{w,beam}$ is the water mass flow rate (kg/s) per beam and L_{beam} is the length of a beam (m). When P_w and P_{air} match to within 0.1 W the subroutine terminates the iteration.

14.1.9.5 Simulation and Control

From the result of the zone simulation we have the heating/cooling demand for the zone equipment. For the cooling demand, we use the load to cooling set point P_c . Part of the demand may be satisfied by the zone supply air:

$$P_{sup} = q_{air} \cdot (c_{p,air,sys} \cdot T_{sys} - c_{p,air,z} \cdot T_z) \quad (14.84)$$

The demand on the actual beams is then:

$$P_{beams,dem} = P_c - P_{sup} \quad (14.85)$$

We want to know the chilled water flow rate that will give a beam cooling output of P_{beams} . To obtain this we need to numerically invert *CalcCoolBeam*: given its desired output, we want to

know the chilled water flow rate. This numerical inversion is carried out by calling the subroutine *SolveRegulaFalsi*. This is a general utility routine for finding the zero of a function (the *residual* function) of a single independent variable. In this case the residual function is basically:

$$(P_{beams,out} - P_{beams,dem})/P_{beams,out,max} \quad (14.86)$$

SolveRegulaFalsi varies the cold water mass flow rate to zero the residual. The water inlet and outlet node flow rates are set to the flow rate found by *SolveRegulaFalsi* and the water outlet node temperature is set to the outlet water temperature from *SolveRegulaFalsi*.

14.1.10 Constant Volume Dual Duct Air Terminal

14.1.10.1 Overview

The input object AirTerminal:DualDuct:ConstantVolume provides a model for dual duct constant-air-volume (DDCAV) systems that are typically used in special applications where precise temperature and humidity control are required and energy efficiency is not of primary concern. Thermal control for each zone is achieved by mixing air from the hot deck with air from the cold deck to achieve a supply air temperature that will exactly meet the zone load and satisfy the zone thermostat demand. Each zone has its own mixing box which is connected directly to the hot and cold decks. The mixing box dampers change the relative amount of hot and cold air that will be delivered (at a constant volumetric flow rate) to the zone.

14.1.10.2 Model Description

The DDCAV model will attempt to meet all of the thermostatic loads of a particular zone by explicitly calculating the hot and cold deck mass flow rates. For the energy and mass balance equations shown below, the zone load, temperatures, specific heats and the design mass flow rate are all known. These equations can then be solved directly for the hot deck and cold deck mass flow rates.

$$\dot{Q}_{zone} = \dot{m}_c C_{p,c} T_c + \dot{m}_h C_{p,h} T_h - \dot{m}_d C_{p,z} T_z \quad (14.87)$$

$$\dot{m}_d = \dot{m}_c + \dot{m}_h \quad (14.88)$$

where:

\dot{Q}_{zone} is the zone load, W (positive = heating, negative = cooling)

$C_{p,zz}$ is the specific heat of zone air, J/kg-K

$C_{p,c}$ is the specific heat of cold deck air, J/kg-K

$C_{p,h}$ is the specific heat of hot deck air, J/kg-K

T_z is the zone air dry-bulb temperature, °C

T_c is the cold deck air dry-bulb temperature, °C

T_h is the hot deck air dry-bulb temperature, °C

\dot{m}_d is the system design air mass flow rate through both heating or cooling duct, kg/s
 \dot{m}_c is the cold deck air mass flow rate, kg/s
 \dot{m}_h is the hot deck air mass flow rate, kg/s.

14.1.10.3 Simulation and Control

The simulation first calculates the hot deck and cold deck air mass flow rates required to satisfy the heating/cooling demand on the zone. Once the individual flow rates have been calculated based on temperature control, the zone mixed air conditions are calculated assuming adiabatic mixing of the two air streams.

14.1.11 Variable Air Volume Dual Duct Air Terminal

14.1.11.1 Overview

The input object `AirTerminal:DualDuct:VAV` provides a model for dual duct variable-air-volume (DDVAV) systems that are typically used in special applications where both temperature and humidity control as well as energy efficiency are of primary concern. This system combines the advantages of the standard dual duct system for better thermal control with the possibility to reduce fan energy using a variable speed fan. The DDVAV terminal units contain actuated dampers that vary the amount of central system air supplied to a zone from both the hot and cold deck. Optional user inputs may also be used to control the amount of outdoor air entering the zone.

The DDVAV terminal units described here are used primarily with central air handling equipment with cooling and heating capability. The terminal unit dampers modulate the amount of cold air and hot air as well as the overall flow rate to maintain the zone setpoint temperature(s).

14.1.11.2 Model Description

The DDVAV model will attempt to meet all of the thermostatic loads of a particular zone by first sending air through either the heating duct or the cooling duct depending on whether there is a heating or cooling load (respectively). Flow rate through the opposite duct is kept at zero and flow through the active duct is varied between the minimum air flow rate (minimum zone air fraction multiplied by the maximum flow rate) and the maximum air flow rate. If the flow rate to meet the load through either the heating or cooling duct results in a flow outside these ranges, then air must be passed through the other duct as well to avoid over- or under-heating or -cooling. This is done using a conservation of energy and mass analysis of the terminal unit as well as the known inlet and necessary outlet condition to meet the thermal needs of the zone.

When there is no load on the zone, the system could either be scheduled off or be in a “no load” condition. If the system is scheduled off, the model keeps the flow rate at zero for both the heating and cooling duct. If in a no load condition, the system attempts to throttle back to the minimum possible flow and then find a balance between flow through the heating and cooling duct that will provide no net conditioning to the space. This means that the enthalpy of air delivered to the space must be equal to the enthalpy of the (average) air in the zone.

14.1.11.3 DDVAV Terminal Unit Inputs

Like other terminal units, the DDVAV terminal unit requires an availability schedule and inlet and outlet node designations. The DDVAV terminal unit, like the DD terminal unit, has two inlet

nodes (one for the heating duct and one for the cooling duct) and one outlet node.

In addition, the DDVAV terminal unit also has a maximum flow rate and a minimum flow fraction like the VAV terminal unit. This allows the flow to be throttled back when it is possible to provide the proper amount of conditioning with less flow. The maximum flow rate can be auto-sized, if desired.

14.1.11.4 Minimum Outdoor Air Control

This dual duct air terminal may also be used to provide a minimum outdoor air quantity. When the air flow rate required to meet the zone load does not provide sufficient outdoor air, the terminal device damper will open to allow sufficient outdoor air to enter the zone. In this case, the terminal damper is controlled based on the air loop's outdoor air fraction. The outdoor air may be specified as a fixed value per person, per floor area, or per zone or as the required minimum air changes per hour. In addition, these values may be added together to provide a combined minimum outdoor air flow rate or the maximum of each of these values may be used. An outdoor air fraction schedule may also be used to modify the calculation for the minimum amount of outdoor air throughout the simulation (Ref. DesignSpecification:OutdoorAir).

14.1.11.5 Simulation and Control

The simulation begins by determining the air mass flow rate required to satisfy the heating/cooling demand using either the heating duct or cooling duct.

$$C_{p,zone} = PsyCpAirFnW(\omega_{zone}) \quad (14.89)$$

$$C_{p,inlet} = PsyCpAirFnW(\omega_{inlet}) \quad (14.90)$$

$$\Delta C_p T = (C_{p,inlet})(T_{inlet}) - (C_{p,zone})(T_{zone}) \quad (14.91)$$

$$\dot{m} = \min \left(\dot{m}_{max}, \max \left(\dot{m}_{max} \cdot MinAirFlowFrac \times MinAirFlowTurnDownFrac, \frac{\dot{Q}_{zone}}{\Delta C_p T} \right) \right) \quad (14.92)$$

where

$C_{p,zone}$ is the specific heat of zone air, J/kg-K

$C_{p,inlet}$ is the specific heat of terminal unit inlet air, J/kg-K

ω_{zone} is the zone air humidity ratio, kg/kg

T_{zone} is the zone air dry-bulb temperature, °C

ω_{inlet} is the terminal unit inlet air humidity ratio, kg/kg

T_{inlet} is the terminal unit inlet air dry-bulb temperature, °C

\dot{Q}_{zone} is the zone load, W (positive values denote heating, negative values denote cooling)

\dot{m} is the terminal unit air mass flow rate through either heating or cooling duct, kg/s

$PsyCpAirFnW$ is the psychrometric function calculating air specific heat given air humidity ratio

$MinAirFlowFrac$ is the user-specified zone minimum air flow fraction

MinAirFlowTurnDownFrac is the user-specified zone minimum air flow turndown fraction
 \dot{m}_{max} is the terminal unit maximum air mass flow rate, kg/s.

The outdoor air input requirements, if entered, are then used to adjust the terminal unit air mass flow rate to ensure the correct amount of outdoor air enters the zone (within the constraints of the terminal unit maximum and minimum flow rate inputs). The amount of outdoor air is calculated per the outdoor air requirements and is adjusted by the fraction of outdoor air entering the air loop outdoor air system.

$$\dot{m} = \max \left(\dot{m}, \frac{\dot{m}_{OA}}{OAFrac} \right) \quad (14.93)$$

where:

\dot{m}_{OA} is the zone outdoor air flow rate, kg/s

OAFrac is the fraction of outdoor air entering the air loop outside air system.

The damper position is then calculated as:

$$FRAC_{damper} = \frac{\dot{m}}{\dot{m}_{max}} \quad (14.94)$$

where $FRAC_{damper}$ is the output variable ‘Zone Air Terminal VAV Damper Position’ in fraction of maximum flow.

If the flow rate was between the maximum flow rate and the minimum flow rate for the terminal unit, then no other calculations are needed. However, if the flow was reset to either the maximum or minimum flow rate, then flow through the active duct must be balanced by flow through the other duct to achieve the proper conditioning.

14.1.12 Dual Duct Dedicated Outside Air Terminal with VAV Cooling

14.1.12.1 Overview

The input object `AirTerminal:DualDuct:VAV:OutdoorAir` provides a model for dedicated outside air combined with recirculated air for cooling. This air terminal has two inlets and one outlet. The outdoor air inlet has one damper that is controlled to meet the air flow requirements for ventilation. The second inlet is for cool recirculated air and has a second damper that is controlled to meet the zone’s cooling loads. The two streams are then mixed and inlet to the zone. This unit is for central air systems (using `AirLoopHVAC` object). Because of the limitation in EnergyPlus of allowing only one air terminal per zone, the dual duct approach offers advantages in that it allows modeling dedicated outdoor air systems (DOAS) and central VAV cooling at the same time. The original motivation for adding this terminal was to model twin-fan, twin-coil systems.

The recirculated cool air duct is actually optional. If no node name is input for the recirculated air inlet node, then only the outdoor air duct is operational and the air terminal behaves as a single duct. This offers additional capabilities for single duct DOAS in that this terminal can request outdoor air flows that change over time but are not controlled to meet zone loads.

14.1.12.2 Model Description

The model attempts to meet the ventilation requirements and the cooling loads of a particular zone. If the zone requires heating, ancillary heating equipment is needed as this terminal cannot do any heating. The model first determines the current required outdoor air flow rate for ventilation and then calculates the flow of cool air needed to reach the cooling setpoint.

The outdoor air rate is controlled by the schedule and specifications contained in a DesignSpecification:OutdoorAir object and can be based on flows per person, per zone, per area, or air changes per hour. Using the key CurrentOccupancy, the per person rate can be set to operate based on the current occupancy level to model demand controlled ventilation. Using the key DesignOccupancy it can be set to operate based on the design, or maximum, level of occupancy. The outdoor air inlet side of the terminal is assigned a design maximum flow rate based on the largest flow rates specified by the associated DesignSpecification:OutdoorAir object. This maximum for the outdoor air is used to calculate the damper position and contributes to the overall maximum if that is autosized.

The recirculated cool air flow rate is controlled to meet the zone cooling loads. The first step is to calculate the impact that the outdoor air flow has on the loads starting with the specific heats.

$$c_{p,zone} = PsyCpAirFnW(\omega_{zone}) \quad (14.95)$$

$$c_{p,OA} = PsyCpAirFnW(\omega_{OA}) \quad (14.96)$$

$$c_{p,RC} = PsyCpAirFnW(\omega_{RC}) \quad (14.97)$$

where:

$c_{p,zone}$ is the specific heat of zone air being served by the terminal unit, J/kg-K

$c_{p,OA}$ is the specific heat of outdoor air entering the terminal unit, J/kg-K

$c_{p,RC}$ is the specific heat of the recirculated (cool) air entering the terminal unit (if present), J/kg-K

ω_{zone} is the humidity ratio of the zone air, kg/kg

ω_{OA} is the humidity ratio of the outdoor air entering the terminal unit, kg/kg

ω_{RC} is the humidity ratio of the recirculated air entering the terminal unit, kg/kg

T_{zone} is the air drybulb temperature of the zone, °C

T_{OA} is the air drybulb temperature of the outdoor air entering the terminal unit, °C

T_{RC} is the air drybulb temperature of the recirculated cool air entering the terminal unit, °C

$PsyCpAirFnW$ is a psychrometric function for calculating the specific heat of moist air as a function of humidity ratio.

The contribution to zone load provided by the outdoor air toward meeting the cooling setpoint, \dot{Q}_{OA} (W), is then calculated using:

$$\dot{Q}_{OA} = \dot{m}_{OA} (c_{p,OA}T_{OA} - c_{p,zone}T_{zonesetpoint}) \quad (14.98)$$

where:

\dot{m}_{OA} is the mass flow rate of outdoor air determined by the outdoor air requirement, kg/s

$T_{zonesetpoint}$ is the zone cooling setpoint drybulb temperature, °C.

This is then used to calculate the load that the recirculated cool air should deliver, Q_{RC} (W):

$$\dot{Q}_{RC} = \dot{Q}_{ToCoolSetpointRemain} - \dot{Q}_{OA} \quad (14.99)$$

where $\dot{Q}_{ToCoolSetpointRemain=}$ is the remaining load to cooling setpoint as determined by Predictor and including the impacts of any other zone equipment sequenced before this terminal. Then the recirculated cool air mass flow rate, \dot{m}_{RC} (kg/s), is calculated using:

$$\dot{m}_{RC} = \frac{\dot{Q}_{RC}}{(c_{p,RC}T_{RC} - c_{p,zone}T_{zone})} \quad (14.100)$$

The model also includes a form of damping where the last three values for \dot{m}_{RC} are stored and used to detect if the solution is oscillating from one iteration to the next and if it is then the new value is not used but rather the value from the previous iteration is used. Once the two mass flows are known, the moist air properties of the outlet node are calculated using mass flow weighting.

14.2 Boilers

14.2.1 Simple Hot Water Boiler

The input object Boiler:HotWater provides a simple model for boilers that only requires the user to supply the nominal boiler capacity and thermal efficiency. An efficiency curve can also be used to more accurately represent the performance of non-electric boilers but is not considered a required input. The fuel type is input by the user for energy accounting purposes.

The model is based the following three equations

$$OperatingPartLoadRatio = \frac{BoilerLoad}{BoilerNomCapacity} \quad (14.101)$$

$$TheoreticalFuelUse = \frac{BoilerLoad}{NominalThermalEfficiency} \quad (14.102)$$

$$FuelUsed = \frac{TheoreticalFuelUse}{BoilerEfficiencyCurveOutput} \quad (14.103)$$

or

$$FuelUsed = \frac{BoilerLoad}{(NominalThermalEfficiency)(BoilerEfficiencyCurveOutput)} \quad (14.104)$$

The final equation above includes the impact of the optional boiler efficiency performance curve. To highlight the use of the normalized boiler efficiency curve, the fuel use equation is also shown in an expanded format. The normalized boiler efficiency curve represents the changes in the boiler's nominal thermal efficiency due to loading and changes in operating temperature. If the optional boiler efficiency curve is not used, the boiler's nominal thermal efficiency remains constant throughout the simulation (i.e., BoilerEfficiencyCurveOutput = 1).

When a boiler efficiency performance curve is used, any valid curve object with 1 or 2 independent variables may be used. The performance curves are accessed through EnergyPlus' built-in performance curve equation manager (curve objects). The linear, quadratic, and cubic curve types may be used when boiler efficiency is solely a function of boiler loading, or part-load ratio (PLR). These curve types are used when the boiler operates at the specified setpoint temperature throughout the simulation. Other curve types may be used when the boiler efficiency can be represented by both PLR and boiler operating temperature. Examples of valid single and dual independent variable equations are shown below. For all curve types, PLR is always the x independent variable. When using curve types with 2 independent variables, the boiler water temperature (T_{water}) is always the y independent variable and can represent either the inlet or outlet temperature depending on user input.

14.2.1.1 Single independent variable:

- $BoilerEfficiencyCurve = C1 + C2(PLR)$ (Linear)
- $BoilerEfficiencyCurve = C1 + C2(PLR) + C3(PLR)^2$ (Quadratic)
- $BoilerEfficiencyCurve = C1 + C2(PLR) + C3(PLR)^2 + C4(PLR)^3$ (Cubic)

14.2.1.2 Dual independent variables:

- $BoilerEfficiencyCurve = C1 + C2(PLR) + C3(PLR)^2 + (C4 + C5(PLR) + C6(PLR)^2)(T_{water})$ (QuadraticLinear)
- $BoilerEfficiencyCurve = C1 + C2(PLR) + C3(PLR)^2 + C4(T_{water}) + C5(T_{water})^2 + C6(PLR)(T_{water})$ (Biquadratic)
- $BoilerEfficiencyCurve = C1 + C2(PLR) + C3(PLR)^2 + C4(T_{water}) + C5(T_{water})^2 + C6(PLR)(T_{water}) + C7(PLR)^3 + C8(T_{water})^3 + C9(PLR)^2(T_{water}) + C10(PLR)(T_{water})^2$ (Bicubic)

When a boiler efficiency curve is used, a constant efficiency boiler may be specified by setting $C1 = 1$ and all other coefficients to 0. A boiler with an efficiency proportional to part-load ratio or which has a non-linear relationship of efficiency with part-load ratio will typically set the coefficients of a linear, quadratic, or cubic curve to non-zero values. Using other curve types allows a more accurate simulation when boiler efficiency varies as a function of part-load ratio and as the boiler outlet water temperature changes over time due to loading or as changes occur in the water temperature setpoint.

The parasitic electric power is calculated based on the user-defined parasitic electric load and the operating part load ratio calculated above. The model assumes that this parasitic power does not contribute to heating the water.

$$P_{parasitic} = P_{load}(PLR) \quad (14.105)$$

where:

$P_{parasitic}$ is the parasitic electric power (W), average for the simulation time step

P_{load} is the parasitic electric load specified by the user (W).

14.2.2 Steam Boiler

14.2.2.1 Description of Model

A steam boiler is the essential part of a building steam heating system and can be described as primary driver of the steam loop. It is the component that maintains the desired loop temperature.

The emphasis in EnergyPlus was laid on developing a building simulation model for steam boiler with ability to model detailed boiler performance without the cost of exhaustive user inputs to the boiler model. The Boiler:Steam input object is used on the plant loop supply side of EnergyPlus with the primary purpose of supplying steam to the heating coils, which constitute the demand side of the loop.

The steam boiler is a variable mass flow rate device. The mass flow rate of steam through the boiler is determined by the heating demand on the loop which in turn is determined by the equipment that is hooked to the demand side of the loop, namely the steam coils and hot water heater. In short, the steam coil determines the mass flow rate of steam required for heating the zone to its required setpoint, the mixer sums up the total steam demanded by each of the individual coils and reports it to the boiler via the pump.

Figure 14.8: Schematic of Steam Boiler in the Steam loop

Figure 14.8 describes the rudimentary loop structure with steam flowing from coils to boiler. It is essential to mention that it is the coils that determine the mass of steam required and the boiler simply delivers the required mass flow at desired temperature provided it is adequately sized. The algorithm for determining the mass flow rate is structured on the demand side and the variable flow boiler has no role to play in determining the steam mass flow.

Figure 14.9 outlines the simple steam boiler model. Sub cooled water enters the variable flow boiler through the pump, the boiler inputs energy to water stream consuming fuel, boiler losses are accounted via boiler efficiency. The boiler delivers steam at a quality equal to 1.0 at saturated condition.

The advantage of steam heating systems over hot water is the high latent heat carrying capacity of steam, which reduces the mass flow rate of the fluid required. The amount of superheated and

sub cooled heat transfer in Steam heating systems is negligible, latent heat transfer accounts for almost all of the heat exchange into the zones via steam to air heat exchangers.

Figure 14.9: Schematic of Steam Boiler Operation

Boiler Load is a summation of sensible and latent heat addition to the water stream as described with the following equation. The mass flow rate through the boiler is known, while delta temp is the temperature difference between the boiler inlet and boiler outlet. Latent heat of steam is calculated at loop operating temperature.

$$Q_B = \dot{m} \times [(c_{p,w} \times \Delta T) + h_{fg}] \quad (14.106)$$

Theoretical fuel used is calculated with the following equation. Boiler efficiency is a user input and accounts for all the losses in the steam boiler.

$$F_t = \frac{Q_B}{\eta_B} \quad (14.107)$$

The operation part load ratio is calculated with the following equation. This is later used to calculate the actual fuel consumption, its ratio of boiler load to boiler nominal capacity.

$$O_{PLR} = \frac{Q_B}{Q_{B,N}} \quad (14.108)$$

The actual fuel consumption by the boiler is calculated as using the following equation, where C1, C2, and C3 are the Part Load Ratio coefficients:

$$F = \frac{F_t}{C_1 + C_2 \times O_{PLR} + C_3 \times O_{PLR}^2} \quad (14.109)$$

Essentially the boiler model provides a first order approximation of performance for fuel oil, gas, and electric boilers. Boiler performance is based on theoretical boiler efficiency and a single quadratic fuel use-part load ratio curve represented in the equation above. This single curve accounts for all combustion inefficiencies and stack losses.

The control algorithm for a steam boiler is an important issue. The user may want the boiler to be undersized and in such a case it will not be able to meet the demand side steam flow request. Subsequently the boiler load exceeds the boiler nominal capacity. The boiler operates at its nominal capacity but is unable to meet the plant heating demand. Pseudo code from EnergyPlus has been used to describe the control logic used in the steam boiler simulation.

*****PSEUDO CODE SECTION STARTS*****

At start of simulation an initial value of steam mass flow rate is calculated. This is required to start the flow of steam around the loop.

IF (FirstTimeThrough) THEN

Calculate the boiler supply steam mass flow rate at start of simulation.

$$\dot{m}_s = \frac{Q_B}{h_{fg} + c_{p,w} \times \Delta T_{loop}} \quad (14.110)$$

ELSE ! Not first time through

Steam boiler calculations rely heavily on the variable \dot{m}_b , boiler mass flow rate. This variable \dot{m}_b is the assigned equal to mass flow at boiler inlet node for preliminary calculations.

$$\dot{m}_b = \dot{m}_{InletNode} \quad (14.111)$$

Calculating the boiler delta temperature difference between the inlet and outlet nodes. This calculation is used to determine various boiler control situation.

$$\Delta T_{inout} = T_{SP} - T_{in} \quad (14.112)$$

In case the temperature difference calculated with Equation 14.112 is zero then the boiler just needs to supply latent heat to steam, else the boiler performs its normal load calculations by providing both sensible and latent heat to the inlet stream.

IF ($\Delta T_{inout} < 0$) THEN

$$Q_B = \dot{m}_b \times h_{fg} \quad (14.113)$$

ELSE

$$Q_B = \dot{m}_b \times (h_{fg} + c_{p,w} \times \Delta T_{inout}) \quad (14.114)$$

ENDIF

Sometimes the boiler load Q_B is greater than the demand side requested load at the current time step, which may occur because the boiler inlet conditions is from previous time step. There is sudden fall in request of steam mass flow from the demand side. The boiler now recalculates its new mass flow and adjusts to these new conditions.

IF ($Q_B > Q_{HeatingDemand}$) THEN

Boiler load is set equal to the new boiler heating demand and steam mass flow rate is recalculated.

$$Q_B = Q_{HeatingDemand} \quad (14.115)$$

$$\dot{m}_s = \frac{Q_B}{h_{fg} + c_{p,w} \times \Delta T_{loop}} \quad (14.116)$$

ENDIF

In case the requested load exceeds the boiler nominal capacity, which is its maximum heating capacity. In this case the requested steam mass flow is not met and the zone is not heated adequately. This happens if the boiler is undersized. The steam mass flow rate is recalculated at nominal capacity.

IF ($Q_B > Q_{NominalCapacity}$) THEN

Boiler load is set equal to boiler nominal capacity and steam mass flow rate recalculated.

$$Q_B = Q_{NominalCapacity} \quad (14.117)$$

$$\dot{m}_s = \frac{Q_B}{h_{fg} + c_{p,w} \times \Delta T_{loop}} \quad (14.118)$$

ENDIF

ENDIF

End If statement for the boiler load control algorithm. This algorithm determines all possible control conditions that might arise while simulating a system in EnergyPlus.

*****PSEUDO CODE SECTION ENDS*****

If the boiler operating pressure exceeds the maximum allowable boiler pressure, the simulation trips and outputs a warning regarding the same. This notifies the user about potential system pressure sizing problems.

Integration of the steam boiler simulation model in EnergyPlus required developing number of subroutines, which operate in sequence. These subroutines are designed to read inputs from the input file, initialize the variables used in the boiler simulation model, simulate the boiler performance, update the node connections, and report the required variables. In case the user has difficulty with boiler inputs, provisions have been made to auto size the boiler nominal capacity and maximum steam flow rate. These two values play an important role in sizing the boiler.

14.2.2.2 Model Assumptions

The EnergyPlus boiler model is “simple” in the sense that it requires the user to supply the theoretical boiler efficiency. The combustion process is not considered in the model. The model is independent of the fuel type, which is input by the user for energy accounting purposes only. This is an ideal model for Building Simulation Program such that it utilizes the desired amount of resources in terms of simulation run time, but successfully provides fairly good sizing parameters for an actual boiler.

It is assumed that the steam boiler operates to maintain a desired temperature, the temperature being saturation temperature of steam and corresponding to this saturation temperature there exist a single value of saturation pressure at which the loop operates. Hence the boiler could either be saturation pressure controlled or temperature controlled. Since users would have better idea of steam temperatures rather than pressure the boiler inputs are designed for temperature control.

14.2.2.3 Nomenclature for Steam Loop

Table 14.1: Steam Loop Nomenclature

Q_B	Boiler Heat Transfer, W
$Q_{B,N}$	Boiler Nominal Capacity, W
O_{PLR}	Boiler Operating Part Load Ratio
ΔT_{sc}	Degree of subcooling in coil
ΔT_{inout}	Temperature difference across the steam boiler, °C
ρ_w	Density of condensate entering the pump, kg/m ³
Q_{Des}	Design Load on the steam coil, W
$h_{f,n}$	Enthalpy of fluid at point n on the Ts diagram, J/kg
P_{Frac}	Fraction of Pump Full Load Power, W
$F_{m,f}$	Fractional Motor Power Lost to Fluid, W
$Q_{a,l}$	Heating load on the Air Loop Steam Coil, W
$Q_{z,c}$	Heating load on the Zone Steam Coil, W
h_{fg}	Latent Heat of Steam, J/kg
$Q_{L,H}$	Latent Heat Part of the Heating Coil Load, W
ΔQ_{loss}	Loop losses in steam coil, W
ΔT_{loop}	Loop Temperature Difference, °C
\dot{m}_a	Mass flow rate for steam coil, kg/s
\dot{m}_{in}	Mass flow rate of steam entering the steam coil, kg/s
$\dot{m}_{a,l}$	Mass flow rate of steam for Air loop steam coil, kg/s
$\dot{m}_{z,c}$	Mass flow rate of steam for zone steam coil, kg/s
\dot{m}_s	Mass flow rate of steam, kg/s
\dot{m}_{loop}	Mass flow rate of steam for the steam loop, kg/s
\dot{m}	Mass of condensate entering the pump, kg/s
$\dot{m}_{a,max}$	Maximum allowed mass flow rate of air, kg/s
$\dot{m}_{S,max}$	Maximum Mass flow rate of steam, kg/s
$\dot{m}_{B,Supply}$	Maximum steam mass flow rate supplied by boiler, kg/s
$\dot{V}_{w,max}$	Maximum Volume flow rate of condensate in pump, m ³ /s
$\dot{V}_{w,loop}$	Maximum Volume flow rate of condensate in steam loop, m ³ /s
$T_{a,in,min}$	Minimum inlet air temperature possible, °C
P_n	Nominal Power Capacity for condensate pump, W
P_{nom}	Nominal power of the pump, W
H_n	Nominal Pump Head, m
\dot{V}_{nom}	Nominal volume flow rate through the condensate pump, m ³ /s
PLR	Part Load Ratio for condensate pump
η_p	Pump efficiency

Table 14.1: Steam Loop Nomenclature

η_m	Pump Motor Efficiency
P	Pump Power, W
$Q_{S,H}$	Sensible Heat Part of the Heating Coil Load, W
T_{sp}	Setpoint Temperature of the zone, °C
$T_{a,out,SP}$	Setpoint air outlet temperature for the steam coil, °C
P_S	Shaft power of the pump, W
$c_{p,a}$	Specific Heat Capacity for Air, J/kg-K
$c_{p,w}$	Specific Heat Capacity for Water, J/kg-K.
η_B	Steam Boiler Efficiency
$T_{a,in}$	Temperature of air entering the coil, °C
T_a	Temperature of air entering the steam coil, °C
$T_{a,out}$	Temperature of air leaving the coil, °C
$T_{s,in}$	Temperature of steam entering the coil, °C
F_{in}	Theoretical Fuel Consumption by the Steam Boiler, W
$\dot{m}_{coils,R}$	Total Mass flow rate requested by all the steam coils, kg/s
\dot{V}	Volume of condensate entering the pump, m ³ /s
$T_{w,out}$	Water outlet temperature from pump, °C

14.3 Chillers

14.3.1 Absorption Chiller

The input object `Chiller:Absorption` provides a model for absorption chillers that is an empirical model of a standard absorption refrigeration cycle. The condenser and evaporator are similar to that of a standard chiller, which are both water-to-water heat exchangers. The assembly of a generator and absorber provides the compression operation. Low-pressure vapor from the evaporator is absorbed by the liquid solution in the absorber. A pump receives low-pressure liquid from the absorber, elevates the pressure of the liquid, and delivers the liquid to the generator. In the generator, heat from a high temperature source (hot water or steam) drives off the vapor that has been absorbed by the solution. The liquid solution returns to the absorber through a throttling valve whose purpose is to provide a pressure drop to maintain the pressure difference between the generator and absorber. The heat supplied to the absorber can be waste heat from a diesel jacket, or the exhaust heat from diesel, gas, and steam turbines. For more information on absorption chillers, see the Input/Output Reference Document (Object: `Chiller:Absorption`).

The part-load ratio of the absorption chiller's evaporator is simply the actual cooling effect produced by the chiller divided by the maximum cooling effect available.

$$PLR = \frac{\dot{Q}_{evap}}{\dot{Q}_{evap,rated}} \quad (14.119)$$

where:

PLR is the part-load ratio of chiller evaporator

\dot{Q}_{evap} is the chiller evaporator load [W]

$\dot{Q}_{evap,rated}$ is the rated chiller evaporator capacity [W].

This absorption chiller model is based on a polynomial fit of absorber performance data. The Generator Heat Input Part Load Ratio Curve is a quadratic equation that determines the ratio of the generator heat input to the *demand* on the chiller's evaporator (\dot{Q}_{evap}).

$$GeneratorHeatInputRatio = \frac{C1}{PLR} + C2 + C3 (PLR) \quad (14.120)$$

The Pump Electric Use Part Load Ratio Curve is a quadratic equation that determines the ratio of the actual absorber pumping power to the nominal pumping power.

$$ElectricInputRatio = C1 + C2 * PLR + C3 * PLR^2 \quad (14.121)$$

Thus, the coefficient sets establish the ratio of heat power in-to-cooling effect produced as a function of part load ratio. The ratio of heat-power-in to cooling-effect-produced is the inverse of the coefficient of performance.

If the operating part-load ratio is greater than the minimum part-load ratio, the chiller will run the entire time step and cycling will not occur (i.e. $CyclingFrac = 1$). If the operating part-load ratio is less than the minimum part-load ratio, the chiller will be on for a fraction of the time step equal to $CyclingFrac$. Steam (or hot water) and pump electrical energy use are also calculated using the chiller part-load cycling fraction.

$$CyclingFrac = MIN \left(1, \frac{PLR}{PLR_{min}} \right) \quad (14.122)$$

$$\dot{Q}_{generator} = GeneratorHeatInputRatio \left(\dot{Q}_{evap} \right) (CyclingFrac) \quad (14.123)$$

$$\dot{Q}_{pump} = ElectricInputRatio (P_{pump}) (CyclingFrac) \quad (14.124)$$

where:

CyclingFrac is the chiller part-load cycling fraction

PLR_{min} is the chiller minimum part-load ratio

$\dot{Q}_{generator}$ is the generator input power (W)

\dot{Q}_{pump} is the absorption chiller pumping power (W).

The evaporator water mass flow rate is calculated based on the Chiller Flow Mode as follows.

Constant Flow Chillers:

$$\dot{m}_{evap} = \dot{m}_{evap,max} \quad (14.125)$$

Variable Flow Chillers:

$$\Delta T_{evap} = T_{evap,in} - T_{evap,SP} \quad (14.126)$$

$$\dot{m}_{evap} = \frac{\dot{Q}_{evap}}{C_{p,evap} \Delta T_{evap}} \quad (14.127)$$

where:

\dot{m}_{evap} is the chiller evaporator water mass flow rate (kg/s)

$\dot{m}_{evap,max}$ is the chiller design evaporator water mass flow rate (kg/s)

ΔT_{evap} is the chiller evaporator water temperature difference (°C)

$T_{evap,in}$ is the chiller evaporator inlet water temperature (°C)

$T_{evap,SP}$ is the chiller evaporator outlet water setpoint temperature (°C)

C_p is the = specific heat of water entering evaporator (J/kg-°C).

The evaporator outlet water temperature is then calculated based on the cooling effect produced and the evaporator entering water temperature.

$$T_{evap,out} = T_{evap,in} + \frac{\dot{Q}_{evap}}{\dot{m}_{evap} C_{p,evap}} \quad (14.128)$$

where:

$T_{evap,out}$ is the chiller evaporator outlet water temperature (°C)

$T_{evap,in}$ is the chiller evaporator inlet water temperature (°C)

$C_{p,evap}$ is the specific heat of chiller evaporator inlet water (J/kg-°C)

\dot{m}_{evap} is the chiller evaporator water mass flow rate (kg/s).

The condenser heat transfer and condenser leaving water temperature are also calculated.

$$\dot{Q}_{cond} = \dot{Q}_{evap} + \dot{Q}_{generator} + \dot{Q}_{pump} \quad (14.129)$$

$$T_{cond,out} = T_{cond,in} + \frac{\dot{Q}_{cond}}{\dot{m}_{cond} C_{p,cond}} \quad (14.130)$$

where:

\dot{Q}_{cond} is the chiller condenser heat transfer rate (W)

$T_{cond,out}$ is the chiller condenser outlet water temperature (°C)

$T_{cond,in}$ is the chiller condenser inlet water temperature (°C)

$C_{p,cond}$ is the specific heat of chiller condenser inlet water (J/kg-°C)

\dot{m}_{cond} is the chiller condenser water mass flow rate (kg/s).

The absorption chiller can model the impact of steam or hot water entering the generator, although the connection of the steam (hot water) nodes to a plant is not actually required. The calculations specific to the generator depend on the type of fluid used and are described here in further detail.

14.3.1.1 Steam Loop Calculations

When a steam loop is used and the inlet and outlet node names are specified (i.e. the nodes are connected to a steam loop), the generator outlet node steam mass flow rate and temperature are calculated based on the generator input power, latent heat of steam, the specific heat of water, and the amount of subcooling in the steam generator. The model assumes dry saturated steam enters the absorption chiller's generator and exits the generator as a subcooled liquid. The temperature leaving the generator is calculated based on the user entered amount of liquid subcooling in the generator. The effect of subcooling of the liquid (condensate) in the pipe returning to the boiler is not modeled.

$$\dot{m}_{steam} = \frac{\dot{Q}_{generator}}{h_{fg} + c_{p,water} \times \Delta T_{sc}} \quad (14.131)$$

$$T_{generator,out} = T_{generator,in} - \Delta T_{sc} \quad (14.132)$$

where:

\dot{m}_{steam} is the chiller steam mass flow rate (kg/s)

h_{fg} is the latent heat of steam (J/kg)

$c_{p,water}$ is the specific heat of saturated water in the generator (J/kg-°C)

ΔT_{sc} is the amount of subcooling in steam generator (°C)

$T_{generator,out}$ is the generator steam outlet node temperature (°C)

$T_{generator,in}$ is the generator steam inlet node temperature (°C).

14.3.1.2 Hot Water Loop Calculations

When a hot water loop is used and the inlet and outlet node names are specified (i.e. the nodes are connected to a hot water loop), the generator outlet node temperature is calculated based on the generator input power, mass flow rate of water, and the specific heat of water entering the hot water generator. The calculations are based on the Chiller Flow Mode as follows.

Constant Flow Chillers:

$$\dot{m}_{generator} = \dot{m}_{generator,max} \quad (14.133)$$

Variable Flow Chillers:

$$\dot{m}_{generator} = \frac{\dot{Q}_{generator}}{C_{p,water} \Delta T_{generator}} \quad (14.134)$$

$$T_{generator,out} = T_{generator,in} - \frac{\dot{Q}_{generator}}{\dot{m}_{generator} (C_{p,water})} \quad (14.135)$$

where:

$\dot{m}_{generator}$ is the generator hot water mass flow rate (kg/s)

$\dot{m}_{generator,max}$ is the generator design hot water mass flow rate (kg/s)

$\Delta T_{generator}$ is the generator design hot water temperature difference (°C).

14.3.2 Indirect Absorption Chiller

The Chiller:Absorption:Indirect object is an enhanced version of the absorption chiller model found in the Building Loads and System Thermodynamics (BLAST) program. This enhanced model is nearly identical to the existing absorption chiller model (Ref. Chiller:Absorption) with the exceptions that: 1) the enhanced indirect absorption chiller model provides more flexible performance curves and 2) chiller performance now includes the impact of varying evaporator, condenser, and generator temperatures. Since these absorption chiller models are nearly identical (i.e., the performance curves of the enhanced model can be manipulated to produce similar results to the previous model), it is quite probable that the Chiller:Absorption model will be deprecated in a future release of EnergyPlus.

The indirect absorption chiller's condenser and evaporator are similar to that of a standard chiller, which are both water-to-water heat exchangers. The assembly of a generator and absorber provides the compression operation. A schematic of a single-stage absorption chiller is shown in the figure below. Low-pressure vapor from the evaporator is absorbed by the liquid solution in the absorber. A pump receives low-pressure liquid from the absorber, elevates the pressure of the liquid, and delivers the liquid to the generator. In the generator, heat from a high temperature source (hot water or steam) drives off the vapor that has been absorbed by the solution. The liquid solution returns to the absorber through a throttling valve whose purpose is to provide a pressure drop to maintain the pressure difference between the generator and absorber. The heat supplied to the generator can be either hot water or steam, however, connection to an actual plant loop is not required. For more information on indirect absorption chillers, see the Input/Output Reference Document (Object: Chiller:Absorption:Indirect).

The chiller cooling effect (capacity) will change with a change in condenser water temperature. Similarly, the chiller cooling effect will change as the temperature of the evaporator water changes. The chiller cooling effect will also change with a change in or generator inlet water temperature and only applies when Hot Water is used as the generator heat source. A quadratic or cubic equation is used to modify the rated chiller capacity as a function of both the condenser and generator inlet water temperatures and the evaporator outlet water temperature. If any or all of the capacity correction factor curves are not used, the correction factors are assumed to be 1.

$$CAPFT_{evaporator} = a + b(T_{evaporator}) + c(T_{evaporator})^2 + d(T_{evaporator})^3 \quad (14.136)$$

$$CAPFT_{condenser} = e + f(T_{condenser}) + g(T_{condenser})^2 + h(T_{condenser})^3 \quad (14.137)$$

$$CAPFT_{generator} = i + j(T_{generator}) + k(T_{generator})^2 + l(T_{generator})^3 \quad (Hot\ Water\ only)$$

$$\dot{Q}_{evap,max} = \dot{Q}_{evap,rated} (CAPFT_{evaporator}) (CAPFT_{condenser}) (CAPFT_{generator}) \quad (14.138)$$

Figure 14.10: Schematic Diagram of a Single-Stage Absorption Chiller

where:

$CAPFT_{evaporator}$ is the capacity correction (function of evaporator temperature) factor

$CAPFT_{condenser}$ is the capacity correction (function of condenser temperature) factor

$CAPFT_{generator}$ is the capacity correction (function of generator temperature) factor

$T_{evaporator}$ is the evaporator outlet water temperature ($^{\circ}\text{C}$)

$T_{condenser}$ is the condenser inlet water temperature ($^{\circ}\text{C}$)

$T_{generator}$ is the generator inlet water temperature ($^{\circ}\text{C}$)

$\dot{Q}_{evap,max}$ is the maximum chiller capacity (W)

$\dot{Q}_{evap,rated}$ is the rated chiller capacity (W).

The part-load ratio of the indirect absorption chiller's evaporator is simply the actual cooling effect required (load) divided by the maximum cooling effect available.

$$PLR = \frac{\dot{Q}_{evap}}{\dot{Q}_{evap,max}} \quad (14.139)$$

where:

PLR is the part-load ratio of chiller evaporator

\dot{Q}_{evap} is the chiller evaporator operating capacity (W).

The generator's heat input is also a function of several parameters. The primary input for determining the heat input requirements is the Generator Heat Input function of Part-Load Ratio Curve. The curve is a quadratic or cubic equation that determines the ratio of the generator heat input to the chiller's maximum capacity ($\dot{Q}_{evap,max}$) and is solely a function of part-load ratio. Typical generator heat input ratios at full load (i.e., $PLR = 1$) are between 1 and 2. Two additional curves are available to modify the heat input requirement based on the generator inlet water temperature and the evaporator outlet water temperature.

$$GeneratorHIR = a + b(PLR) + c(PLR)^2 + d(PLR)^3 \quad (14.140)$$

$$GenfCondT = e + f(T_{generator}) + g(T_{generator})^2 + h(T_{generator})^3 \quad (14.141)$$

$$GenfEvapT = i + j(T_{evaporator}) + k(T_{evaporator})^2 + l(T_{evaporator})^3 \quad (14.142)$$

where:

$GeneratorHIR$ is the ratio of generator heat input to chiller operating capacity

$GenfCondT$ is the heat input modifier based on generator inlet water temperature

$GenfEvapT$ is the heat input modifier based on evaporator outlet water temperature.

The Pump Electric Use function of Part-Load Ratio Curve is a quadratic or cubic equation that determines the ratio of the actual absorber pumping power to the nominal pumping power.

$$ElectricInputRatio = a + b(PLR) + c(PLR)^2 + d(PLR)^3 \quad (14.143)$$

If the chiller operating part-load ratio is greater than the minimum part-load ratio, the chiller will run the entire time step and cycling will not occur (i.e. $CyclingFrac = 1$). If the operating part-load ratio is less than the minimum part-load ratio, the chiller will be on for a fraction of the time step equal to $CyclingFrac$. Generator heat input and pump electrical energy use are also calculated using the chiller part-load cycling fraction.

$$CyclingFrac = MIN \left(1, \frac{PLR}{PLR_{min}} \right) \quad (14.144)$$

$$\dot{Q}_{generator} = GeneratorHIR \left(\dot{Q}_{evap, max} \right) (GenfCondT) (GenfEvapT) (CyclingFrac) \quad (14.145)$$

$$\dot{Q}_{generator} = ElectricInputRatio(P_{pump})(CyclingFrac) \quad (14.146)$$

where:

$CyclingFrac$ is the chiller part-load cycling fraction

PLR_{min} is the chiller minimum part-load ratio

$\dot{Q}_{generator}$ is the generator heat input (W)

\dot{Q}_{pump} is the chiller pumping power (W).

The evaporator water mass flow rate is calculated based on the Chiller Flow Mode as follows.

Constant Flow Chillers:

$$\dot{m}_{evap} = \dot{m}_{evap, max} \quad (14.147)$$

Variable Flow Chillers:

$$\Delta T_{evap} = T_{evap, in} - T_{evap, SP} \quad (14.148)$$

$$\dot{m}_{evap} = \frac{\dot{Q}_{evap}}{C_{p, evap} \Delta T_{evap}} \quad (14.149)$$

where:

\dot{m}_{evap} is the chiller evaporator water mass flow rate (kg/s)

$\dot{m}_{evap, max}$ is the chiller design evaporator water mass flow rate (kg/s)

ΔT_{evap} is the chiller evaporator water temperature difference (°C)

$T_{evap, in}$ is the chiller evaporator inlet water temperature (°C)

$T_{evap, SP}$ is the chiller evaporator outlet water setpoint temperature (°C)

$C_{p, evap}$ is the specific heat of water entering evaporator (J/kg-°C).

The evaporator outlet water temperature is then calculated based on the cooling effect produced and the evaporator entering water temperature.

$$T_{evap, out} = T_{evap, in} + \frac{\dot{Q}_{evap}}{\dot{m}_{evap} C_{p, evap}} \quad (14.150)$$

where:

$T_{evap, out}$ is the chiller evaporator outlet water temperature (°C)

$T_{evap, in}$ is the chiller evaporator inlet water temperature (°C)

$C_{p, evap}$ is the specific heat of chiller evaporator inlet water (J/kg-°C)

\dot{m}_{evap} is the chiller evaporator water mass flow rate (kg/s).

The condenser heat transfer and condenser leaving water temperature are also calculated.

$$\dot{Q}_{cond} = \dot{Q}_{evap} + \dot{Q}_{generator} + \dot{Q}_{pump} \quad (14.151)$$

$$T_{cond,out} = T_{cond,in} + \frac{\dot{Q}_{cond}}{\dot{m}_{cond}C_{p,cond}} \quad (14.152)$$

where:

\dot{Q}_{cond} = chiller condenser heat transfer rate (W)

$T_{cond,out}$ = chiller condenser outlet water temperature (°C)

$T_{cond,in}$ = chiller condenser inlet water temperature (°C)

$C_{p,cond}$ = specific heat of chiller condenser inlet water (J/kg-°C)

\dot{m}_{cond} = chiller condenser water mass flow rate (kg/s).

The absorption chiller can model the impact of steam or hot water entering the generator, although the connection of the steam (hot water) nodes to a plant is not actually required. The calculations specific to the generator depend on the type of fluid used and are described here in further detail.

14.3.2.1 Steam Loop Calculations

When a steam loop is used and the inlet and outlet node names are specified (i.e. the nodes are connected to a steam loop), the generator outlet node steam mass flow rate and temperature are calculated based on the generator heat input, latent heat of steam, the specific heat of water, and the amount of subcooling in the steam generator. The model assumes dry saturated steam enters the generator and exits the generator as a subcooled liquid. The temperature leaving the generator is calculated based on the user entered amount of liquid subcooling in the generator. The effect of subcooling of the liquid (condensate) in the pipe returning to the boiler is also modeled using the user entered amount of steam condensate loop subcooling.

$$\dot{m}_{steam} = \frac{\dot{Q}_{generator}}{h_{fg} + c_{p,water} \times \Delta T_{sc}} \quad (14.153)$$

$$T_{generator,out} = T_{generator,in} - \Delta T_{sc} \quad (14.154)$$

$$T_{loop,out} = T_{generator,out} - \Delta T_{sc, loop} \quad (14.155)$$

where:

\dot{m}_{steam} is the chiller steam mass flow rate (kg/s)

h_{fg} is the latent heat of steam (J/kg)

$c_{p,water}$ is the specific heat of water (J/kg-°C)

ΔT_{sc} is the amount of subcooling in steam generator (°C)

$\Delta T_{sc,loop}$ is the amount of condensate subcooling in steam loop (°C)

$T_{generator,out}$ is the generator steam outlet node temperature (°C)

$T_{generator,in}$ is the generator steam inlet node temperature (°C).

14.3.2.2 Hot Water Loop Calculations

When a hot water loop is used and the inlet and outlet node names are specified (i.e. the nodes are connected to a hot water loop), the generator outlet node temperature is calculated based on the generator heat input, mass flow rate of water, and the specific heat of water entering the hot water generator. The calculations are based on the Chiller Flow Mode as follows.

Constant Flow Chillers:

$$\dot{m}_{generator} = \dot{m}_{generator,max} \quad (14.156)$$

Variable Flow Chillers:

$$\dot{m}_{generator} = \frac{\dot{Q}_{generator}}{C_{p,water}\Delta T_{generator}} \quad (14.157)$$

$$T_{generator,out} = T_{generator,in} - \frac{\dot{Q}_{generator}}{\dot{m}_{generator}(C_{p,water})} \quad (14.158)$$

where:

$\dot{m}_{generator}$ is the generator hot water mass flow rate (kg/s)

$\dot{m}_{generator,max}$ is the generator design hot water mass flow rate (kg/s)

$\Delta T_{generator}$ is the generator design hot water temperature difference (°C).

14.3.3 Combustion Turbine Chiller

The input object Chiller:CombustionTurbine provides a chiller model that is the empirical model from the Building Loads and System Thermodynamics (BLAST) program. Fitting catalog data to a third order polynomial equations generates the chiller performance curves. Three sets of coefficients are required to model the open centrifugal chiller as discussed in the section, titled, ‘Electric Chiller Based on Fluid Temperature Differences’.

The gas turbine-driven chiller is an open centrifugal chiller driven directly by a gas turbine. The BLAST model of an open centrifugal chiller is modeled as standard vapor compression refrigeration cycle with a centrifugal compressor driven by a shaft power from an engine. The centrifugal compressor has the incoming fluid entering at the eye of a spinning impeller that throws the fluid by centrifugal force to the periphery of the impeller. After leaving the compressor, the refrigerant is condensed to liquid in a refrigerant to water condenser. The heat from the condenser is rejected to a cooling tower, evaporative condenser, or well water condenser depending on which one is selected by the user based on the physical parameters of the plant. The refrigerant pressure is then dropped through a throttling valve so that fluid can evaporate at a low pressure that provides cooling to the evaporator. The evaporator can chill water that is pumped to chilled water coils in the building. For more information, see the Input/Output Reference Document.

This chiller is modeled like the electric chiller with the same numerical curve fits and then some additional curve fits to model the turbine drive. Shown below are the definitions of the curves that describe this model.

The chiller’s temperature rise coefficient which is defined as the ratio of the required change in condenser water temperature to a given change in chilled water temperature, which maintains the capacity at the nominal value. This is calculated as the following ratio:

$$\frac{TCEnt_{required} - TCEnt_{rated}}{TELv_{required} - TELv_{rated}} \quad (14.159)$$

where:

$TCEnt_{required}$ is the required entering condenser air or water temperature to maintain rated capacity

$TCent_{rated}$ is the rated entering condenser air or water temperature at rated capacity

$TELv_{required}$ is the required leaving evaporator water outlet temperature to maintain rated capacity

$TELv_{rated}$ is the rated leaving evaporator water outlet temperature at rated capacity.

The Capacity Ratio Curve is a quadratic equation that determines the Ratio of Available Capacity to Nominal Capacity. The defining equation is:

$$AvailToNominalCapacityRatio = C_1 + C_2\Delta_{temp} + C_3\Delta_{temp}^2 \quad (14.160)$$

where the Delta Temperature is defined as:

$$\Delta_{Temp} = \frac{TempCondIn - TempCondInDesign}{TempRiseCoefficient} - (TempEvapOut - TempEvapOutDesign) \quad (14.161)$$

where:

$TempCondIn$ is the temperature entering the condenser (water or air temperature depending on condenser type)

$TempCondInDesign$ is the temperature of the design condenser inlet from user input above

$TempEvapOut$ is the temperature leaving the evaporator

$TempEvapOutDesign$ is the temperature of the design evaporator outlet from user input above

$TempRiseCoefficient$ is based on user input from above.

The following three fields contain the coefficients for the quadratic equation.

The Power Ratio Curve is a quadratic equation that determines the Ratio of Full Load to Power. The defining equation is:

$$FullLoadtoPowerRatio = C_1 + C_2AvailToNominalCapRatio + C_3AvailToNominalCapRatio^2 \quad (14.162)$$

The Full Load Ratio Curve is a quadratic equation that determines the fraction of full load power. The defining equation is:

$$FracFullLoadPower = C_1 + C_2PartLoadRatio + C_3PartLoadRatio^2 \quad (14.163)$$

The Fuel Input Curve is a polynomial equation that determines the Ratio of Fuel Input to Energy Output. The equation combines both the Fuel Input Curve Coefficients and the Temperature Based Fuel Input Curve Coefficients. The defining equation is:

$$FuelEnergyInput = PLoad * (FIC_1 + FIC_2RLoad + FIC_3RLoad^2) * (TBFIC_1 + TBFIC_2AT_{air} + TBFIC_3AT_{air}^2) \quad (14.164)$$

where FIC represents the Fuel Input Curve Coefficients, TBFIC represents the Temperature Based Fuel Input Curve Coefficients, Rload is the Ratio of Load to Combustion Turbine Engine Capacity, and AT_{air} is the difference between the current ambient and design ambient temperatures.

The Exhaust Flow Curve is a quadratic equation that determines the Ratio of Exhaust Gas Flow Rate to Engine Capacity. The defining equation is:

$$ExhaustFlowRate = GTCapacity * (C_1 + C_2AT_{air} + C_3AT_{air}^2) \quad (14.165)$$

where $GTCapacity$ is the Combustion Turbine Engine Capacity, and AT_{air} is the difference between the current ambient and design ambient temperatures.

The Exhaust Gas Temperature Curve is a polynomial equation that determines the Exhaust Gas Temperature. The equation combines both the Exhaust Gas Temperature Curve Coefficients (Based on the Part Load Ratio) and the (Ambient) Temperature Based Exhaust Gas Temperature Curve Coefficients. The defining equation is:

$$ExhaustTemperature = (C_1 + C_2 RLoad + C_3 RLoad^2) * (TBC_1 + TBC_2 AT_{air} + TBC_3 AT_{air}^2) - 273.15 \quad (14.166)$$

where C represents the Exhaust Gas Temperature Curve Coefficients, TBC are the Temperature Based Exhaust Gas Temperature Curve Coefficients, $RLoad$ is the Ratio of Load to Combustion Turbine Engine Capacity, and AT_{air} is the difference between the actual ambient and design ambient temperatures.

The Recovery Lubricant Heat Curve is a quadratic equation that determines the recovery lube energy. The defining equation is:

$$RecoveryLubeEnergy = PLoad * (C_1 + C_2 RL + C_3 RL^2) \quad (14.167)$$

where $PLoad$ is the engine load and RL is the Ratio of Load to Combustion Turbine Engine Capacity

The UA is an equation that determines the overall heat transfer coefficient for the exhaust gasses with the stack. The heat transfer coefficient ultimately helps determine the exhaust stack temperature. The defining equation is:

$$UAToCapacityRatio = C_1 GasTurbineEngineCapacity^{C_2} \quad (14.168)$$

14.3.3.1 Chiller Basin Heater

This chiller's basin heater (for evaporatively-cooled condenser type) operates in the same manner as the Engine driven chiller's basin heater. The calculations for the chiller basin heater are described in detail at the end of the engine driven chiller description (Ref. Engine Driven Chiller).

14.3.4 ChillerHeater:Absorption:DirectFired

14.3.4.1 Overview

This model (object name ChillerHeater:Absorption:DirectFired) simulates the performance of a direct fired two-stage absorption chiller with optional heating capability. The model is based on the direct fired absorption chiller model (ABSORG-CHLR) in the DOE-2.1 building energy simulation program. The EnergyPlus model contains all of the features of the DOE-2.1 chiller model, plus some additional capabilities.

This model simulates the thermal performance of the chiller and the fuel consumption of the burner(s). This model does not simulate the thermal performance or the power consumption of associated pumps or cooling towers. This auxiliary equipment must be modeled using other EnergyPlus models (e.g. Cooling Tower:Single Speed).

14.3.4.2 Model Description

The chiller model uses user-supplied performance information at design conditions along with five performance curves (curve objects) for cooling capacity and efficiency to determine chiller operation at off-design conditions. Two additional performance curves for heating capacity and efficiency are used when the chiller is operating in a heating only mode or simultaneous cooling and heating mode.

14.3.4.3 Cooling

The following nomenclature is used in the cooling equations:

AvailCoolCap is the available full-load cooling capacity at current conditions (W)

CEIR is the user input “Electric Input to Cooling Output Ratio”

CEIRfPLR is the electric input to cooling output factor, equal to 1 at full load, user input “Electric Input to Cooling Output Ratio Function of Part Load Ratio Curve Name”

CEIRfT is the electric input to cooling output factor, equal to 1 at design conditions, user input “Electric Input to Cooling Output Ratio Function of Temperature Curve Name”

CFIR is the user input “Fuel Input to Cooling Output Ratio”

CFIRfPLR is the fuel input to cooling output factor, equal to 1 at full load, user input “Fuel Input to Cooling Output Ratio Function of Part Load Ratio Curve Name”

CFIRfT is the fuel input to cooling output factor, equal to 1 at design conditions, user input “Fuel Input to Cooling Output Ratio Function of Temperature Curve Name”

CondenserLoad is the condenser heat rejection load (W)

CoolCapfT is the cooling capacity factor, equal to 1 at design conditions, user input “Cooling Capacity Function of Temperature Curve Name”

CoolElectricPower is the cooling electricity input (W)

CoolFuelInput is the cooling fuel input (W)

CoolingLoad is the current cooling load on the chiller (W)

CPLR is the cooling part-load ratio = $CoolingLoad / AvailCoolCap$

HeatingLoad is the current heating load on the chiller heater (W)

HFIR is the user input “Fuel Input to Heating Output Ratio”

HPLR is the heating part-load ratio = $HeatingLoad / AvailHeatCap$

MinPLR is the user input “Minimum Part Load Ratio”

NomCoolCap is the user input “Nominal Cooling Capacity” (W)

RunFrac is the fraction of time step which the chiller is running

T_{cond} is the entering or leaving condenser fluid temperature (°C). For a water-cooled condenser this will be the water temperature returning from the condenser loop (e.g., leaving the cooling tower) if the entering condenser fluid temperature option is used. For air- or evap-cooled condensers this will be the entering outdoor air dry-bulb or wet-bulb temperature, respectively, if the entering condenser fluid temperature option is used.

$T_{cw,l}$ is the leaving chilled water temperature (°C).

Five performance curves are used in the calculation of cooling capacity and efficiency:

- 1) Cooling Capacity Function of Temperature Curve
- 2) Fuel Input to Cooling Output Ratio Function of Temperature Curve
- 3) Fuel Input to Cooling Output Ratio Function of Part Load Ratio Curve
- 4) Electric Input to Cooling Output Ratio Function of Temperature Curve
- 5) Electric Input to Cooling Output Ratio Function of Part Load Ratio Curve

The cooling capacity function of temperature ($CoolCapfT$) curve represents the fraction of the cooling capacity of the chiller as it varies by temperature. This a biquadratic curve with the input variables being the leaving chilled water temperature and either the entering or leaving condenser fluid temperature. The output of this curve is multiplied by the nominal cooling capacity to give the full-load cooling capacity at specific temperature operating conditions (i.e., at temperatures different from the design temperatures). The curve should have a value of 1.0 at the design temperatures and flow rates specified in the input data file by the user. The biquadratic curve should be valid for the range of water temperatures anticipated for the simulation.

$$CoolCapfT = a + bT_{cw,l} + cT_{cw,l}^2 + dT_{cond} + eT_{cond}^2 + fT_{cw,l}T_{cond} \quad (14.169)$$

The available cooling capacity of the chiller is then computed as follows:

$$AvailCoolCap = NomCoolCap \cdot CoolCapfT(T_{cw,l}, T_{cond}) \quad (14.170)$$

The fuel input to cooling output ratio function of temperature ($CFIRfT$) curve represents the fraction of the fuel input to the chiller at full load as it varies by temperature. This a biquadratic curve with the input variables being the leaving chilled water temperature and either the entering or leaving condenser fluid temperature. The output of this curve is multiplied by the nominal fuel input to cooling output ratio ($CFIR$) to give the full-load fuel input to cooling capacity ratio at specific temperature operating conditions (i.e., at temperatures different from the design temperatures). The curve should have a value of 1.0 at the design temperatures and flow rates specified in the input data file by the user. The biquadratic curve should be valid for the range of water temperatures anticipated for the simulation.

$$CFIRfT = a + bT_{cw,l} + cT_{cw,l}^2 + dT_{cond} + eT_{cond}^2 + fT_{cw,l}T_{cond} \quad (14.171)$$

The fuel input to cooling output ratio function of part load ratio ($CFIRfPLR$) curve represents the fraction of the fuel input to the chiller as the load on the chiller varies at a given set of operating temperatures. The curve is normalized so that at full load the value of the curve should be 1.0. The curve is usually linear or quadratic.

$$CFIRfPLR = a + b \cdot CPLR + c \cdot CPLR^2 \quad (14.172)$$

The fraction of the time step during which the chiller heater is operating is computed as a function of the cooling and heating part-load ratios and the user-input minimum part-load ratio:

$$RunFrac = \text{MIN}(1.0, \text{MAX}(HPLR, CPLR) / MinPLR) \quad (14.173)$$

The cooling fuel input to the chiller is then computed as follows:

$$CoolFuelInput = AvailCoolCap * RunFrac * CFIR * CFIRfT(T_{cw,l}, T_{cond}) * CFIRfPLR(CPLR) \quad (14.174)$$

The electric input to cooling output ratio as function of temperature ($CEIRfT$) curve represents the fraction of electricity to the chiller at full load as it varies by temperature. This a biquadratic curve with the input variables being the leaving chilled water temperature and either the entering or leaving condenser fluid temperature.

$$CEIRfT = a + bT_{cw,l} + cT_{cw,l}^2 + dT_{cond} + eT_{cond}^2 + fT_{cw,l}T_{cond} \quad (14.175)$$

The electric input to cooling output ratio function of part load ratio (*CEIRfPLR*) curve represents the fraction of electricity to the chiller as the load on the chiller varies at a given set of operating temperatures. The curve is normalized so that at full load the value of the curve should be 1.0. The curve is usually linear or quadratic.

$$CEIRfPLR = a + b \cdot CPLR + c \cdot CPLR^2 \quad (14.176)$$

The cooling electric input to the chiller is computed as follows:

$$CoolElectricPower = NomCoolCap \cdot RunFrac \cdot CEIR \cdot CEIRfT(T_{cw,l}, T_{cond}) \cdot CEIRfPLR(CPLR) \quad (14.177)$$

All five of these cooling performance curves are accessed through EnergyPlus' built-in performance curve equation manager (objects *Curve:Linear*, *Curve:Quadratic* and *Curve:Biquadratic*). It is not imperative that the user utilize all coefficients in the performance curve equations if their performance equation has fewer terms (e.g., if the user's *CFIRfPLR* performance curve is linear instead of quadratic, simply enter the values for a and b, and set coefficient c equal to zero).

The condenser load is computed as follows:

$$CondenserLoad = CoolingLoad + CoolFuelInput / HFIR + CoolElectricPower \quad (14.178)$$

14.3.4.4 Heating

The following nomenclature is used in the heating equations:

AvailHeatCap is the available full-load heating capacity at current conditions (W)

CPLRh is the cooling part-load ratio for heating curve = *CoolingLoad* / *NomCoolCap*

HeatCapfCPLR is the heating capacity factor as a function of cooling part load ratio, equal to 1 at zero cooling load, user input "Heating Capacity Function of Cooling Capacity Curve Name"

HeatCoolCapRatio is the user input "Heating to Cooling Capacity Ratio"

HeatElectricPower is the heating electricity input (W)

HeatFuelInput is the heating fuel input (W)

HeatingLoad is the current heating load on the chiller (W)

HEIR is the user input "Electric Input to Heating Output Ratio"

HFIR is the user input "Fuel Input to Heating Output Ratio"

HFIRfHPLR is the fuel input to heating output factor, equal to 1 at full load, user input "Fuel Input to Heat Output Ratio During Heating Only Operation Curve Name"

HPLR is the heating part-load ratio = *HeatingLoad* / *AvailHeatCap*

MinPLR is the user input "Minimum Part Load Ratio"

NomCoolCap is the user input "Nominal Cooling Capacity" (W)

RunFrac is the fraction of time step which the chiller is running

TotalElectricPower is the total electricity input (W)

TotalFuelInput is the total fuel input (W).

Cooling is the primary purpose of the Direct Fired Absorption Chiller so that function is satisfied first and if energy is available for providing heating that is provided next.

The two performance curves for heating capacity and efficiency are:

- 1) Heating Capacity Function of Cooling Capacity Curve
- 2) Fuel-Input-to Heat Output Ratio Function

The heating capacity function of cooling capacity curve (*HeatCapfCool*) determines how the heating capacity of the chiller varies with cooling capacity when the chiller is simultaneously heating and cooling. The curve is normalized so an input of 1.0 represents the nominal cooling capacity and an output of 1.0 represents the full heating capacity. An output of 1.0 should occur when the input is 0.0.

$$HeatCapfCPLR = a + b \cdot CPLRh + c \cdot CPLRh^2 \quad (14.179)$$

The available heating capacity is then computed as follows:

$$AvailHeatCap = NomCoolCap \cdot HeatCoolCapRatio \cdot HeatCapfCPLR(CPLRh) \quad (14.180)$$

The fuel input to heat output ratio curve (*HFIRfHPLR*) function is used to represent the fraction of fuel used as the heating load varies as a function of heating part load ratio. It is normalized so that a value of 1.0 is the full available heating capacity. The curve is usually linear or quadratic and will probably be similar to a boiler curve for most chillers.

$$HFIRfHPLR = a + b \cdot HPLR + c \cdot HPLR^2 \quad (14.181)$$

The fuel use rate when heating is computed as follows:

$$HeatFuelInput = AvailHeatCap \cdot HFIR \cdot HFIRfHPLR(HPLR) \quad (14.182)$$

The fraction of the time step during which the chiller is operating is computed as a function of the cooling and heating part-load ratios and the user-input minimum part-load ratio:

$$RunFrac = \text{MIN}(1.0, \text{MAX}(HPLR, CPLRh) / MinPLR) \quad (14.183)$$

The heating electric input to the chiller is computed as follows:

$$HeatElectricPower = NomCoolCap \cdot HeatCoolCapRatio \cdot HEIR \cdot RunFrac \quad (14.184)$$

If the chiller is delivering heating and cooling simultaneously, the parasitic electric load will be double-counted, so the following logic is applied:

```
IF ( HeatElectricPower <= CoolElectricPower ) THEN
  HeatElectricPower = 0.0
ELSE
  HeatElectricPower = HeatElectricPower - CoolElectricPower
ENDIF
```

The total fuel and electric power input to the chiller is computed as shown below:

$$TotalElectricPower = HeatElectricPower + CoolElectricPower \quad (14.185)$$

$$TotalFuelInput = HeatFuelInput + CoolFuelInput \quad (14.186)$$

14.3.5 ChillerHeater:Absorption:DoubleEffect

14.3.5.1 Overview

This model (object name ChillerHeater:Absorption:DoubleEffect) simulates the performance of an exhaust fired two-stage (double effect) absorption chiller with optional heating capability. The model is based on the direct fired absorption chiller model (ABSORG-CHLR) in the DOE-2.1 building energy simulation program. The EnergyPlus model contains all of the features of the DOE-2.1 chiller model, plus some additional capabilities. The model uses the exhaust gas output from Microturbine.

This model simulates the thermal performance of the chiller and the thermal energy input to the chiller. This model does not simulate the thermal performance or the power consumption of associated pumps or cooling towers. This auxiliary equipment must be modeled using other EnergyPlus models (e.g. Cooling Tower:Single Speed).

14.3.5.2 Model Description

The chiller model uses user-supplied performance information at design conditions along with five performance curves (curve objects) for cooling capacity and efficiency to determine chiller operation at off-design conditions. Two additional performance curves for heating capacity and efficiency are used when the chiller is operating in a heating only mode or simultaneous cooling and heating mode.

14.3.5.3 Cooling

The following nomenclature is used in the cooling equations:

AvailCoolCap is the available full-load cooling capacity at current conditions (W)

CEIR is the user input “Electric Input to Cooling Output Ratio”

CEIRfPLR is the electric input to cooling output factor, equal to 1 at full load, user input “Electric Input to Cooling Output Ratio Function of Part Load Ratio Curve Name”

CEIRfT is the electric input to cooling output factor, equal to 1 at design conditions, user input “Electric Input to Cooling Output Ratio Function of Temperature Curve Name”

TeFIR is the user input “Thermal Energy Input to Cooling Output Ratio”

TeFIRfPLR is the thermal energy input to cooling output factor, equal to 1 at full load, user input “Thermal Energy Input to Cooling Output Ratio Function of Part Load Ratio Curve Name”

TeFIRfT is the thermal energy input to cooling output factor, equal to 1 at design conditions, user input “Thermal Energy Input to Cooling Output Ratio Function of Temperature Curve Name”

CondenserLoad is the condenser heat rejection load (W)

CoolCapfT is the cooling capacity factor, equal to 1 at design conditions, user input “Cooling Capacity Function of Temperature Curve Name”

CoolElectricPower is the cooling electricity input (W)

CoolThermalEnergyInput is the cooling thermal energy input (W)

CoolingLoad is the current cooling load on the chiller (W)

CPLR is the cooling part-load ratio = $CoolingLoad / AvailCoolCap$

HeatingLoad is the current heating load on the chiller heater (W)

HFIR is the user input “Thermal Energy Input to Heating Output Ratio”

HPLR is the heating part-load ratio = $HeatingLoad / AvailHeatCap$

\dot{m}_{ExhAir} is the exhaust air mass flow rate from microturbine (kg/s)

$MinPLR$ is the user input “Minimum Part Load Ratio”

$NomCoolCap$ is the user input “Nominal Cooling Capacity” (W)

$RunFrac$ is the fraction of time step which the chiller is running

$T_{a,o}$ is the exhaust air outlet temperature from microturbine entering the chiller (°C)

$T_{abs,gen,o}$ is the temperature of exhaust leaving the chiller (the generator component of the absorption chiller)

T_{cond} is the entering condenser fluid temperature (°C). For a water-cooled condenser this will be the water temperature returning from the condenser loop (e.g., leaving the cooling tower). For air- or evap-cooled condensers this will be the entering outdoor air dry-bulb or wet-bulb temperature, respectively.

$T_{cw,l}$ is the leaving chilled water temperature (°C)

The selection of entering or leaving condense fluid temperature can be made through the optional field-Temperature Curve Input Variable.

Five performance curves are used in the calculation of cooling capacity and efficiency:

- 1) Cooling Capacity Function of Temperature Curve
- 2) Thermal Energy Input to Cooling Output Ratio Function of Temperature Curve
- 3) Thermal Energy Input to Cooling Output Ratio Function of Part Load Ratio Curve
- 4) Electric Input to Cooling Output Ratio Function of Temperature Curve
- 5) Electric Input to Cooling Output Ratio Function of Part Load Ratio Curve

The cooling capacity function of temperature ($CoolCapfT$) curve represents the fraction of the cooling capacity of the chiller as it varies with temperature. This a biquadratic curve with the input variables being the leaving chilled water temperature and the entering condenser fluid temperature. The output of this curve is multiplied by the nominal cooling capacity to give the full-load cooling capacity at specific temperature operating conditions (i.e., at temperatures different from the design temperatures). The curve should have a value of 1.0 at the design temperatures and flow rates specified in the input data file by the user. The biquadratic curve should be valid for the range of water temperatures anticipated for the simulation.

$$CoolCapfT = a + bT_{cw,l} + cT_{cw,l}^2 + dT_{cond} + eT_{cond}^2 + fT_{cw,l}T_{cond} \quad (14.187)$$

The available cooling capacity of the chiller is then computed as follows:

$$AvailCoolCap = NomCoolCap \cdot CoolCapfT(T_{cw,l} - T_{cond}) \quad (14.188)$$

The thermal energy input to cooling output ratio function of temperature ($TeFIRfT$) curve represents the fraction of the thermal energy input to the chiller at full load as it varies with temperature. This a biquadratic curve with the input variables being the leaving chilled water temperature and the entering condenser fluid temperature. The output of this curve is multiplied by the nominal thermal energy input to cooling output ratio ($TeFIR$) to give the full-load thermal energy input to cooling capacity ratio at specific temperature operating conditions (i.e., at temperatures different from the design temperatures). The curve should have a value of 1.0 at the design temperatures and flow rates specified in the input data file by the user. The biquadratic curve should be valid for the range of water temperatures anticipated for the simulation.

$$TeFIRfT = a + bT_{cw,l} + cT_{cw,l}^2 + dT_{cond} + eT_{cond}^2 + fT_{cw,l}T_{cond} \quad (14.189)$$

The thermal energy input to cooling output ratio function of part load ratio ($TeFIRfPLR$) curve represents the fraction of the thermal energy input to the chiller as the load on the chiller varies at

a given set of operating temperatures. The curve is normalized so that at full load the value of the curve should be 1.0. The curve is usually linear or quadratic.

$$TeFIRfPLR = a + b \cdot CPLR + c \cdot CPLR^2 \quad (14.190)$$

The fraction of the time step during which the chiller heater is operating is computed as a function of the cooling and heating part-load ratios and the user-input minimum part-load ratio:

$$RunFrac = MIN(1.0, MAX(HPLR, CPLR) / MinPLR) \quad (14.191)$$

The cooling thermal energy input to the chiller is then computed as follows:

$$CoolThermalEnergyInput = AvailCoolCap \cdot RunFrac \cdot TeFIR \cdot TeFIRfT(T_{cw,l}, T_{cond}) \cdot TeFIRfPLR(CPLR) \quad (14.192)$$

To make sure that the exhaust mass flow rate and temperature from microturbine are sufficient to drive the chiller, the heat recovery potential is compared with the cooling thermal energy input to the chiller (CoolThermalEnergyInput). The heat recovery potential should be greater than the CoolThermalEnergyInput. Heat recovery potential is calculated as:

$$Q_{Recovery} = \dot{m}_{ExhAir} \cdot Cp_{Air} \cdot (T_{a,o} - T_{Abs,gen,o}) \quad (14.193)$$

$T_{abs,gen,o}$ is the minimum temperature required for the proper operation of the double-effect chiller. It will be defaulted to 176°C.

The electric input to cooling output ratio as function of temperature ($CEIRfT$) curve represents the fraction of electricity to the chiller at full load as it varies with temperature. This a biquadratic curve with the input variables being the leaving chilled water temperature and either the entering or leaving condenser fluid temperature.

$$CEIRfT = a + bT_{cw,l} + cT_{cw,l}^2 + dT_{cond} + eT_{cond}^2 + fT_{cw,l}T_{cond} \quad (14.194)$$

The electric input to cooling output ratio function of part load ratio ($CEIRfPLR$) curve represents the fraction of electricity to the chiller as the load on the chiller varies at a given set of operating temperatures. The curve is normalized so that at full load the value of the curve should be 1.0. The curve is usually linear or quadratic.

$$CEIRfPLR = a + b \cdot CPLR + c \cdot CPLR^2 \quad (14.195)$$

The cooling electric input to the chiller is computed as follows:

$$CoolElectricPower = NomCoolCap \cdot RunFrac \cdot CEIR \cdot CEIRfT(T_{cw,l}, T_{cond}) \cdot CEIRfPLR(CPLR) \quad (14.196)$$

All five of these cooling performance curves are accessed through EnergyPlus' built-in performance curve equation manager (objects Curve:Linear, Curve:Quadratic and Curve:Biquadratic). It is not imperative that the user utilize all coefficients in the performance curve equations if their performance equation has fewer terms (e.g., if the user's $TeFIRfPLR$ performance curve is linear instead of quadratic, simply enter the values for a and b, and set coefficient c equal to zero). A set of

curves derived from manufacturer's data are also provided in the dataset (ExhaustFiredChiller.idf) which is provided with the standard EnergyPlus installation.

The condenser load is computed as follows:

$$\text{CondenserLoad} = \text{CoolingLoad} + \text{CoolThermalEnergyInput} / \text{HFIR} + \text{CoolElectricPower} \quad (14.197)$$

14.3.5.4 Heating

The following nomenclature is used in the heating equations:

AvailHeatCap is the available full-load heating capacity at current conditions (W)

CPLRh is the cooling part-load ratio for heating curve = $\text{CoolingLoad} / \text{NomCoolCap}$

HeatCapfCPLR is the heating capacity factor as a function of cooling part load ratio, equal to 1 at zero cooling load, user input "Heating Capacity Function of Cooling Capacity Curve Name"

HeatCoolCapRatio is the user input "Heating to Cooling Capacity Ratio"

HeatElectricPower is the heating electricity input (W)

HeatThermalEnergyInput is the heating thermal energy input (W)

HeatingLoad is the current heating load on the chiller (W)

HEIR is the user input "Electric Input to Heating Output Ratio"

HFIR is the user input "Thermal Energy Input to Heating Output Ratio"

HFIRfHPLR is the thermal energy input to heating output factor, equal to 1 at full load, user input "Thermal Energy Input to Heat Output Ratio During Heating Only Operation Curve Name"

HPLR is the heating part-load ratio = $\text{HeatingLoad} / \text{AvailHeatCap}$

MinPLR is the user input "Minimum Part Load Ratio"

NomCoolCap is the user input "Nominal Cooling Capacity" (W)

RunFrac is the fraction of time step which the chiller is running

TotalElectricPower is the total electricity input (W)

TotalThermalEnergyInput is the total thermal energy input (W)

Cooling is the primary purpose of the Exhaust Fired Absorption Chiller so that function is satisfied first and if energy is available for providing heating that is provided next.

The two performance curves for heating capacity and efficiency are:

- 1) Heating Capacity Function of Cooling Capacity Curve
- 2) Thermal Energy Input to Heat Output Ratio Function

The heating capacity function of cooling capacity curve (*HeatCapfCPLR*) determines how the heating capacity of the chiller varies with cooling capacity when the chiller is simultaneously heating and cooling. The curve is normalized so an input of 1.0 represents the nominal cooling capacity and an output of 1.0 represents the full heating capacity. An output of 1.0 should occur when the input is 0.0.

$$\text{HeatCapfCPLR} = a + b \cdot \text{CPLRh} + c \cdot \text{CPLRh}^2 \quad (14.198)$$

The available heating capacity is then computed as follows:

$$\text{AvailHeatCap} = \text{NomCoolCap} \cdot \text{HeatCoolCapRatio} \cdot \text{HeatCapfCPLR}(\text{CPLRh}) \quad (14.199)$$

The thermal energy input to heat output ratio curve ($HFIRfHPLR$) function is used to represent the fraction of thermal energy used as the heating load varies as a function of heating part load ratio. It is normalized so that a value of 1.0 is the full available heating capacity. The curve is usually linear or quadratic and will probably be similar to a boiler curve for most chillers.

$$HFIRfHPLR = a + b \cdot HPLR + c \cdot HPLR^2 \quad (14.200)$$

The thermal energy use rate when heating is computed as follows:

$$HeatThermalEnergyInput = AvailHeatCap \cdot HFIR \cdot HFIRfHPLR(HPLR) \quad (14.201)$$

The fraction of the time step during which the chiller is operating is computed as a function of the cooling and heating part-load ratios and the user-input minimum part-load ratio:

$$RunFrac = MIN(1.0, MAX(HPLR, CPLRh) / MinPLR) \quad (14.202)$$

The heating electric input to the chiller is computed as follows:

$$HeatElectricPower = NomCoolCap \cdot HeatCoolCapRatio \cdot HEIR \cdot RunFrac \quad (14.203)$$

If the chiller is delivering heating and cooling simultaneously, the parasitic electric load would be double-counted, so the following logic is applied:

If HeatElectricPower is less than or equal to CoolElectricPower:

$$HeatElectricPower = 0.0 \quad (14.204)$$

Else:

$$HeatElectricPower = HeatElectricPower - CoolElectricPower \quad (14.205)$$

The total thermal energy and electric power input to the chiller is computed as shown below:

$$TotalElectricPower = HeatElectricPower + CoolElectricPower \quad (14.206)$$

$$TotalThermalEnergyInput = HeatThermalEnergyInput + CoolThermalEnergyInput \quad (14.207)$$

14.3.6 Constant COP Chiller

The input object Chiller:ConstantCOP provides a chiller model that is based on a simple, constant COP simulation of the chiller. In this case, performance does not vary with chilled water temperature or condenser conditions. The nominal capacity of the chiller and the COP are user specified along with the connections to the plant and condenser loop and mass flow rates. *Such a model is useful when the user does not have access to detailed performance data.*

The chiller power is calculated from the load divided by the COP. This chiller will meet the load as long as it does not exceed the nominal capacity specified by the user.

$$Q_{\text{Evaporator}} = \text{Load}$$

$$\text{Power} = \text{Load} / \text{ConstCOPChiller}(\text{ChillNum})\% \text{COP}$$

Then the evaporator temperatures are calculated from the load

$$\text{EvapDeltaTemp} = Q_{\text{Evaporator}} / \text{EvapMassFlowRate} / \text{CP}_{\text{water}}$$

$$\text{EvapOutletTemp} = \text{Node}(\text{EvapInletNode})\% \text{Temp} - \text{EvapDeltaTemp}$$

The condenser load and temperatures are calculated from the evaporator load and the power to the chiller.

$$Q_{\text{Condenser}} = \text{Power} + Q_{\text{Evaporator}}$$

IF (ConstCOPChiller(ChillNum)%CondenserType == WaterCooled) THEN

IF (CondMassFlowRate > WaterMassFlowTol) THEN

CondOutletTemp = QCondenser/CondMassFlowRate/CPCW(CondInletTemp) + CondInletTemp

ELSE

CALL ShowSevereError('CalcConstCOPChillerModel: Condenser flow = 0, for CONST COP Chiller =') // &

TRIM(ConstCOPChiller(ChillNum)%Name))

CALL ShowContinueErrorTimeStamp('')

CALL ShowFatalError('Program Terminates due to previous error condition.')

END IF

ELSE ! Air Cooled or Evap Cooled

! Set condenser outlet temp to condenser inlet temp for Air Cooled or Evap Cooled

! since there is no CondMassFlowRate and would divide by zero

$$\text{CondOutletTemp} = \text{CondInletTemp}$$

END IF

14.3.6.1 Chiller Basin Heater

This chiller's basin heater (for evaporatively-cooled condenser type) operates in the same manner as the Engine driven chiller's basin heater. The calculations for the chiller basin heater are described in detail at the end of the engine driven chiller description (Ref. Engine Driven Chiller).

14.3.7 Hot Water Heat Recovery from Chillers

+The electric chillers (e.g., Chiller:Electric, Chiller:EngineDriven, Chiller:CombustionTurbine, Chiller:Electric:EIR, and Chiller:Electric:ReformulatedEIR) all have the option of connecting a third plant loop for heating hot water at the same time the chiller cools the chilled water. The engine and combustion turbine chillers models include curves for heat recovery from oil and or

jacket coolers. The other three chillers can model heat recovery where part of its condenser section is connected to a heat recovery loop for what is commonly known as a double bundled chiller, or single condenser with split bundles. The heat recovery chiller is simulated as a standard vapor compression refrigeration cycle with a double bundled condenser. A double bundle condenser involves two separate flow paths through a split condenser. One of these paths is condenser water typically connected to a standard cooling tower; the other path is hot water connected to a heat recovery loop. After leaving the compressor, the refrigerant is condensed to liquid in a refrigerant to water condenser. In a split bundle, the chiller's internal controls will direct a part of the refrigerant to heat recovery condenser bundle and/or to the tower water condenser bundle depending on the chilled water load, the condenser inlet temperatures and internal chiller controls (and possibly a leaving hot water temperature setpoint). The refrigerant pressure is then dropped through a throttling valve so that fluid can evaporate at a low pressure that provides cooling to the evaporator. Note that the heat recovery side of the chiller is placed on the demand-side of a heat recovery loop which will typically supply a hot water storage tank. Heat recovery is a passive benefit when the chiller is dispatched for cooling. The standard plant controls cannot dispatch the chiller based on a heat recovery requirement.

Figure 14.11: Diagram of Chiller:Electric with Heat Recovery

The algorithm for the heat recovery portion of the chiller needs to be determined from relatively simple inputs to estimate the amount of the heat that is recovered and then send the rest of the heat to the cooling tower. For the chiller models associated with the object Chiller:Electric, air- or evaporatively-cooled condensers are allowed to be used with heat recovery and, when used, the condenser specific heat, mass flow rate, and temperatures shown below refer to outdoor air. A

condenser air volume flow rate must be specified when using heat recovery with air- or evaporatively-cooled chillers.

The basic energy balance for the condenser section of a heat recovery chiller is

$$\dot{Q}_{tot} = \dot{Q}_{Evap} + \dot{Q}_{Elec} = \dot{Q}_{Cond} + \dot{Q}_{HR} \quad (14.208)$$

In practice, if the entering temperature of the heat recovery hot fluid is too high, the chiller's internal controls will redirect refrigerant away from the heat recovery bundle. A user input is available for declaring the inlet high temperature limit, and if it is exceeded, the chiller will shut down heat recovery and request no flow and will not reject any condenser heat to that fluid.

The heat recovery condenser bundle is often physically smaller than the tower water condenser bundle and therefore may have limited heat transfer capacity. User input for the relative capacity of the heat recovery bundle, $F_{HR,Cap}$, is used to define a maximum rate of heat recovery heat transfer using

$$\dot{Q}_{HR,Max} = F_{HR,Cap} \left(\dot{Q}_{Evap,Ref} + \frac{\dot{Q}_{Evap,Ref}}{COP_{Ref}} \right) \quad (14.209)$$

This capacity factor is also used to autosize the heat recovery design fluid flow rate when it is set to autosize. The design heat recover flow rate is calculated by multiplying $F_{HR,Cap}$ by the condenser tower water design flow rate. If no capacity factor is input, it is assumed to be 1.0.

A heat recovery chiller may control the temperature of heat recovery fluid leaving the device by modulating the flow of refrigerant to the heat recovery condenser bundle. There are two different algorithms used depending on if the input has declared a leaving setpoint node.

If no control setpoint node was named, then the model developed by Liesen and Chillar (2004) is used to approximate the relative distribution of refrigerant flow and condenser heat transfer between the bundles. This model approximates the heat transfer situation by using average temperatures in and out of the condenser section.

$$Q_{Tot} = (\dot{m}_{HeatRec} * C_{p,HeatRec} + \dot{m}_{Cond} * C_{p,Cond}) * (T_{AvgOut} - T_{AvgIn}) \quad (14.210)$$

Then the inlet temperature is flow-weighted to determine lumped inlet and outlet conditions.

$$T_{AvgIn} = \frac{(\dot{m}_{HeatRec} * C_{p,HeatRec} * T_{HeatRecIn} + \dot{m}_{Cond} * C_{p,Cond} * T_{CondIn})}{(\dot{m}_{HeatRec} * C_{p,HeatRec} + \dot{m}_{Cond} * C_{p,Cond})} \quad (14.211)$$

$$T_{AvgOut} = \frac{Q_{Tot}}{(\dot{m}_{HeatRec} * C_{p,HeatRec} + \dot{m}_{Cond} * C_{p,Cond})} + T_{AvgIn} \quad (14.212)$$

The lumped outlet temperature is then used for an approximate method of determining the heat recovery rate

$$\dot{Q}_{HR} = \dot{m}_{HR} c_{pHR} (T_{Avg,out} - T_{HR,in}) \quad (14.213)$$

This rate is then limited by the physical size of the heat recovery bundle.

$$\dot{Q}_{HR} = Min(\dot{Q}_{HR}, \dot{Q}_{HR,max}) \quad (14.214)$$

If user input for the leaving temperature setpoint is available, then a second model is used to distribute refrigerant flow and condenser heat transfer between the bundles that attempts to meet

the heat recovery load implied by the leaving setpoint. When setpoint control is used, the desired rate of heat recovery heat transfer is:

$$\dot{Q}_{HR,Setpoint} = \dot{m}_{HR} C_{p,HR} (T_{HR,set} - T_{HR,in}) \quad (14.215)$$

$$\dot{Q}_{HR,Setpoint} = Max \left(\dot{Q}_{HR,Setpoint}, 0.0 \right) \quad (14.216)$$

Then the heat recovery rate is simply modeled as the lower of the three different heat flow rates: the desired capacity, the maximum capacity, and the current total heat rejection rate.

$$\dot{Q}_{HR} = Min \left(\dot{Q}_{HR,Setpoint}, \dot{Q}_{HR,max}, \dot{Q}_{Tot} \right) \quad (14.217)$$

For both models, the condenser heat transfer rate is then

$$\dot{Q}_{Cond} = \dot{Q}_{Tot} - \dot{Q}_{HR} \quad (14.218)$$

The outlet temperatures are then calculated using

$$T_{HR,out} = T_{HR,in} + \frac{\dot{Q}_{HR}}{\dot{m}_{HR} C_{p,HR}} \quad (14.219)$$

$$T_{Cond,out} = T_{Cond,in} + \frac{\dot{Q}_{Cond}}{\dot{m}_{Cond} C_{p,Cond}} \quad (14.220)$$

A heat recovery chiller may need to work harder because the refrigeration system faces a higher lift owing to an elevated effective temperature for heat rejection. With heat recovery, the condenser temperature used with the chiller's performance curves is determined using one of the following heat-flow-weighted methods. The first is used for the chiller model for the objects Chiller:Electric, and Chiller:Electric:EIR which use the condensing entering temperature for performance.

$$T_{Cond,in,Avg} = \frac{\left(\dot{Q}_{HR} T_{HR,in} + \dot{Q}_{Cond} T_{Cond,in} \right)}{\left(\dot{Q}_{HR} + \dot{Q}_{Cond} \right)} \quad (14.221)$$

The second is used for the chiller model for the object Chiller:Electric:ReformulatedEIR which uses the leaving condenser fluid temperature.

$$T_{Cond,out,Avg} = \frac{\left(\dot{Q}_{HR} T_{HR,out} + \dot{Q}_{Cond} T_{Cond,out} \right)}{\left(\dot{Q}_{HR} + \dot{Q}_{Cond} \right)} \quad (14.222)$$

Both of these are available as an output variable called Chiller Effective Heat Rejection Temperature in °C.

14.3.7.1 Chiller Basin Heater

This chiller's basin heater (for evaporatively-cooled condenser type) operates in the same manner as the Engine driven chiller's basin heater. The calculations for the chiller basin heater are described in detail at the end of the engine driven chiller description (Ref. Engine Driven Chiller).

14.3.8 Electric Chiller Model Based on Fluid Temperature Differences

The centrifugal chiller model (object name Chiller:Electric) was originally developed for the BLAST program. The model is based on a 'capacity ratio' curve, which is a quadratic equation that determines the Ratio of Available Capacity to Nominal Capacity. The defining equation is:

$$CapRatio = \frac{AvailableChillerCapacity}{NominalChillerCapacity} = A_1 + A_2\Delta T_{chiller} + A_3\Delta T_{chiller}^2 \quad (14.223)$$

where the Delta Temperature is defined as:

$$\Delta T_{chiller} = \frac{T_{cond,in} - T_{cond,in,design}}{TempRiseRatio} - (T_{evap,out} - T_{evap,out,design}) \quad (14.224)$$

where the temperature rise coefficient is defined as the ratio of the required change in condenser water temperature to a given change in chilled water temperature, which maintains the capacity at the nominal value. If the chiller is a heat recovery chiller, then the condenser inlet temperature is adjusted to account for both fluid streams as described in the section above on heat recovery chillers. This is calculated as the following ratio:

$$TempRiseRatio = \frac{T_{cond,in,required} - T_{cond,in,rated}}{T_{evap,out,required} - T_{evap,out,rated}} - (T_{evap,out} - T_{evap,out,design}) \quad (14.225)$$

where:

$T_{cond,in,required}$ is the required entering condenser air or water temperature to maintain rated capacity (°C)

$T_{cond,in,rated}$ is the rated entering condenser air or water temperature at rated capacity (°C)

$T_{evap,out,required}$ is the required leaving evaporator water outlet temperature to maintain rated capacity (°C)

$T_{evap,out,rated}$ is the rated leaving evaporator water outlet temperature at rated capacity (°C)

The Power Ratio Curve is a quadratic equation that determines the Ratio of Full Load to Power. The defining equation is:

$$PowerRatio = B_1 + B_2PLR + B_3PLR^2 \quad (14.226)$$

where the part load ratio, PLR is defined as:

$$PLR = \frac{chiller\ cooling\ load}{nominal\ chiller\ capacity} \quad (14.227)$$

The Load Ratio Curve is a quadratic equation that determines the Ratio of Actual Cooling Load to Full Cooling Load. The defining equation is:

$$LoadRatio = C_1 + C_2 CapRatio + C_3 CapRatio^2 \quad (14.228)$$

The evaporator heat transfer rate and the power required by the chiller are then calculated as:

$$Q_{evap} = AvailableChillerCap * PLR \quad (14.229)$$

$$Power = PowerRatio * LoadRatio * \frac{AvailableChillerCap}{RatedCOP} \quad (14.230)$$

14.3.9 Electric Chiller Model Based on Condenser Entering Temperature

14.3.9.1 Overview

This model (object name Chiller:Electric:EIR) simulates the performance of an electric liquid chiller. The model is based on the compression chiller model (COMREF) in the DOE-2.1 building energy simulation program. The EnergyPlus model contains all of the features of the DOE-2.1 chiller model, plus additional abilities for modeling evaporatively-cooled condensers and heat recovery for water heating.

This model simulates the thermal performance of the chiller and the power consumption of the compressor(s). It also models the power consumption of condenser fans if modeling an air-cooled or evaporatively-cooled condenser. This model does not simulate the thermal performance or the power consumption of associated pumps or cooling towers. This auxiliary equipment must be modeled using other EnergyPlus models (e.g. CoolingTower:SingleSpeed).

14.3.9.2 Model Description

The chiller model uses user-supplied performance information at reference conditions along with three performance curves (curve objects) for cooling capacity and efficiency to determine chiller operation at off-reference conditions. The three performance curves are:

1. Cooling Capacity Function of Temperature Curve
2. Energy Input to Cooling Output Ratio Function of Temperature Curve
3. Energy Input to Cooling Output Ratio Function of Part Load Ratio Curve

The cooling capacity function of temperature curve is a biquadratic performance curve with two independent variables: the leaving chilled water temperature and the entering condenser fluid temperature. The output of this curve is multiplied by the reference capacity to give the full-load cooling capacity at specific temperature operating conditions (i.e., at temperatures different from the reference temperatures). The curve should have a value of 1.0 at the reference temperatures and flow rates specified in the input data file by the user. The biquadratic curve should be valid for the range of water temperatures anticipated for the simulation. If the chiller is a heat recovery chiller, then the condenser inlet temperature is adjusted to account for both fluid streams as described in the section above on heat recovery chillers.

Note: The curve is evaluated at the leaving chilled water (=evaporator outlet) *setpoint* temperature, not the *actual* leaving chilled water temperature.

$$ChillerCapFTemp = a + b(T_{cw,ls}) + c(T_{cw,ls})^2 + d(T_{cond,e}) + e(T_{cond,e})^2 + f(T_{cw,ls})(T_{cond,e}) \quad (14.231)$$

where:

ChillerCapFTemp is the cooling capacity factor, equal to 1 at reference conditions

$T_{cw,ls}$ is the leaving chilled water *setpoint* temperature (°C)

$T_{cond,e}$ is the entering condenser fluid temperature (°C). For a water-cooled condenser this will be the water temperature returning from the condenser loop (e.g., leaving the cooling tower). For air- or evap-cooled condensers this will be the entering outdoor air dry-bulb or wet-bulb temperature, respectively.

The energy input to cooling output ratio function of temperature curve is a biquadratic performance curve that parameterizes the variation of the energy input to cooling output ratio (EIR) as a function of the leaving chilled water temperature and the entering condenser fluid temperature. The EIR is the inverse of the COP. The output of this curve is multiplied by the reference EIR (inverse of the reference COP) to give the full-load EIR at specific temperature operating conditions (i.e., at temperatures different from the reference temperatures). The curve should have a value of 1.0 at the reference temperatures and flow rates specified in the input data file by the user. The biquadratic curve should be valid for the range of water temperatures anticipated for the simulation.

$$ChillerEIRFTemp = a + b(T_{cw,l}) + c(T_{cw,l})^2 + d(T_{cond,e}) + e(T_{cond,e})^2 + f(T_{cw,l})(T_{cond,e}) \quad (14.232)$$

where:

ChillerEIRFTemp is the energy input to cooling output factor, equal to 1 at reference conditions

$T_{cw,l}$ is the leaving chilled water temperature (°C)

$T_{cond,e}$ is the entering condenser fluid temperature (°C). For a water-cooled condenser this will be the water temperature returning from the condenser loop (e.g., leaving the cooling tower). For air- or evap-cooled condensers this will be the entering outdoor air dry-bulb or wet-bulb temperature, respectively. If the chiller is a heat recovery chiller, then the condenser inlet temperature is adjusted to account for both fluid streams as described in the section above on heat recovery chillers.

The energy input to cooling output ratio function of part-load ratio curve is a quadratic performance curve that parameterizes the variation of the chiller input power ratio as a function of the part-load ratio. The part-load ratio is the actual cooling load divided by the chiller's available cooling capacity. The output of this curve *ChillerEIRFPLR* is multiplied by the reference EIR (inverse of the reference COP), chiller capacity as a function of temperature curve *ChillerCapFTemp* and the Energy Input to Cooling Output Ratio Function of Temperature Curve *ChillerEIRFTemp* to give the normalized power input at the specific temperature and part-load ratio at which the chiller is operating. Normalized power input is the ratio of chiller power input at a given operating condition to the chiller power input at reference condition. This curve should have a value of 1.0 when the part-load ratio equals 1.0. The quadratic curve should be valid for the range of part-load ratios anticipated for the simulation.

$$\begin{aligned}
ChillerEIRFPLR &= a + b(PLR) + c(PLR)^2 \\
&= \frac{P_{chiller}}{P_{ref}(ChillerCapFTemp)(ChillerEIRFTemp)}
\end{aligned} \tag{14.233}$$

where:

$ChillerEIRFPLR$ = energy input to cooling output factor, equal to 1 at reference conditions

PLR = part-load ratio = (cooling load) / (chiller's available cooling capacity)

$P_{chiller}$ = chiller power at specific PLR

$P_{ref} = \dot{Q}_{ref} / COP_{ref}$.

All three of the performance curves are accessed through EnergyPlus' built-in performance curve equation manager (curve:quadratic and curve:biquadratic). It is not imperative that the user utilize all coefficients in the performance curve equations if their performance equation has fewer terms (e.g., if the user's ChillerEIRFPLR performance curve is linear instead of quadratic, simply enter the values for a and b, and set coefficient c equal to zero). Performance curves for more than 160 chillers, including the default DOE-2.1E reciprocating and centrifugal chillers, are provided in the EnergyPlus Reference DataSets (Chillers.idf and AllDataSets.idf).

Note: Chiller:Electric:EIR objects and their associated performance curve objects are developed using performance information for a specific chiller and should normally be used together for an EnergyPlus simulation. Changing the object input values, or swapping performance curves between chillers, should be done with caution.

For any simulation time step, the chiller's available cooling capacity is calculated as follows:

$$\dot{Q}_{avail} = \dot{Q}_{ref} (ChillerCapFTemp) \tag{14.234}$$

where:

\dot{Q}_{ref} is the chiller capacity at reference conditions (reference temperatures and flow rates defined by the user) (W)

\dot{Q}_{avail} is the available chiller capacity adjusted for current fluid temperatures (W).

The model then calculates the evaporator heat transfer rate required to bring the entering chilled water temperature down to the leaving chilled water setpoint temperature (established using a SetpointManager object and referenced in the PlantLoop object). If this calculated heat transfer rate is greater than the heat transfer rate being requested by the plant equipment operation scheme, then the evaporator heat transfer rate is reset to the requested cooling rate.

The evaporator heat transfer rate is then compared to the available capacity. If the available chiller capacity is sufficient to meet the evaporator heat transfer rate, the leaving chilled water temperature is set equal to the chilled water setpoint temperature. If the requested evaporator heat transfer rate is larger than the available capacity the chilled water leaving the evaporator is allowed to float upward. For this case, the exiting chilled water temperature is calculated based on the water temperature entering the evaporator, the available cooling capacity, and the evaporator mass flow rate as follows:

$$T_{cw,l} = T_{cw,e} - \frac{\dot{Q}_{avail}}{\dot{m}_{evap} C_{p,evap}} \tag{14.235}$$

where:

$T_{cw,l}$ is the water temperature leaving the evaporator (°C)

$T_{cw,e}$ is the water temperature entering the evaporator (°C)

\dot{m}_{evap} is the evaporator mass flow rate (kg/s)

$C_{p,evap}$ is the specific heat of water entering evaporator at $T_{cw,e}$ (J/kg-°C).

The part-load ratio is then calculated as the ratio of the evaporator heat transfer rate to the available chiller capacity. The part-load ratio is not allowed to be greater than the maximum part-load ratio specified by the user or less than zero as follows:

$$PLR = \max \left(0.0, \min \left(\frac{\dot{Q}_{evap}}{\dot{Q}_{avail}}, PLR_{max} \right) \right) \quad (14.236)$$

where:

PLR is the part-load ratio

\dot{Q}_{evap} is the load to be met by the chiller (W)

PLR_{max} is the maximum part-load ratio (specified by the user in the input data file).

The model assumes that the cooling load is met through chiller unloading down to the minimum unloading ratio. False loading (e.g. hot-gas bypass) is assumed to occur between the minimum unloading ratio and the minimum part load ratio yielding constant electrical power consumption under these conditions. Below the minimum part load ratio, the chiller cycles on and off to meet very small loads and the power consumption during the on cycle is the same as when the chiller is operating at the minimum part load ratio. When the chiller part load ratio is less than the minimum part load ratio, the on-off cycling ratio of the chiller is calculated as follows and is available as an output variable.

$$ChillerCyclingRatio = \min \left(\frac{PLR}{PLR_{min}}, 1.0 \right) \quad (14.237)$$

To properly account for chiller electric power consumption when PLR is less than the minimum unloading ratio, the PLR is reset to the greater of the PLR calculated above and the PLR at the minimum unloading ratio. The result is available as the output variable Chiller Part Load Ratio.

$$PLR = \text{MAX}(PLR, PLR_{MinUnloadRatio}) \quad (14.238)$$

This revised PLR accounts for the “false loading” (e.g., hot gas bypass) that is assumed to occur whenever the PLR (based on cooling load divided by available capacity) is less than the minimum unloading ratio specified. The amount of false loading on the chiller is calculated using this revised PLR and is reported as an output variable as follows:

$$\dot{Q}_{falseloading} = \left(\dot{Q}_{avail} \right) (PLR) (ChillerCyclingRatio) - \dot{Q}_{evap} \quad (14.239)$$

The electrical power consumption for the chiller compressor(s) for any simulation time step is then calculated using the following equation:

$$P_{chiller} = \left(\dot{Q}_{avail} \right) \left(\frac{1}{COP_{ref}} \right) (ChillerEIRFTemp) (ChillerEIRFPLR) (ChillerCyclingRatio) \quad (14.240)$$

where:

$P_{chiller}$ is the chiller compressor power (W)

COP_{ref} is the reference coefficient of performance (W/W).

Heat rejected by the chiller condenser includes the heat transferred in the evaporator plus a portion or all of the compressor electrical energy consumption. For electric chillers with hermetic

compressors, all compressor energy consumption is rejected by the condenser (compressor motor efficiency = $eff_{motor} = 1.0$). For chillers with semi-hermetic or open compressors, only a portion of the compressor energy use is rejected by the condenser. The heat transfer rate for the chiller condenser is calculated as follows:

$$\dot{Q}_{cond} = (P_{chiller} * eff_{motor}) + \dot{Q}_{evap} + \dot{Q}_{falseloading} \quad (14.241)$$

where:

\dot{Q}_{cond} is the condenser heat transfer rate (W)

eff_{motor} is the compressor motor efficiency = fraction of compressor electrical energy consumption rejected as condenser heat.

For water-cooled chillers, the water temperature leaving the condenser is then calculated as shown below.

$$T_{cond,l} = T_{cond,e} + \frac{\dot{Q}_{cond}}{\dot{m}_{cond} C_{p,cond}} \quad (14.242)$$

where:

$T_{cond,l}$ is the water temperature leaving the condenser (°C)

$T_{cond,e}$ is the water temperature entering the condenser (°C)

\dot{m}_{cond} is the mass flow rate through the condenser, kg/s

$C_{p,cond}$ is the specific heat of water entering the condenser at $T_{cond,e}$, J/kg-(°C).

For air- and evaporatively-cooled condensers, the exiting air temperature is not calculated and is set equal to the entering air or wet-bulb temperature, respectively.

The model then calculates the condenser fan energy for air- and evaporatively-cooled condensers. The amount of condenser fan energy is assumed to be proportional to the chiller cycling ratio and is calculated as follows:

$$P_{cond} = \dot{Q}_{ref} (P_{condfanratio}) (ChillerCyclingRatio) \quad (14.243)$$

where:

P_{cond} is the chiller condenser fan electric power (W)

$P_{condfanratio}$ is the condenser fan power ratio (W/W).

The final calculations determine the total heat transfer energy for the condenser and evaporator, as well as the total electric energy consumed by the chiller compressor motor(s) and condenser fan(s). The results are available as output variables.

$$Q_{cond} = \dot{Q}_{cond} * TimeStepSys * 3600 \quad (14.244)$$

$$Q_{evap} = \dot{Q}_{evap} * TimeStepSys * 3600 \quad (14.245)$$

$$E_{chiller} = P_{chiller} * TimeStepSys * 3600 \quad (14.246)$$

$$E_{cond} = P_{cond} * TimeStepSys * 3600 \quad (14.247)$$

where:

Q_{cond} is the chiller condenser heat transfer energy (J)

Q_{evap} is the chiller evaporator cooling energy (J)
 $E_{chiller}$ is the chiller (compressor) electric energy (J)
 E_{cond} is the chiller condenser fan electric energy (J)
 $TimeStepSys$ is the HVAC system simulation time step (hr)
 3600 is the conversion factor (sec/hr).

14.3.9.3 Electric EIR Chiller with Heat Recovery Option

Heat from the electric EIR chiller condenser may be recovered when a water-cooled condenser is selected for simulation. The heat recovery water flow rate is specified by the user along with the input and output nodes connected to the heat recovery loop. The algorithms are identical to those used for Chiller:Electric. Refer to the section entitled Chillers with Plant Heat Recovery for details.

14.3.9.4 Standard Rating (Integrated Part Load Value)

For the Chiller:Electric:EIR and Chiller:Electric:ReformulatedEIR objects in EnergyPlus, the industry standard rating of Integrated Part Load Value (IPLV) is calculated according to ANSI/AHRI Standard 550/590 (2011). This standard rating is not direct input to the model and is calculated using user-entered information for these objects. These standard rating values are provided in the eplusout.eio output file (Ref. Output Details document) and also in the predefined tabular output reports (Output:Table:SummaryReports object, Equipment Summary).

Note: The standard ratings described in this section require that the EIR/Reformulated EIR chiller models be evaluated at specific operating conditions (e.g., specific evaporator outlet temperature (6.67°C) and dry-bulb temperatures for air entering the air-cooled [outdoor] condenser). If the chiller performance curves can not be evaluated at the required test conditions, then the standard rating value will be determined at user specified curve limit and warning error message is provided. For example, if the curve object (Curve:Biquadratic) for Cooling Capacity Function of Temperature Curve has a minimum value of 21°C for dry-bulb temperature entering the air-cooled condenser coil, the IPLV calculation requires that EER_D be calculated at 13°C – so, this would result in IPLV value calculated at 21°C and reported in the output and a warning message in the eplusout.err file.

The IPLV is a single number part-load performance figure of merit for Water-Chilling Packages. The IPLV equations and procedures described below are taken from Appendix D of ANSI/AHRI Std. 550/590, 2011 and provide a consistent method for calculating IPLV. These equations provide representative average part-load efficiency for a single chiller. For equipment covered by this standard, the *IPLV* is calculated using the following formula:

$$IPLV = (0.01A) + (0.42B) + (0.45C) + (0.12D) \quad (14.248)$$

where:

A is the *EER* or *COP* at 100% capacity at AHRI standard rating conditions

B is the *EER* or *COP* at 75% capacity and reduced ambient (see Table 14.2)

C is the *EER* or *COP* at 50% capacity and reduced ambient (see Table 14.2)

D is the *EER* or *COP* at 25% capacity and reduced ambient (see Table 14.2).

The Coefficient of Performance (COP) at the various load capacity points (100%, 75%, 50%, and 25% part-load ratios) are calculated using the procedure outlined below and applicable test conditions specified in Table 14.2.

EER at desired reduced capacity (75%, 50%, and 25%) is calculated as follows

$$COP = \frac{1}{EIR} \quad (14.249)$$

$$EIR = EnergyInputRatio = \left(\frac{Power}{PartLoadRatio * AvailChillerCap} \right) \quad (14.250)$$

$$Power = \left(\frac{AvailChillerCap}{COP_{reference}} \right) (EIRTempModFac_{ReducedTemp})(EIRPLRModFac_{ReducedPLR}) \quad (14.251)$$

$$AvailChillerCap = Capacity_{reference}(CapTempModFac_{ReducedTemp}) \quad (14.252)$$

where:

$Capacity_{reference}$ is the reference chiller capacity specified by the user (W)

$COP_{reference}$ is the reference coefficient of performance specified by the user (W/W)

$EIRTempModFac_{ReducedTemp}$ is the user-specified bi-quadratic curve for modifying EIR as a function of leaving chilled water temperature (6.7°C) and entering condenser temperature obtained from Table 14.2 for reduced capacities (dimensionless)

$EIRPLRModFac_{ReducedPLR}$ is the user-specified quadratic curve for modifying EIR as a function of part load ratio

$CapTempModFac_{ReducedTemp}$ is the capacity (W) of the chiller determined per the ANSI/AHRI Standard 550/590 reduced ambient test conditions as shown in Table 14.2.

If the equipment cannot be unloaded to the desired reduced capacity (75%, 50%, and 25%) i.e. if the minimum unloading ratio of the chiller is greater than desired reduced capacity, then the model is run at the minimum unloading PLR of the equipment at the condenser entering conditions defined in Table 14.2 and the efficiency is adjusted for cyclic performance.

$$COP = \frac{1}{C_D \cdot EIRatMinPLR} \quad (14.253)$$

where:

$EIRatMinPLR$ is the EIR of chiller at minimum unloading ratio

C_D is the degradation coefficient to account for cycling of the compressor for capacity less than the minimum capacity.

The degradation coefficient C_D for the desired reduced load points (75%, 50%, or 25%) is determined using the following equation:

$$C_D = 1.13 - 0.13LF \quad (14.254)$$

The load factor (LF) for the desired reduced load points (75%, 50%, or 25%) calculated from the following equation:

$$LF = \frac{\left(\frac{\%Load}{100} \right) \cdot Full\ load\ unit\ capacity}{Part\ load\ unit\ capacity} \quad (14.255)$$

where:

$(\frac{\%Load}{100})$ is the standard rating part load ratio (*PLR*) points, 75%, 50%, 25%

Full load unit capacity is the full load heating capacity (W) of the air-source heat pump equipment determined from ANSI/AHRI Standard 550/590 and test conditions shown in Table 14.2 for 100% load

Part load unit capacity is the part load heating capacity (W) of the air-source heat pump units determined from ANSI/AHRI Standard 550/590 at the standard desired reduced ambient test conditions as shown in Table 14.2 and the minimum part load capacity of the unit.

$$Full\ load\ unit\ capacity = \dot{Q}_{total,Reference} (CapTempModFac_{Rated})$$

(14.256)

$$Part\ load\ unit\ capacity = MinPLR \cdot \dot{Q}_{total,Reference} (CapTempModFac_{ReducedTemp})$$

(14.257)

where:

$\dot{Q}_{total,Reference}$ is the reference capacity specified by the user (W)

$CapTempModFac_{Rated}$ is the user-specified bi-quadratic curve evaluated at full load (100%) test conditions shown in Table 14.2 (dimensionless)

$CapTempModFac_{ReducedTemp}$ is the part load capacity (W) of the chiller determined from ANSI/AHRI Standard 550/590 at the standard desired reduced ambient test conditions as shown in Table 14.2

$MinPLR$ = Minimum PLR up to which chiller can be unloaded.

Table 14.2: Standard Rating (Integrated Part Load Value)

IPLV			NPLV	
Evaporator (All types)

14.3.10 Electric Chiller Model Based on Condenser Leaving Temperature

14.3.10.1 Overview

This model (object name Chiller:Electric:ReformulatedEIR) simulates the thermal performance of an electric liquid chiller and the power consumption of its compressor(s). The model, developed by Hydeman et al. (2002) as part of the CoolTools™ project sponsored by Pacific Gas and Electric Company (PG&E), is an empirical model similar to EnergyPlus’ Chiller:Electric:EIR model. The model uses performance information at reference conditions along with three curve fits for cooling capacity and efficiency to determine chiller operation at off-reference conditions. The model has the same capabilities as the Chiller:Electric:EIR model, but can potentially provide significant accuracy improvement over the Chiller:Electric:EIR model for chillers with variable-speed compressor motor drives and/or variable condenser water flow applications.

Chiller performance curves can be generated by fitting manufacturer’s catalog data or measured data. Performance curves developed primarily from manufacturer’s performance data are provided in the EnergyPlus Reference DataSets (Chillers.idf and AllDataSets.idf). This chiller model can be used to predict the performance of various chiller types (e.g., reciprocating, screw, scroll, and centrifugal) with water-cooled condensers. The model does not simulate the thermal performance or the power consumption of associated pumps or cooling towers. This auxiliary equipment must be modeled using other EnergyPlus models (e.g. CoolingTower:SingleSpeed).

The main difference between this model and the Chiller:Electric:EIR model is the condenser fluid temperature used in the associated performance curves: the Chiller:Electric:ReformulatedEIR model uses the LEAVING condenser water temperature while the Chiller:Electric:EIR model uses the ENTERING condenser water temperature. In addition, the Energy Input to Cooling Output Function of Part Load Ratio curve for this reformulated EIR chiller model includes the condenser leaving water temperature as an independent variable in addition to part-load ratio. Since the leaving condenser water temperature is a function of load, chiller performance, and condenser entering water temperature, EnergyPlus must iterate to converge on a solution for each simulation

time step.

14.3.10.2 Model Description

The chiller model uses user-supplied performance information at reference conditions along with three performance curves (curve objects) for cooling capacity and efficiency to determine chiller operation at off-reference conditions. The three performance curves are:

- 1) Cooling Capacity Function of Temperature Curve
- 2) Energy Input to Cooling Output Ratio Function of Temperature Curve
- 3) Energy Input to Cooling Output Ratio Function of Part Load Ratio Curve

The cooling capacity function of temperature curve is a biquadratic performance curve with two independent variables: the leaving chilled water temperature and the leaving condenser water temperature. The output of this curve is multiplied by the reference capacity to give the full-load cooling capacity at specific temperature operating conditions (i.e., at temperatures different from the reference temperatures). The curve should have a value of 1.0 at the reference temperatures and flow rates specified in the input data file by the user. The biquadratic curve should be valid for the range of water temperatures anticipated for the simulation (otherwise the program issues warning messages).

$$ChillerCapFTemp = a + b(T_{cw,l}) + c(T_{cw,l})^2 + d(T_{cond,l}) + e(T_{cond,l})^2 + f(T_{cw,l})(T_{cond,l}) \quad (14.258)$$

where:

ChillerCapFTemp is the cooling capacity factor, equal to 1 at reference conditions

$T_{cw,l}$ is the leaving chilled water temperature (°C)

$T_{cond,l}$ is the leaving condenser water temperature (°C). This will be the water temperature entering the condenser loop (e.g., entering the cooling tower). If the chiller is a heat recovery chiller, then the condenser leaving temperature is adjusted to account for both fluid streams as described in the section above on heat recovery chillers.

The energy input to cooling output ratio function of temperature curve is a biquadratic performance curve that parameterizes the variation of the energy input to cooling output ratio (EIR) as a function of the leaving chilled water temperature and the leaving condenser water temperature. The EIR is the inverse of the COP. The output of this curve is multiplied by the reference EIR (inverse of the reference COP) to give the full-load EIR at specific temperature operating conditions (i.e., at temperatures different from the reference temperatures). The curve should have a value of 1.0 at the reference temperatures and flow rates specified in the input data file by the user. The biquadratic curve should be valid for the range of water temperatures anticipated for the simulation (otherwise the program issues warning messages).

$$ChillerEIRFTemp = a + b(T_{cw,l}) + c(T_{cw,l})^2 + d(T_{cond,l}) + e(T_{cond,l})^2 + f(T_{cw,l})(T_{cond,l}) \quad (14.259)$$

where:

ChillerEIRFTemp is the energy input to cooling output factor, equal to 1 at reference conditions

$T_{cw,l}$ is the leaving chilled water temperature (°C)

$T_{cond,l}$ is the leaving condenser water temperature (°C). This will be the water temperature entering the condenser loop (e.g., entering the cooling tower). If the chiller is a heat recovery

chiller, then the condenser leaving temperature is adjusted to account for both fluid streams as described in the section above on heat recovery chillers.

The energy input to cooling output ratio function of part-load ratio curve parameterizes the variation of the energy input ratio (EIR). The output of this curve is multiplied by the reference EIR (inverse of the reference COP) and the Energy Input to Cooling Output Ratio Function of Temperature Curve to give the EIR at the specific temperatures and part-load ratio at which the chiller is operating. This curve should have a value of 1.0 at the reference leaving condenser water temperature with part-load ratio equal to 1.0. It is recommended that this performance curve be developed using both full- and part-load performance data. The bicubic curve should be valid for the range of condenser water temperatures and part-load ratios anticipated for the simulation (otherwise the program issues warning messages). Either of the following two types of curves can be used.

The first type is a bicubic performance curve that parameterizes the variation of the chiller input power ratio as a function of the leaving condenser water temperature and the part-load ratio. The part-load ratio is the actual cooling load divided by the chiller's available cooling capacity.

$$ChillerEIRFPLR = a + b(T_{cond,l}) + c(T_{cond,l})^2 + d(PLR) + e(PLR)^2 + f(T_{cond,l})(PLR) + g(PLR)^3 \quad (14.260)$$

$$ChillerEIRFPLR = \frac{P_{chiller}}{P_{ref}} (ChillerCapFTemp) (ChillerEIRFTemp) \quad (14.261)$$

where:

$ChillerEIRFPLR$ is the energy input to cooling output factor, equal to 1 at the reference leaving condenser water temperature and $PLR = 1.0$

$T_{cond,l}$ is the leaving condenser water temperature ($^{\circ}\text{C}$). This will be the water temperature entering the condenser loop (e.g., entering the cooling tower). If the chiller is a heat recovery chiller, then the condenser leaving temperature is adjusted to account for both fluid streams as described in the section above on heat recovery chillers.

PLR is the part load ratio = (cooling load) / (chiller's available cooling capacity)

$P_{chiller}$ is the chiller power at specific PLR

$P_{ref} = \dot{Q}_{ref} / COP_{ref}$.

Note: Although a bicubic curve requires 10 coefficients (ref. Curve:Bicubic), coefficients 7, 9 and 10 are typically not used in the performance curve described here and should be entered as 0 unless sufficient performance data and regression accuracy exist to justify the use of these terms of the bicubic curve.

The second type is a Chiller Part Load Custom Curve that parameterizes the variation of EIR as a function of the normalized dT , normalized T_{dev} and the PLR .

$$ChillerEIRFPLR = a + b(dT^*) + c(dT^*)^2 + d \cdot PLR + e \cdot PLR^2 + f \cdot (dT^*) \cdot PLR + g \cdot (dT^*)^3 + h \cdot PLR^3 + i \cdot (dT^*)^2 \cdot PLR + j \cdot (dT^*) \cdot PLR^2 + k \cdot (dT^*)^2 \cdot PLR^2 + l \cdot (T_{dev}^*) \cdot PLR^3 \quad (14.262)$$

$$dT^* = dT / dT_{ref} \quad (14.263)$$

$$T_{dev}^* = T_{dev}/dT_{ref} \quad (14.264)$$

where:

dT is the delta of temperature across the leaving condenser water temperature and leaving evaporator water temperature of a chiller (lift)

dT^* is the normalized fractional lift

dT_{ref} is the lift under the reference condition

PLR is the part load ratio

T_{dev} is the deviation of leaving chilled water temperature from the reference condition

T_{dev}^* is the normalized Tdev term.

All of these performance curves are accessed through EnergyPlus' built-in performance curve equation manager (curve:biquadratic, curve:bicubic, and Curve:ChillerPartLoadWithLift). Note that the above three performance curves use the leaving condenser water temperature as an independent variable, instead of the entering condenser water temperature used in the performance curves for the Chiller:Electric:EIR model. Since the leaving condenser water temperature is calculated based on the condenser heat transfer rate, which is a function of the load to be met by the chiller, chiller compressor power, and the false loading (detailed calculations are given below), iterative calculations are required to determine the actual (converged) leaving condenser water temperature. The program uses the leaving condenser water temperature from the previous iteration to calculate values for each of the three performance curves described above. After obtaining the condenser heat transfer rate, the leaving condenser water temperature is recalculated. When the difference between the leaving condenser water temperature calculated on successive iterations is less than 0.0001°C, the solution is assumed to have converged. Warning messages are issued if the calculated solution for leaving condenser water temperature and/or part-load ratio falls outside the valid range specified for the chiller's performance curves. If these warnings are issued, the user may choose to extend the range for the performance curves (only if a small extension is required since model extrapolation may produce significant errors) or a different chiller and associated performance curves with extended performance range can be located and used for the simulation.

Note: Chiller:Electric:ReformulatedEIR objects and their associated performance curve objects are developed using performance information for a specific chiller and should almost always be used together for an EnergyPlus simulation. Changing the object input values, or swapping performance curves between chillers, should be done with extreme caution. For example, if the user wishes to model a chiller size that is different from the reference capacity, it is highly recommended that the reference flow rates be scaled proportionately to the change in reference capacity. Although this model can provide more accurate prediction than the Chiller:Electric:EIR model, it requires more performance data to develop the associated performance curves (at least 12 points from full-load performance and 7 points from part-load performance).

Although performance curve data sets for 160 chillers are provided in the EnergyPlus Reference DataSets (Chillers.idf and AllDataSets.idf), they may not meet the requirements for specific applications. One can develop performance curves from performance data using two available techniques (Hydeman and Gillespie 2002). The first technique is called the Least-squares Linear Regression method and is used when sufficient performance data exist to employ standard least-square linear regression techniques. The second technique is called Reference Curve Method and is used when insufficient performance data exist to apply linear regression techniques. A detailed description of both techniques can be found in the reference mentioned above.

For any simulation time step, the chiller’s available cooling capacity is calculated as follows:

$$\dot{Q}_{avail} = \dot{Q}_{ref} (ChillerCapFTemp) \quad (14.265)$$

where

\dot{Q}_{ref} is the chiller capacity at reference conditions (reference temperatures and flow rates defined by the user) (W)

\dot{Q}_{avail} is the available chiller capacity adjusted for current water temperatures (W).

The model then calculates the evaporator heat transfer rate required to bring the entering chilled water temperature down to the leaving chilled water setpoint temperature (established using a SetpointManager object and referenced in the PlantLoop object). If this calculated heat transfer rate is greater than the heat transfer rate being requested by the plant equipment operation scheme, then the evaporator heat transfer rate is reset to the requested cooling rate.

The evaporator heat transfer rate is then compared to the available capacity. If the available chiller capacity is sufficient to meet the evaporator heat transfer rate, the leaving chilled water temperature is set equal to the chilled water setpoint temperature. If the requested evaporator heat transfer rate is larger than the available capacity the chilled water leaving the evaporator is allowed to float upward. For this case, the exiting chilled water temperature is calculated based on the water temperature entering the evaporator, the available cooling capacity, and the evaporator mass flow rate as follows:

$$T_{cw,l} = T_{cw,e} - \frac{\dot{Q}_{avail}}{\dot{m}_{evap} C_{p,evap}} \quad (14.266)$$

where:

$T_{cw,l}$ is the water temperature leaving the evaporator (°C)

$T_{cw,e}$ is the water temperature entering the evaporator (°C)

\dot{m}_{evap} is the evaporator mass flow rate (kg/s)

$C_{p,evap}$ is the specific heat of water entering evaporator at $T_{cw,e}$ (J/kg-°C).

The part-load ratio is then calculated as the ratio of the evaporator heat transfer rate to the available chiller capacity. The part-load ratio is not allowed to be greater than the maximum part-load ratio specified by the user or less than zero as follows:

$$PLR = \max \left(0.0, \min \left(\frac{\dot{Q}_{evap}}{\dot{Q}_{avail}}, PLR_{max} \right) \right) \quad (14.267)$$

where:

PLR is the part-load ratio

\dot{Q}_{evap} is the load to be met by the chiller (W)

PLR_{max} is the maximum part-load ratio (specified by the user in the input data file).

Note that the maximum part-load ratio (PLR_{max} , specified in the Chiller:Electric:ReformulatedEIR object) used in the equation should be less than or equal to the maximum part-load ratio specified in the “Energy Input to Cooling Output Ratio Function of Part-Load Ratio” performance curve object.

The model assumes that the cooling load is met through chiller unloading down to the minimum unloading ratio. False loading (e.g. hot-gas bypass) is assumed to occur between the minimum unloading ratio and the minimum part-load ratio yielding constant electrical power consumption under these conditions. Below the minimum part-load ratio, the chiller cycles on/off to meet

very small loads and the power consumption during the on cycle is the same as when the chiller is operating at the minimum part load ratio. When the chiller part-load ratio is less than the minimum part-load ratio, the on-off cycling ratio of the chiller is calculated as follows and is available as an output variable.

$$ChillerCyclingRatio = \min \left(\frac{PLR}{PLR_{min}}, 1.0 \right) \quad (14.268)$$

To properly account for chiller electric power consumption when PLR is less than the minimum unloading ratio, the PLR is reset to the greater of the PLR calculated above and the PLR at the minimum unloading ratio. The result is available as the output variable Chiller Part Load Ratio.

$$PLR = MAX(PLR, PLR_{MinUnloadRatio}) \quad (14.269)$$

This revised PLR accounts for the “false loading” (e.g., hot-gas bypass) that is assumed to occur whenever the PLR (based on cooling load divided by available capacity) is less than the minimum unloading ratio specified. The amount of false loading on the chiller is calculated using this revised PLR and is reported as an output variable as follows:

$$\dot{Q}_{falseloading} = \left(\dot{Q}_{avail} \right) (PLR) (ChillerCyclingRatio) - \dot{Q}_{evap} \quad (14.270)$$

The electrical power consumption for the chiller compressor(s) for any simulation time step is then calculated using the following equation:

$$P_{chiller} = \left(\dot{Q}_{avail} \right) \left(\frac{1}{COP_{ref}} \right) (ChillerEIRFTemp) (ChillerEIRFPLR) (ChillerCyclingRatio) \quad (14.271)$$

where:

$P_{chiller}$ is the chiller compressor power (W)

COP_{ref} is the reference coefficient of performance (W/W).

Heat rejected by the chiller condenser includes the heat transferred in the evaporator plus a portion or all of the compressor electrical energy consumption. For electric chillers with hermetic compressors, all compressor energy consumption is rejected by the condenser (compressor motor efficiency = $eff_{motor} = 1.0$). For chillers with semi-hermetic or open compressors, only a portion of the compressor energy use is rejected by the condenser. The heat transfer rate for the chiller condenser is calculated as follows:

$$\dot{Q}_{cond} = (P_{chiller} * eff_{motor}) + \dot{Q}_{evap} + \dot{Q}_{falseloading} \quad (14.272)$$

where:

\dot{Q}_{cond} is the condenser heat transfer rate (W)

eff_{motor} is the compressor motor efficiency = fraction of compressor electrical energy consumption rejected as condenser heat.

The above curve values are calculated based on the leaving condenser water temperature found through iteration. After obtaining the condenser heat transfer rate, the final leaving condenser water temperature is then calculated as:

$$T_{cond,l} = T_{cond,e} + \frac{\dot{Q}_{cond}}{\dot{m}_{cond}C_{p,cond}} \quad (14.273)$$

where:

$T_{cond,l}$ is the water temperature leaving the condenser (°C)

$T_{cond,e}$ is the water temperature entering the condenser (°C)

\dot{m}_{cond} is the mass flow rate through the condenser (kg/s)

$C_{p,cond}$ is the specific heat of water entering the condenser at $T_{cond,e}$ (J/kg·°C)

The final calculations determine the total heat transfer energy for the condenser and evaporator, as well as the total electric energy consumed by the chiller compressor motor(s) and condenser fan(s). The results are available as output variables.

$$Q_{cond} = \dot{Q}_{cond} * TimeStepSys * 3600 \quad (14.274)$$

$$Q_{evap} = \dot{Q}_{evap} * TimeStepSys * 3600 \quad (14.275)$$

$$E_{chiller} = P_{chiller} * TimeStepSys * 3600 \quad (14.276)$$

$$E_{cond} = P_{cond} * TimeStepSys * 3600 \quad (14.277)$$

where

Q_{cond} is the chiller condenser heat transfer energy (J)

Q_{evap} is the chiller evaporator cooling energy (J)

$E_{chiller}$ is the chiller (compressor) electric energy (J)

E_{cond} is the chiller condenser fan electric energy (J)

$TimeStepSys$ is the HVAC system simulation time step (hr)

3600 is a conversion factor (sec/hr).

14.3.10.3 Electric Reformulated EIR Chiller with Heat Recovery Option

Heat from the electric reformulated EIR chiller condenser may be recovered. The heat recovery water flow rate is specified by the user along with the input and output nodes connected to the heat recovery loop. The algorithms are identical to those used for Chiller:Electric and Chiller:Electric:EIR. Refer to the section entitled Chillers with Plant Heat Recovery for details.

14.3.10.4 Standard Rating (Integrated Part Load Value)

Integrated Part Load Value (IPLV) calculations for Reformulated EIR chiller are similar to what are described above for EIR chillers. The only difference with Reformulated EIR chiller is that it calls an iterative subroutine (SolveRegulaFalsi) to obtain a condenser water outlet temperature which corresponds to condenser inlet temperature at reduced capacity conditions as outlined in Table 14.2 above. SolveRegulaFalsi is a general utility routine for finding the zero of a function. In this case it finds the condenser inlet temperature that will zero the residual function – the difference between calculated condenser inlet temperature and desired condenser inlet temperature per ANSI/AHRI 550/590, 2011 (Table 14.2 above) divided by desired condenser inlet temperature.

Hydeman, M., K. Gillespie, and R. Kammerud. 1997. PG&E's CoolTools project: A toolkit to improve evaluation and operation of chilled water plants. Presented at the CoolSense National Forum on Integrated Chilled Water Retrofits, Sep. 1997. Berkeley California: Lawrence Berkeley National Laboratory.

14.3.11 Engine Driven Chiller

The engine driven chiller (Object name: Chiller:EngineDriven) is the empirical model from the Building Loads and System Thermodynamics (BLAST) program. Fitting catalog data to a third order polynomial equations generates the chiller performance curves. Three sets of coefficients are required to model the open centrifugal chiller as discussed in the section, titled, 'Electric Chiller Based on Fluid Temperature Differences'. Additional curve fits are required to model the engine. Because the model inherently involves the lower heating value of the fuel, a reference temperature is also involved in the calculations, which manufacturers present at 25°C.

The engine model was also developed for the BLAST program. It was adapted for use in EnergyPlus. This model is used for both the engine driven generator and the engine driven chiller. It uses the following set of equations all of which are quadratic fits to the PLR (Part Load Ratio) of the generator. The coefficients must be derived from manufacturers data.

$$\frac{\text{chiller cooling load}}{\text{fuel energy input}} = \frac{\text{chiller cooling load}}{(\dot{m}_{\text{fuel}} \{ \text{kg/s} \} \cdot \text{LHV} \{ \text{J/kg} \})} = a_1 + a_2 \text{PLR} + a_3 \text{PLR}^2 \quad (14.278)$$

The exhaust gas temp and flow rate are used if a stack heat exchanger is used to recover waste heat from the exhaust. This temperature is the inlet temperature to the heat exchanger which is modeled in a UA-effectiveness form:

$$\frac{\text{Total Exhaust heat}}{\text{fuel energy input}} = \frac{\text{Total Exhaust heat}}{(\dot{m}_{\text{fuel}} \{ \text{kg/s} \} \cdot \text{LHV} \{ \text{J/kg} \})} = d_1 + d_2 \text{PLR} + d_3 \text{PLR}^2 \quad (14.279)$$

$$\frac{\text{Exhaust Gas Temp} \{ \text{K} \}}{\text{fuel energy input}} = \frac{\text{Exhaust Gas Temp} \{ \text{K} \}}{(\dot{m}_{\text{fuel}} \{ \text{kg/s} \} \cdot \text{LHV} \{ \text{J/kg} \})} = e_1 + e_2 \text{PLR} + e_3 \text{PLR}^2 \quad (14.280)$$

The exhaust flow rate is then calculated as:

$$\dot{m}_{\text{exhaust}} = \frac{\text{Total Exhaust heat}}{Cp_{\text{exhaust}} \cdot (T_{\text{exhaust}} - T_{\text{reference}})} \quad (14.281)$$

where $T_{\text{reference}}$ is the reference temperature for the fuel lower heating value, and is given as 25°C in manufacturer's data, and

$$T_{stack} = T_{DesignMinExhaust} + \frac{(T_{exhaust} - T_{DesignMinExhaust})^2}{\exp\left(\frac{UA}{\dot{m}_{exhaust} C_{p_{exhaust}}}\right)} \quad (14.282)$$

Finally, heat recovered from the lube oil and the water jacket are accounted for as follows:

$$\frac{\text{Recoverable jacket heat}}{\text{fuel energy input}} = \frac{\text{Recoverable jacket heat}}{(\dot{m}_{fuel} \{kg/s\} \cdot LHV \{J/kg\})} = b_1 + b_2 PLR + b_3 PLR^2 \quad (14.283)$$

$$\frac{\text{Recoverable lube oil heat}}{\text{fuel energy input}} = \frac{\text{Recoverable lube oil heat}}{(\dot{m}_{fuel} \{kg/s\} \cdot LHV \{J/kg\})} = c_1 + c_2 PLR + c_3 PLR^2 \quad (14.284)$$

14.3.11.1 Chiller Basin Heater

Calculations are also made to estimate the electric power input to the basin heater for chillers with evaporatively-cooled condensers. The chillers which calculate basin heater power are Chiller:Electric:EIR, Chiller:Electric, Chiller:ConstantCOP, Chiller:EngineDriven and Chiller:CombustionTurbine. A schedule may be used to disable the basin heater during regular maintenance periods or other time periods (e.g., during summer). If a schedule is not provided, the basin heater is assumed to be available the entire simulation time period. The basin heater operates when it is scheduled on, the outdoor air dry-bulb temperature is below the basin heater setpoint temperature, and the chiller is not active (i.e., chiller is not operating for the simulation time step — for example, when there is no cooling load to be met by the chiller, *or if there is no water flow through the chiller due to a chiller or pump availability schedule, etc.*). The user is required to enter a basin heater capacity (watts per degree Kelvin) and a heater setpoint temperature (°C) if they want to model basin heater electric power.

Here is sample of pseudo-code for the chiller basin heater model:

```

Pheater,basin = 0.0
IF (ChillerIsOFF) THEN
  IF (Scheduleheater,basin is Defined) THEN
    IF (CAPheater,basin > 0 AND Scheduleheater,basin = ON) THEN
      Pheater,basin = MAX(0.0, CAPheater,basin * (Tsetpoint,basin - Tdb,outdoor))
    ENDIF
  ELSE
    IF (CAPheater,basin > 0) THEN
      Pheater,basin = MAX(0.0, CAPheater,basin * (Tsetpoint,basin - Tdb,outdoor))
    ENDIF
  ENDIF
ENDIF

```

$$E_{heater,basin} = (P_{heater,basin}) (TimeStepSys) 3600 \quad (14.285)$$

where:

$P_{heater,basin}$ is the chiller basin heater electric power (W)

$E_{heater,basin}$ is the chiller basin heater electric consumption (J)

$T_{setpoint,basin}$ is the basin heater setpoint temperature, user input (°C)

$T_{db,outdoor}$ is the outdoor air dry-bulb temperature ($^{\circ}\text{C}$)

$CAP_{heater,basin}$ is the basin heater capacity, user input (W/K)

$Schedule_{heater,basin}$ is the basin heater schedule, user input (schedule value > 0 means ON)

$ChillerIsOFF$ is the logical variable denoting that the chiller is not operating for the current simulation time step (e.g., there is no cooling load to be met by the chiller, or if there is no water flow through the chiller due to a chiller or pump availability schedule, etc.).

Chapter 15

Simulation Models - Encyclopedic Reference

The following descriptions are grouped alphabetically (as much as possible) with some also having additional tags of “Heat Balance”, “HVAC”, and “Plant”. With the integrated solution, these designations signify where the effects of these models have their first impacts.

Main Sections:

- Ice Thermal Storage
- Coils
- HVAC Controllers
- Baseboard Heaters

15.1 Ice Thermal Storage

15.1.1 Simple Ice Storage Model

15.1.1.1 Overview

This model (object name `ThermalStorage:Ice:Simple`) simulates the performance of an ice storage tank. The model is based on an integrated chiller and storage tank model developed for a special optimization project (Henze and Krarti 2002). This implementation removed the integrated chiller and allows the tank to be charged by any chiller configuration in an EnergyPlus plant loop..

This thermal storage model is based on a simple simulation of an ice storage tank with a fixed capacity. The tank is charged, or frozen, in an ice-on-coil configuration where ice builds up on the outside of the tubes carrying the brine or glycol solution from the chiller. There are two discharge (melt) options, internal or external. Internal melt uses the same fluid tubes for charging and discharging. External melt uses a separate fluid path for discharge such that the outer layers of ice melt first. The ice storage model includes an implied 3-way valve to control the amount if charge/discharge based on the incoming water temperature and the outlet node setpoint temperature. The tank is controlled using the `PlantEquipmentOperation:ComponentSetpoint` plant operation scheme, and requires that a setpoint be placed by a setpoint manager on the ice storage Plant Outlet Node. The model currently does not calculate any tank losses.

15.1.1.2 Model Description

15.1.1.2.1 Initialization

The storage tank is assumed to be fully charged (full of ice) at the beginning of each environment. The tank is then allowed to charge and discharge during the warmup days of the environment.

15.1.1.2.2 Control

The ice storage module is a passive component and will accept any flow rate placed on the inlet node. The load on the ice storage tank is determined by the inlet node flow rate, the inlet node temperature, and the outlet node setpoint temperature. A positive load indicates a request for cooling and the tank discharges if possible. A negative load indicates a request for charging the tank if possible. A zero load indicates the tank is dormant in which case all flow bypasses the tank and the outlet node temperature is set to the inlet node temperature. The model includes an implied 3-way valve which controls the leaving water temperature to the outlet node setpoint temperature if possible.

15.1.1.2.3 Charging

When charging is requested, the following limits are calculated to determine the actual charging rate:

1. If the entering water temperature is greater than -1°C , the charging rate is zero.
2. If the entering water temperature is greater than or equal to the outlet setpoint temperature, the charging rate is zero.
3. If the current fraction of ice stored is 1.0, the tank is fully charge, and the charging rate is zero.
4. If the requested charging rate times the current system timestep is more than the remaining uncharged storage capacity, the charging rate is limited to that required to completely fill the tank.
5. The maximum charging rate which the chilled water flow can provide is determined by the entering water temperature and flow rate and an outlet temperature which is the minimum of -1°C or the outlet setpoint temperature.
6. The maximum charging rate which the tank can accept is calculated by the following equations developed in the prior work (Henze and Krarti 2002):

$$UA_{IceCh} = (1.3879 - 7.6333 * y + 26.3423 * y^2 - 47.6084 * y^3 + 41.8498 * y^4 - 14.2948 * y^5) * ITS_{NomCap} / TimeInterval / 10.0 \quad (15.1)$$

where:

UA_{IceCh} is the UA value for charging

y is the current ice fraction stored

ITS_{NomCap} is the nominal storage capacity (GJ)

TimeInterval is 3600 (s).

The smallest charging rate determined by the above rules is selected and the corresponding leaving water temperature is calculated.

15.1.1.2.4 Discharging

When discharging is requested, the following limits are calculated to determine the actual charging rate:

1. If the entering water temperature is less than 1°C, the discharge rate is zero.
2. If the entering water temperature is less than or equal to the outlet setpoint temperature, the discharge rate is zero.
3. If the current fraction of ice stored is 0.0, the tank is fully discharged, and the discharge rate is zero.
4. If the requested discharge rate times the current system timestep is more than the remaining charged storage capacity, the discharge rate is limited to that required to completely deplete the ice in the tank.
5. The maximum discharge rate which the chilled water flow can accept is determined by the entering water temperature and flow rate and an outlet temperature which is the maximum of 1°C or the outlet setpoint temperature.
6. The maximum discharge rate which the tank can deliver is calculated by the following equations developed in the prior work (Henze and Krarti 2002):

For ice-on-coil internal melt:

$$UA_{IceDisCh} = (1.3879 - 7.6333 * y + 26.3423 * y^2 - 47.6084 * y^3 + 41.8498 * y^4 - 14.2948 * y^5) * ITS_{NomCap} / TimeInterval / 10.0 \quad (15.2)$$

For ice-on-coil external melt:

$$UA_{IceDisCh} = (1.1756 - 5.3689 * y + 17.3602 * y^2 - 30.1077 * y^3 + 25.6387 * y^4 - 8.5102 * y^5) * ITS_{NomCap} / TimeInterval / 10.0 \quad (15.3)$$

where:

$UA_{IceDisCh}$ is the UA value for discharging

$y = 1$ - current ice fraction stored

ITS_{NomCap} is the nominal storage capacity (GJ)

TimeInterval is 3600 (s).

The smallest discharge rate determined by the above rules is selected and the corresponding leaving water temperature is calculated.

15.1.2 Detailed Ice Storage Model

The following section describes how the detailed ice storage model works in EnergyPlus (object name ThermalStorage:Ice:Detailed).

15.1.2.1 Charging and Discharging Equation

The actual performance of the ice storage unit depends on the physical geometry, materials, and characteristics of the ice storage unit. Modeling both the charging and discharging performance of a particular ice storage unit is accomplished in EnergyPlus using Curve objects that establish the relationships between various parameters of the unit and the output of the unit itself. The input that controls what curve objects are used and what parameters are the independent variables in those curves are: Discharging Curve Variable Specifications, Discharging Curve Name, Charging Curve Variable Specifications, and Charging Curve Name.

The Variable Specifications input fields determine which parameters are used as the independent variables in the curves referenced by the Curve Name inputs. There are four options for the Variable Specifications fields: FractionChargedLMTD, FractionDischargedLMTD, LMTDMassFlow, and LMTDFractionCharged. Each option defines which two variables are the independent variables in the curve equation as well as the order. For example, FractionChargedLMTD uses the fraction of full charge of the storage component as the first variable and the normalized LMTD (or LMTD*) as the second variable. Note that using options that use either LMTD or MassFlow actually use normalized values LMTD* and MassFlow*. LMTD is normalized by dividing the actual value by 10°C while MassFlow is normalized by dividing the actual mass flow rate by the equivalent of 100 gallons per minute.

One equation that might be used to characterize the discharging performance of an ice storage component is a QuadraticLinear Curve. If the discharging equation referenced in the detailed ice storage unit is a QuadraticLinear equation that uses FractionDischargedLMTD for the variable specification, then this would result in the following equation for characterizing the ice storage component's discharging process:

$$q^* = [C1 + C2(1 - P_c) + C3(1 - P_c)^2] + [C4 + C5(1 - P_c) + C6(1 - P_c)^2] \Delta T_{lm}^* \quad (15.4)$$

or

$$q^* = [C1 + C2(P_d) + C3(P_d)^2] + [C4 + C5(P_d) + C6(P_d)^2] \Delta T_{lm}^* \quad (15.5)$$

where:

$$q^* \equiv \frac{q \Delta t}{Q_{stor}} \quad (15.6)$$

$$\Delta T_{lm}^* \equiv \frac{\Delta T_{lm}}{\Delta T_{nominal}} \quad (15.7)$$

$$\Delta T_{lm} \equiv \frac{T_{brine,in} - T_{brine,out}}{\ln \left(\frac{T_{brine,in} - T_{brine,freeze}}{T_{brine,out} - T_{brine,freeze}} \right)} \quad (15.8)$$

q is the instantaneous heat transfer rate

Q_{stor} is the total latent storage capacity

Δt is a time step used in the curve fit (usually one hour)

$\Delta T_{nominal}$ is a nominal temperature difference ($18^\circ\text{F} = 10^\circ\text{C}$)

$T_{brine,in}$ is the tank brine inlet temperature

$T_{brine,out}$ is the tank brine outlet temperature

T_{freeze} is the freezing temperature of water or the latent energy storage material

P_c is the fraction charged

P_d is the fraction discharged.

Likewise, if the charging equation referenced in the detailed ice storage unit is a QuadraticLinear equation that uses FractionChargedLMTD for the variable specification, then this would result in the following equation for characterizing the ice storage component's charging process:

$$q^* = [C1 + C2(P_c) + C3(P_c)^2] + [C4 + C5(P_c) + C6(P_c)^2] \Delta T_{lm}^* \quad (15.9)$$

Note that the time step used for the curve fit of performance data might differ from the time step used within the EnergyPlus simulation. These are actually two separate time steps and are kept separate.

15.1.2.2 Charging Algorithm

During charging, manufacturers have stated that they attempt to charge the unit at the maximum rate until the unit is completely charged. This, of course, occurs during off-peak electric hours. Thus, once the setpoint has been scheduled for charging, the unit will charge at the maximum possible rate. This means that the flow rate through the ice storage device equals the flow to the component (or no bypass). The only time flow to the ice storage unit would be reduced is at the end of the charge cycle when more ice making capacity is available in a particular time step than is needed to fully charge the tank. In this case, the flow to the tank would be reduced appropriately to top off the tank storage capacity. We also have a setpoint goal for the outlet temperature of the ice storage device as defined by the setpoint schedule.

In solving the performance of the ice storage unit, we have effectively two equations. One of these equations is determined by the user input and characterizes the output of the unit (q^*) as a function of LMTD* and fraction charged/discharged or normalized mass flow rate. The other equation is:

$$q = \dot{m} C_p (T_i - T_o) \quad (15.10)$$

Both of these equations have q and T_o as unknowns. However, since the setpoint temperature is the goal for T_o , we can use this as an initial guess for T_o . Below is an outline of the algorithm:

- Initialize $T_o = T_{set}$

- Calculate LMTD*
- Calculate q^* from charging equation for the current percent charged (We will assume that the EnergyPlus time step is sufficiently small so that we do not need to find the average percent charged for the time step. This was necessary when one hour time steps were used as in BLAST, but EnergyPlus generally uses relatively short time steps. Since there is already some iteration involved in the solution, we would like to avoid another layer of iteration if at all possible. One alternative that could be implemented would be to make a second pass with a closer average value based on what happens during the time step. This would effectively double the execution time for the model and would need to be justified before implementation.)
- Calculate $T_{o,new}$ and compare it to T_o
- Use $T_{o,new}$ to calculate a new LMTD* and iterate until T_o converges to some acceptable level

Charging would continue in subsequent time steps until the final state of the ice storage unit at the end of a particular time step is fully charged. If running a chiller would “overcharge” the tank, then the flow to the tank would be reduced (greater than zero bypass flow) while maintaining the same setpoint temperature coming out of the tank (though not necessarily out of the component).

15.1.2.3 Discharging Algorithm

During discharging, we cannot assume that all of the flow is sent through the ice storage unit and thus some of it may be bypassed around it locally. This ice storage model includes a built-in bypass leg to accommodate this without requiring the user to enter this additional information. This also allows the bypass leg/valve to be controlled by the ice storage unit.

While we cannot assume that all of the flow is sent through the ice storage unit, we can use that as an initial guess in order to determine the current performance of the ice storage system. Most of the discharging algorithm then becomes very similar to the charging process.

In solving the performance of the ice storage unit, we have effectively two equations. One of these equations is determined by the user input and characterizes the output of the unit (q^*) as a function of LMTD* and fraction charged/discharged or normalized mass flow rate. The other equation is:

$$q = \dot{m}C_p (T_i - T_o) \quad (15.11)$$

Both of these equations have q and T_o as unknowns. However, since the setpoint temperature is the goal for T_o , we can use this as an initial guess for T_o . Below is an outline of the algorithm:

- Initialize $T_o = T_{set}$
- Calculate LMTD*
- Calculate q^* from charging equation for the current percent charged (we will assume that the EnergyPlus time step is sufficiently small so that we do not need to find the average percent charged for the time step; this was necessary when one hour time steps were used as in BLAST, but EnergyPlus generally uses relatively short time steps)

- Calculate $T_{o,new}$ and compare it to T_o
- Use $T_{o,new}$ to calculate a new LMTD* and iterate until T_o converges to some acceptable level
- Once T_o has converged, we need to compare this value again to T_{set} . If T_o is greater than or equal to T_{set} , then we either just met the load (equal) or can't quite meet it (greater than). In this case, we simply leave T_o as is because we cannot meet the setpoint temperature.
- If T_o is less than T_{set} , then we have more capacity available than we need. In this case, we need to bypass some of the flow. Since the load on the ice storage device and the outlet temperature are not changing (we are just reducing the flow), we only need to split the flow and do not need to recalculate the action of the ice storage device. Some systems may be slightly dependent on the actual flow through the device itself. However, in an actual application, this only means that a slightly different amount will bypass the device. The overall energy impact will be the same and thus it is not necessary to be concerned about flow rate dependence.

Discharging would continue in subsequent time steps until the final state of the ice storage unit at the end of a particular time step is fully discharged.

15.1.3 Other Ice Thermal Storage Options

Thermal storage can also be modeled as integrated with a packaged air-conditioning unit. For this option, see Section 15.2.27.

15.2 Coils

15.2.1 Chilled-Water-Based Air Cooling Coil

The input object Coil:Cooling:Water is simpler than the detailed geometry model. The simple model provides a good prediction of the air and water outlet conditions without requiring the detailed geometric input required for the detailed model. A greatly simplified schematic of enthalpy and temperature conditions in a counter flow cooling/dehumidifying coil is shown in the schematic Figure 15.1. The input required to model the coil includes only a set of thermodynamic design inputs, which require no specific manufacturer's data. The coil simulation model is essentially a modification of one presented by Elmahdy and Mitalas (1977), TRNSYS, 1990 and Threlkeld, J.L. 1970. The model calculates the UA values required for a Dry, Wet and Part Wet & Part Dry Coil and iterates between the Dry and Wet Coil to output the fraction wet. There are two modes of flow operation for this model: CrossFlow or CounterFlow. The default mode is CounterFlow. In addition the coil has two modes of analysis: Simple Analysis and Detailed Analysis. The Simple analysis mode operates the coil as either wet or dry while the detailed mode simulates the coil as part wet part-dry. While the detailed mode provides more accurate results, it is significantly slower

than the simple model. The simple mode gives good results for an annual simulation but will not be adequate for a time step performance analysis.

Figure 15.1: Simplified Schematic of Cooling/Dehumidifying Coil

15.2.1.1 Heat Transfer and Energy Balance

The cooling coil may be completely dry, completely wet with condensation, or it may have wet and dry sections. The actual condition of the coil surface depends on the humidity and temperature of the air passing over the coil and the coil surface temperature. The part-dry part-wet case represents the most general scenario for the coil surface conditions. There are subroutines present in the model for both the dry and wet regions of the coil, and a subroutine that iterates between the dry and wet subroutines to calculate the fraction of the coil surface that is wet. For each region the heat transfer rate from air to water may be defined by the rate of enthalpy change in the air and in the water. The rates must balance between each medium for energy to be conserved.

15.2.1.2 Model Description

The Model has two blocks: 1st = Design Block with the Design Inputs. This block calculates the Design U-Factor Times Area Value (UA) values required by the model. Using these UA values the model simulates the operating conditions. The operating block is the one containing the operating conditions, the conditions at which the coil operates. Following is the list of Design and Operating inputs and subsequently the Design and Operating variables used in the model.

Table 15.1: Design Inputs (User Inputs)

Input Field	Description
DesWaterVolFlowRate	Maximum Water Volume Flow Rate
DesAirVolFlowRate	Maximum Air Volume Flow Rate
DesInletWaterTemp	Inlet Water Temperature at Design Condition
DesInletAirTemp	Inlet Air Temperature at Design Condition
DesOutletAirTemp	Outlet Air Temperature at Design Condition

Table 15.1: Design Inputs (User Inputs)

Input Field	Description
DesInletAirHumRat	Inlet Air Humidity Ratio at Design Conditions
DesOutletAirHumRat	Outlet Air Humidity Ratio at Design Conditions

Table 15.2: Operating Conditions (From Nodes – not user inputs)

Condition Variable	Description
InletWaterMassFlowRate	Entering Water Mass Flow Rate at operating condition
InletWaterTemp	Inlet Water Temperature at operating condition
InletAirMassFlowRate	Entering Air Mass Flow Rate at operating condition
InletAirTemp	Inlet Air Temperature at operating condition
InletAirHumRat	Entering air humidity ratio at operating conditions

15.2.1.3 Intermediate calculated U-Factor Times Area Values: The Crux of the Model

The various U-Factor Times Area values (UA) required by this model are calculated from the above inputs, which are explained later in the document. The various UA are:

Table 15.3: UA Descriptions of Model

UA Variable Name	Description
CoilUATotal	Overall heat transfer coefficient (W/°C)
CoilUAInternal	Overall internal UA (W/°C)
CoilUAExternal	Overall external UA (W/°C)
CoilUInternal	Internal overall heat transfer coefficient (W/m-°C)
CoilUWetExternal	Wet part external overall heat transfer coefficient (W/m-°C)
CoilUDryExternal	Dry part external overall heat transfer coefficient (W/m-°C)

The UA values are calculated assuming a wet coil at the design conditions. Following are a few important calculations to understand the working of the model. The model is basically divided into two blocks: the Design Block and the Operating Block.

The Design Block is a one time calculation. The aim of the Design Block is to calculate the Coil UA for use in the operating Block.

15.2.1.4 Design Block Calculations

The design block has the code for calculating the six Coil UA values required by the operating block. Reasonable assumptions have been made in the calculations to maintain the simplicity of the model.

Heat transfer in a wet coil model is based on enthalpy rather than temperature to take into account latent effects. While heat transfer rates are commonly expressed as the product of an overall heat transfer coefficient, UA, and a temperature difference, the use of enthalpy-based heat transfer calculations requires an enthalpy-based heat transfer coefficient which we denote as DesUACoilTotalEnth and hence the equation.

$$Q = DesUACoilTotalEnth * (H_{air,mean} - H_{water,mean}) \quad (15.12)$$

The value of Q is calculated using product of air mass flow rate and difference in inlet and outlet air enthalpies at design conditions.

The relation between the enthalpy-based UA and the temperature-based UA is:

$$DesUACoilTotalEnth = CoilUA/C_p \quad (15.13)$$

where CoilUA is the conventional heat transfer coefficient and C_p is the specific heat of the air.

We need the following quantities for our design calculations. The *Psy* functions are the EnergyPlus built-in psychrometric functions.

$$\dot{m}_{air} = \rho_{air} \dot{V}_{air} \quad (15.14)$$

$$h_{air,in} = PsyHFnTdbW(T_{air,in}, w_{air,in}) \quad (15.15)$$

$$h_{air,out} = PsyHFnTdbW(T_{air,out}, w_{air,out}) \quad (15.16)$$

$$h_{w,sat,in} = PsyHFnTdbW(T_{w,in}, PsyWFnTdpPb(T_{w,in}, P_{atm})) \quad (15.17)$$

$$\dot{Q}_{coil} = \dot{m}_{air}(h_{air,in} - h_{air,out}) \quad (15.18)$$

$$T_{w,out} = T_{w,in} + \dot{Q}_{coil}/(\dot{m}_{w,max}C_{p,w}) \quad (15.19)$$

$$h_{w,sat,out} = PsyHFnTdbW(T_{w,out}, PsyWFnTdpPb(T_{w,out}, P_{atm})) \quad (15.20)$$

We now calculate the design coil bypass factor. The bypass factor is not used in subsequent calculations. It is calculated solely to use as check on the reasonableness of the user-input design inlet and outlet conditions. First we make an initial estimate of the apparatus dew point temperature:

$$T_{air,dp,app} = PsyTdpFnWPb(w_{air,out}, P_{atm}) \quad (15.21)$$

We also need the “slope” of temperature versus humidity ratio on the psych chart between the inlet and outlet air conditions:

$$S_{T,w} = (T_{air,in} - T_{air,out}) / (w_{air,in} - w_{air,out}) \quad (15.22)$$

We now obtain the actual design apparatus dewpoint temperature by iterating over the following two equations:

$$w_{air,dp,app} = \text{PsyWFnTdpPb}(T_{air,dp,app}, P_{atm}) \quad (15.23)$$

$$T_{air,dp,app} = T_{air,in} - S_{T,w}(w_{air,in} - w_{air,dp,app}) \quad (15.24)$$

The apparatus dewpoint enthalpy is then:

$$h_{air,dp,app} = \text{PsyHFnTdbW}(T_{air,dp,app}, w_{air,dp,app}) \quad (15.25)$$

and the coil bypass factor is:

$$F_{coilbypass} = (h_{air,out} - h_{air,dp,app}) / (h_{air,in} - h_{air,dp,app}) \quad (15.26)$$

If the iterative procedure doesn't converge, or the coil bypass factor is too large (greater than 0.5), or the apparatus dewpoint enthalpy is less than the saturated air enthalpy at the water inlet temperature, the design outlet air conditions are reset to 90% relative humidity at the same outlet enthalpy. The above design calculations are then repeated.

We are now ready to calculate the design coil UA. This will be accomplished by inverting the simple coil calculation routine *CoolingCoil* using the root solver method. First we make an initial estimate of the coil UA.

$$\Delta h_{lmd} = \frac{(h_{air,in} - h_{w,sat,out}) - (h_{air,out} - h_{w,sat,in})}{\log\left(\frac{h_{air,in} - h_{w,sat,out}}{h_{air,out} - h_{w,sat,in}}\right)} \quad (15.27)$$

$$UA_{coil,enthalpy-based} = \dot{Q}_{coil} / \Delta h_{lmd} \quad (15.28)$$

$$UA_{coil,ext} = C_{p,air} UA_{coil,enthalpy-based} \quad (15.29)$$

We set the internal UA to 3.3 times the external UA (as a typical value for a coil). Then the total UA is:

$$UA_{coil,tot} = \frac{1}{(1/UA_{coil,int} + 1/UA_{coil,ext})} \quad (15.30)$$

The next step is to estimate the coil external heat transfer surface area. This is done in the function *EstimateHEXSurfaceArea*:

$$Area_{coil,ext} = \text{EstimateHEXSurfaceArea} \quad (15.31)$$

using the following assumptions:

- Tube inside diameter = 0.0122 (m)
- Tube side water velocity = 2.0 (m/s)

- Inside to outside coil surface area ratio (A_i/A_o) = 0.07 (-)
- Fins overall efficiency = 0.92 (-)
- Aluminum fins, 12 fins per inch with fins to total outside surface area ratio of 90%.
- Airside combined heat and mass transfer coefficient = 140 ($\text{W}/\text{m}^2\text{-}^\circ\text{C}$)

Interior and exterior U values (really UA's per unit exterior surface area) are calculated by dividing the above UA's by the area. The resulting $U_{coil,ext}$ is assumed to be $U_{coil,ext,wet}$; $U_{coil,ext,dry}$ is set equal to $U_{coil,ext,wet}$. We now have all the starting values needed for inverting the simple coil model using the chosen root solver iterative method. Once the iteration is completed, we have coil UA's and U's that yield the design outlet air and water enthalpies given the inlet design conditions and flow rates. Note that the simple coil model can not exactly match the specified design outlet air temperature and humidity ratio. It can only match the design air outlet enthalpy. Generally the simple coil model will yield outlet conditions near the saturation curve if any dehumidification is occurring. Typical outlet relative humidities are around 95%.

15.2.1.5 Variable UA

The above calculations yield coil UA's for the design inlet conditions and air and water flow rates. As the flow rates vary during the time step calculations, the UA's need to be adjusted, since coil UA's are a rather strong function of air and water side flow rates. Each time step the coil UA's are modified using the same formulas as are used in the hot water coil model. Refer to that model for the flow dependences.

15.2.1.6 Operating Block Calculations:

There are two modes of coil analysis in the operating block. They are the Simple analysis mode and the detailed analysis mode. The simple analysis mode assumes the coil to be either all wet or either all dry and execute the model, on the other hand the detailed mode checks for part wet part dry mode of operation and reports surface area wet fraction of coil, however the program execution time in detailed mode is noticeably higher.

The operating block for Detailed Mode Analysis of this coil model is divided into three modes of coil performance. The modes being:

- Coil is completely dry: There is no moisture condensation on the coil surface and the coil is a dry coil. This is an extreme condition when the entering air has very low humidity ratio or is dry air.
- Coil is completely wet: The entire coil is wet due to complete condensation on the surface of the coil.
- Part Wet Part Dry Mode: This is the usual/frequent mode of operation of coil where part of the coil at entry of air is dry and as air cools condensation occurs and part of the coil becomes wet.

The Part Wet Part Dry Mode of operation is essentially a function the Coil Completely Dry and Coil Completely Wet mode. This subroutine iterates between the Dry Coil and the Wet Coil to give outputs, a detailed explanation is given later in the document. The operating block requires 5 inputs, which are mentioned earlier in the document. These inputs are automatically generated from the node connections in Energy Plus. The user does not have to input any information to run this coil model.

The option to identify which mode of operation the coil should perform ie, for a given set of inputs would the coil be Dry, Wet or Part Wet Part Dry, is decided by set of conditions described below.

- **IF (Temperature Dewpoint Air < Water Inlet Temperature) THEN** the coil is Dry and we call the Subroutine Coil Completely Dry. In this case outlet temperature of air would be higher than the air dewpoint and hence there would be no condensation.
- **IF (Temperature Dewpoint Air > Water Inlet Temperature) THEN** the coil is completely wet, call subroutine Coil Completely Wet, it is assumed that moisture condensation occurs over completely surface of the coil. However we go ahead and check for the coil being partially wet with the following condition.
- **IF (AirDewPointTemp < AirInletCoilSurfTemp) THEN** the coil is Partially Wet because there is possibility that air temperature will go below its dewpoint and moisture will condense on latter part of the cooling coil.

The Operating Block for Simple Mode Analysis is divided into two modes of coil performance, the two modes being:

- Coil is completely dry: There is no moisture condensation on the coil surface and the coil is a dry coil.
- Coil is completely wet: The entire coil is wet due to complete condensation on the surface of the coil.

The option to identify which mode of operation the Simple mode analysis should perform ie, for a given set of inputs would the coil be Dry or Wet is decided by set of conditions described below.

- **IF (Temperature Dewpoint Air < Water Inlet Temperature) THEN** the coil is Dry and we call the Subroutine Coil Completely Dry. In this case outlet temperature of air would be higher than the air dewpoint and hence there would be no condensation.
- **IF (Temperature Dewpoint Air > Water Inlet Temperature) THEN** the coil is completely wet, call subroutine Coil Completely Wet, it is assumed that moisture condensation occurs over completely surface of the coil. However we go ahead and check for the coil being partially wet with the following condition.

The above is a simple mode of analysis and the results are very slightly different from the detailed mode of analysis. The algorithms used in Simple mode and the Detailed mode are identically similar. The surface area wet fraction in the coil is reported as 1.0 or 0.0 for wet or dry coil respectively. The program defaults to simple mode of analysis for enabling higher execution speed.

15.2.1.7 Effectiveness Equations

There are two modes of flow for the coil, CounterFlow or CrossFlow. The default mode is CounterFlow. According to the mode of flow the following NTU - Effectiveness relationships are used to calculate coil effectiveness, which is used later by all the three modes (Dry, Wet, Part Wet) for calculating air outlet conditions and heat transfer.

Following are the relations used for calculating effectiveness equation for the heat exchangers.

Counter Flow Heat Exchanger Effectiveness Equation:

$$\eta_{CounterFlow} = \frac{(1 - \exp(-NTU \times (1 - Ratio_{StreamCapacity})))}{1 - Ratio_{StreamCapacity} \times \exp(-NTU \times (1 - Ratio_{StreamCapacity}))} \quad (15.32)$$

In Equation 15.32, the variable $Ratio_{StreamCapacity}$ is defined as below:

$$Ratio_{StreamCapacity} = \frac{MinCapacity_{Stream}}{MaxCapacity_{Stream}} \quad (15.33)$$

In Equation 15.33, the capacities of stream are defined as below in Equation 15.34:

$$(Min, Max) Capacity_{Stream} = (MassFlowRate \times Cp)_{air,water} \quad (15.34)$$

NTU as shown in Equation 15.32 is defined as the Number of Transfer Units and is a function of Coil UA and the Minimum Capacity of Stream. The Coil UA is a variable in this equation and depends on which mode of the coil operation (Dry, Wet, Part Wet) is calling upon Equation 15.32, i.e., if it is Coil Completely Dry calling upon the effectiveness equation with the value of Dry UA total, which in our case is defined as CoilUA_total. Equation 15.35 gives definition for NTU.

$$NTU = \frac{CoilUA}{MinStreamCapacity} \quad (15.35)$$

Cross Flow Heat Exchanger Effectiveness Equation:

$$\eta_{CrossFlow} = 1 - \exp \left\{ \frac{\exp(-NTU \times Ratio_{StreamCapacity} \times NTU^{-0.22}) - 1}{Ratio_{StreamCapacity} \times NTU^{-0.22}} \right\} \quad (15.36)$$

The variables in the above equation have already been defined earlier. Depending on the mode of operation of the coil model, the CrossFlow or CounterFlow equations are used to calculate the effectiveness.

15.2.1.8 Coil Outlet Conditions

Calculating the Outlet Stream Conditions using the effectiveness value from Equation 15.32 or 15.36 depending on the mode of flow. The energy difference between the outlet and inlet stream conditions gives the amount of heat transfer that has actually take place. The temperature of air and water at the outlet of the coil are given by the following equations:

$$TempAir_{Out} = TempAir_{inlet} - \eta_{cross,counter} \times \frac{MaxHeatTransfer}{StreamCapacity_{Air}} \quad (15.37)$$

$$TempWater_{Out} = TempWater_{Inlet} + \eta_{Cross,counter} \times \frac{MaxHeatTransfer}{StreamCapacity_{Water}} \quad (15.38)$$

In Equations 15.37 and 15.38 above, the maximum heat transfer is calculated as shown in the following equation:

$$MaxHeatTransfer = MinStream_{Capacity} \times (TempAir_{Inlet} - TempWater_{Inlet}) \quad (15.39)$$

15.2.1.9 Coil Completely Dry Calculations (operating block)

Since the coil is dry, the sensible load is equal to total load and the same with the humidity ratios at inlet and outlet, as in Equations 15.40 and 15.41.

$$Q_{SensibleDryCoil} = Q_{TotalDryCoil} \quad (15.40)$$

$$HumRatio_{Inlet} = HumRatio_{Outlet} \quad (15.41)$$

Total Heat Transfer in dry coil is as follows:

$$Q_{TotalDryCoil} = Capacity_{Air} \times (AirTemp_{In} - AirTemp_{Outlet}) \quad (15.42)$$

The variables in the above equation are calculated earlier in Equations 15.37 and 15.38 to give the total cooling load on the coil.

15.2.1.10 Coil Completely Wet Calculations (operating block)

In wet coil we need to account for latent heat transfer, hence calculations are done using enthalpy of air and water instead of stream temperatures. Hence we need to define coil UA for the wet coil based on enthalpy of the operating streams and not design streams.

Similar to Equations 15.37 and 15.38, we calculate the air outlet enthalpy and water outlet enthalpy, i.e. by replacing temperature with enthalpy for the respective streams. The input variable for Coil UA in Equation 15.35 for calculating NTU, in this case it would be enthalpy based and is given as shown in Equation 15.43:

$$CoilUA_{EnthalpyBased} = \frac{1}{\left(\frac{CpSat_{Intermediate}}{CoilUA_{Internal}} + \frac{Cp_{Air}}{CoilUA_{External}} \right)} \quad (15.43)$$

Total Coil Load in the case of a Wet Coil is the product of mass flow rate of air and enthalpy difference between the inlet and outlet streams as given in the following equation:

$$Q_{Total} = \dot{m}_{air} \times (EnthAir_{Inlet} - EnthAir_{Outlet}) \quad (15.44)$$

Once the enthalpy is known the outlet temperatures and outlet humidity ratios of the wet coil are calculated as in equations below.

IF (TempCondensation < PsyTdpFnWPb(InletAirHumRat ,Patm)) THEN

$$AirTemp_{Out} = AirTemp_{inlet} - (AirTemp_{inlet} - Condensation_{Temp}) \times \eta \quad (15.45)$$

and

$$OutletAirHumidityRatio = PsyWFnTdbH(OutletAirTemp, EnthAirOutlet) \quad (15.46)$$

ELSE

There is no condensation. Thus, the inlet and outlet humidity ratios are equal, and the outlet temperature is a function of the outlet air enthalpy as shown below:

$$OutletAirTemp = PsyTdbFnHW(EnthalpyAirOutlet, OutletAirHumRat) \quad (15.47)$$

and

$$OutletAirHumRat = InletAirHumRat \quad (15.48)$$

ENDIF

Effectiveness η used in Equation 15.45 is defined in Equation 15.49 and the condensation temperature is calculated using a psychrometric function as in Equation 15.50.

$$\eta = 1 - Exp \left\{ -\frac{CoilUA_{External}}{Capacitance_{Air}} \right\} \quad (15.49)$$

$$CondensationTemp = PsyTsatFnHPb(Enth_{AirCondensateTemp}, P_{atm}) \quad (15.50)$$

$$Enth_{AirCondensateTemp} = Enth_{AirInlet} - \frac{(Enth_{AirInlet} - Enth_{AirOutlet})}{\eta} \quad (15.51)$$

Once the air outlet temperature are known, then the sensible load is calculated as a product of the capacitance of air and the temperature difference at the inlet and outlet, as in Equation 15.52:

$$Q_{Sensible} = Capacitance_{Air} \times (AirTemp_{Inlet} - AirTemp_{Outlet}) \quad (15.52)$$

15.2.1.11 Coil Part Wet Part Dry Calculations (operating block)

The Coil would perform under part wet part dry conditions when Air Dewpoint Temperature is less than Coil surface temperature at inlet to air. In this case part of the coil used value of Dry UA for heat transfer and part the coil used Wet UA value for heat transfer.

This problem is solved utilizing the fact that the Exit conditions from the Dry Part of the Coil would become the inlet conditions to the wet part of the coil (see Figure 15.1) and the coil model determines by iteration what fraction of the coil is wet and based on that it calculates the areas and subsequently the UA values of that dry and wet part, based on the area of the dry and wet part respectively. Explained below are the steps followed for estimating the wet dry behavior of the coil.

First, iterate between the Dry Coil and the Wet Coil. First calculate Coil Completely Dry performance by estimating the wet dry interface water temperature using equation and inputting this variable as the water inlet temperature to dry Coil.

$$WetDryInterface_{WaterTemp} = WaterTemp_{Inlet} + Area_{WetFraction} * (WaterTemp_{Outlet} - WaterTemp_{Inlet}) \quad (15.53)$$

The value of Surface Area Wet fraction is estimated initially as follows:

$$Area_{WetFractionEstimate} = \frac{AirDewPt_{Temp} - InletWater_{Temp}}{OutletWater_{Temp} - InletWater_{Temp}} \quad (15.54)$$

For the above mentioned iteration the value of Coil UA for Wet and Dry part need to be varied according to the new respective area of the wet and dry parts. This estimate of Wet and Dry area is a product of the estimated Surface Area Fraction and total coil external area, which keeps varying as will be explained further in the document.

UA value for Dry part of the Coil is estimated as below.

$$CoilUA_{DryExternal} = \frac{SurfArea_{Dry}}{\frac{1}{CoilU_{DryExternal}} + \frac{1}{CoilU_{Internal}}} \quad (15.55)$$

where Surface Area Dry = (Total Coil Area – Wet Part Area), where the Wet part area is the product of Surface fraction Wet and Total Coil Area.

UA value for the Wet part of the Coil requires Wet UA external and Wet UA Internal, which are calculated as below.

$$WetPartUA_{External} = CoilU_{WetExternal} \times SurfaceArea_{Wet} \quad (15.56)$$

$$WetPartUA_{Internal} = CoilU_{Internal} \times SurfaceArea_{Wet} \quad (15.57)$$

It is essential to remember that the mode of calculation for the coils remains the same as in completely wet and completely dry mode, only the UA values and water, air outlet and inlet values change.

Now iterate between the Dry Coil and wet Coil with the above respective UA, and usual operating inputs except the variable water inlet temperature for dry Coil is replaced with Wet Dry Interface Water temperature, and in the Wet Coil the Outlet Air Temperature from dry Coil is the inlet air temperature to Wet Coil. The iteration proceeds till the Outlet Water Temperature from Wet Coil equals the Wet Dry Interface Water Temp, which is the input to Dry Coil.

Dry Part Inputs, Iteration Case 1: Explained In Programming Fashion

CALL CoilCompletelyDry(WetDryInterfcWaterTemp, InletAirTemp, DryCoilUA, OutletWaterTemp, WetDryInterfcAirTemp, WetDryInterfcHumRat, DryCoilHeatTransfer)

Input the calculated values calculated by Dry Coil above into Wet Coil below:

CALL CoilCompletelyWet(InletWaterTemp, WetDryInterfcAirTemp, WetDryInterfcHumRat, WetPartUAInternal, WetPartUAExternal, EstimateWetDryInterfcWaterTemp, OutletAirTemp, OutletAirHumRat, WetCoilTotalHeatTransfer, WetCoilSensibleHeatTransfer, EstimateSurfAreaWetFraction, WetDryInterfcSurfTemp)

Iterate Between the above two Wet and Dry Coil calls until **WetDryInterfcWaterTemp = EstimateWetDryInterfcWaterTemp**. The key is to have the difference between the variables (WetDryInterfcWaterTemp - OutletWaterTemp) in the Dry Coil equal to (InletWaterTemp - EstimatedWetDryInterfcWaterTemp) in the Wet Coil. This equality quantized the relative part of coil that is dry and the part that is wet on the basis of the heat transfer that has occurred.

After the above convergence check for the coil being dry, iterate to calculate surface fraction area wet.

IF

$$\{(AreaFraction_{Wet} \leq 0.0) .AND.(WetDryInterface_{SurfTemp} > AirDewPt)\} \quad (15.58)$$

THEN CoilCompletelyDry

If Equation 15.58 is satisfied, then the coil is dry and simply output the value for Dry Coil calculated else the coil is partially wet and then iterate to find the surface fraction area wet. Start with the initial guess value of surface area fraction (Equation 15.54) wet and iterate on the entire loop starting from Equation 15.54 until the Wet Dry Interface Temperature equals the Air Dewpoint Temperature. The value of Surface Area fraction wet at which the interface air temperature equals is dewpoint is the transition point from wet to dry and gives the % of coil that is dry and % that is wet.

Graphs Showing the Performance of the coil model at optimum operating conditions are shown below. All values of variable used have been normalized.

15.2.2 Chilled-Water-Based Detailed Geometry Air Cooling Coil

The input object Coil:Cooling:Water:DetailedGeometry provides a coil model that predicts changes in air and water flow variables across the coil based on the coil geometry. A greatly simplified schematic of enthalpy and temperature conditions in a counterflow cooling/dehumidifying coil is shown in the following schematic figure. In addition, the variables required to model a cooling/dehumidifying coils and their definitions are extensively listed in “Table 15.4. Coil Geometry and Flow Variables for Coils”. The input required to model the coil includes a complete geometric description that, in most cases, should be derivable from specific manufacturer’s data. The coil simulation model is essentially the one presented by Elmahdy and Mitalas (1977) and implemented in HVACSIM+ (Clark 1985), a modular program also designed for energy analysis of building systems. The model solves the equations for the dry and wet sections of the coil using log mean temperature and log mean enthalpy differences between the liquid and the air streams. Elmahdy and Mitalas state that crossflow counterflow coils with at four rows or more are approximated well by this model. This does not constitute a major limitation since cooling and dehumidifying coils typically have more than four rows.

Figure 15.6: Simplified Schematic of Cooling/Dehumidifying Coil

15.2.2.1 Heat Transfer and Energy Balance

The cooling coil may be completely dry, completely wet with condensation, or it may have wet and dry sections. The actual condition of the coil surface depends on the humidity and temperature of the air passing over the coil and the coil surface temperature. The partly wet-partly dry case represents the most general scenario for the coil surface conditions. The all dry and all wet cases can be considered as limiting solutions of the wet or dry areas respectively going to zero. In the general case, equations are written for both the dry and wet regions of the coil. For each region the heat transfer rate from air to water may be defined by the rate of enthalpy change in the air and in the water. The rates must balance between each medium for energy to be conserved. Equations 15.59 through 15.62 express the energy balance between the water and the air for the case of dry and wet coils respectively. Equations 15.63 and 15.64 represent the heat transfer rate between water and air based on the actual performance of the coil. The UA parameter can be calculated from the parameters in the following table.

Table 15.4: Coil Geometry and Flow Variables for Coils

A	area	LMHD	log mean enthalpy difference
A	air, air side	LMTD	log mean temperature difference
aa, bb	coeff. in enthalpy approximation	\dot{m}	mass flow rate
C1, C2	coeff. in air side film coeff.	mf	metal and fouling
C_p	specific heat	μ	viscosity
D	diameter, effective diameter	o	outside (air side)
Dhdr	hydraulic diameter on air side	Pr	Prandtl number
D	dry region	\dot{Q}	heat transfer rate
δ	thickness	R	overall thermal resistance
Δ	spacing	Re	Reynolds number

Table 15.4: Coil Geometry and Flow Variables for Coils

F	heat transfer film coefficient	ρ	ratio of diameters
fai	variable in fin eff. calculation	s	surface, outside of metal
fin, fins	air side fin geometry	St	Stanton number
H	enthalpy	T	temperature
η	efficiency	tube	water tube
I0()	mod Bessel fn, 1st kind, ord 0	UA _{dry}	dry heat xfer coeff. * dry area
I1()	mod Bessel fn, 1st kind, ord 1	UcA _w	wet heat xfer coeff. * wet area
K0()	mod Bessel fn, 2nd kind, ord 0	ub, ue	variables in fin eff. calculation
K1()	mod Bessel fn, 2nd kind, ord 1	V	average velocity
I	inside (water side)	w	water, water side, or wet region
K1	variable in sol'n form of eq.	wa	humidity ratio
K	thermal conductivity	Z	variables in sol'n form of eq.
L	length	1, 2, 3	positions (see diagram)

Equations 15.59 through 15.64 represent two sets of three equations with 7 unknowns: \dot{Q}_d , $T_{a,1}$, $T_{a,2}$, $T_{w,2}$, $T_{w,3}$, \dot{m}_a , \dot{m}_w . However, normally at least four of these variables are specified, for example: inlet water temperature, outlet air temperature, water flow rate, air flow rate, so that the system of equations is effectively closed.

$$\dot{Q}_d = \dot{m}_a C_{p,a} (T_{a,1} - T_{a,2}) \quad (15.59)$$

$$\dot{Q}_d = \dot{m}_w C_{p,w} (T_{w,3} - T_{w,2}) \quad (15.60)$$

$$\dot{Q}_d = (UA_{dry}) (LMTD) \quad (15.61)$$

$$\dot{Q}_w = \dot{m}_a (H_{a,2} - H_{a,3}) \quad (15.62)$$

$$\dot{Q}_w = \dot{m}_w C_{p,w} (T_{w,2} - T_{w,1}) \quad (15.63)$$

$$\dot{Q}_w = (U_c A_w) (LMHD) \quad (15.64)$$

In order to manipulate these equations, the log mean temperature and enthalpy differences are expanded as shown in Equations 15.65 and 15.66. Finally, a linear approximation of the enthalpy

of saturated air over the range of surface temperature is made using Equation 15.67. Note that in Equation 15.66 H_w refers to the enthalpy of saturated air at the water temperature.

$$LMTD = \frac{(T_{a,1} - T_{w,3}) - (T_{a,2} - T_{w,2})}{\ln \frac{T_{a,1} - T_{w,3}}{T_{a,2} - T_{w,2}}} \quad (15.65)$$

$$LMHD = \frac{(H_{a,2} - H_{w,2}) - (H_{a,3} - H_{w,1})}{\ln \frac{H_{a,2} - H_{w,2}}{H_{a,3} - H_{w,1}}} \quad (15.66)$$

$$H_w = aa + bbT_w \quad (15.67)$$

Equation 15.68 is derived from the above equations and is used to solve for the coil conditions when all of the inlet conditions are given as input. Operating in this manner, the coil does not have a controlled outlet air temperature.

$$T_{w,2} = \frac{(1 - Z)(H_{a,1} - aa - K1C_{p,a}T_{a,1}) + ZT_{w,1} \left(bb - \frac{m_w C_{p,w}}{m_a} \right)}{bb - Z \frac{m_w C_{p,w}}{m_a} - (1 - Z) K1C_{p,a}} \quad (15.68)$$

An alternative solution method is to define the coil leaving air temperature as an input with a variable water flow rate. In this case Equations 15.69 and 15.70 are more convenient. Equations 15.71 through 15.73 define terms that are used to simplify Equations 15.68, 15.69 and 15.70.

$$T_{w,2} = \frac{(1 - Z)(H_{a,3} - aa) + T_{w,1} \left(\frac{m_w C_{p,w}}{m_a} - bbZ \right)}{\frac{m_w C_{p,w}}{m_a} - bb} \quad (15.69)$$

$$T_{w,2} = \frac{(Z_d - 1)T_{a1}C_{p,a} + T_{w,3} \left(C_{p,a} - Z_d \frac{m_w C_{p,w}}{m_a} \right)}{Z_d \left(C_{p,a} - \frac{m_w C_{p,w}}{m_a} \right)} \quad (15.70)$$

$$Z = \exp \left(U_c A_w \left(\frac{1}{m_a} - \frac{bb}{m_w C_{p,w}} \right) \right) \quad (15.71)$$

$$K1 = \frac{Z_d - 1}{Z_d - \frac{m_a C_{p,a}}{m_w C_{p,w}}} \quad (15.72)$$

$$Z_d = \exp \left(U_c A_{dry} \left(\frac{1}{m_a C_{p,a}} - \frac{1}{m_w C_{p,w}} \right) \right) \quad (15.73)$$

15.2.2.2 Underlying Correlations, Properties, and Assumptions

Overall heat transfer coefficients are calculated from the specified coil geometry and by using empirical correlations from fluid mechanics and heat transfer. For the water side, Equation 15.74 gives the film heat transfer coefficient in SI units:

$$f_i = 1.429 (1 + 0.0146T_w) V_w^{0.8} D_i^{-0.2} \quad (15.74)$$

This is valid for Reynolds numbers greater than 3100 based on water flow velocity and pipe inside diameter and is given in Elmahdy and Mitalas(1977) as recommended in the standard issued

by the Air-Conditioning and Refrigeration Institute (1972) for air-cooling coils. The definition of overall inside thermal resistance follows directly as shown in Equation 15.75.

$$R_i = \frac{1}{f_i A_i} \quad (15.75)$$

Equation 15.76 gives the film coefficient for the air side. Another form of the same equation is Equation 15.77, which is familiar from the data presented in Kays and London (1984). For coil sections that have a wet surface due to condensation, the air side film coefficient is modified according to Equation 15.78. The correction term, a function of air Reynolds number, is valid for Reynolds numbers between 400 and 1500. The coefficients in Equations 15.76 and 15.77 are calculated by Equations 15.79 and 15.80 that are functions of the coil geometry. Elmahdy (1977) explains the modifier for the wet surface and coefficients for the film coefficient. Equations 15.81 through 15.84 show definitions and values of common parameters and properties.

$$f_o = C_1 Re_a^{C_2} \frac{m_a}{A_{a,minflow}} C_{p,a} Pr_a^{2/3} \quad (15.76)$$

$$C_1 Re_a^{C_2} = St_a Pr_a^{2/3} \quad (15.77)$$

$$f_{o,w} = f_o (1.425 - 5.1 \times 10^{-4} Re_a + 2.63 \times 10^{-7} Re_a^2) \quad (15.78)$$

$$C_1 = 0.159 \left(\frac{\delta_{fin}}{D_{hdr}} \right)^{-0.065} \left(\frac{\delta_{fin}}{L_{fin}} \right)^{0.141} \quad (15.79)$$

$$C_2 = -0.323 \left(\frac{\Delta_{fins}}{L_{fin}} \right)^{0.049} \left(\frac{D_{fin}}{\Delta_{tuberows}} \right)^{0.549} \left(\frac{\delta_{fin}}{\Delta_{fins}} \right)^{-0.028} \quad (15.80)$$

$$D_{hdr} = \frac{4A_{a,minflow}\delta_{coil}}{A_{s,total}} \quad (15.81)$$

$$Re_a = \frac{4\delta_{coil}(1 + w_a)m_a}{A_{s,total}\mu_a} \quad (15.82)$$

$$Pr_a = 0.733 \quad (15.83)$$

$$\mu_a = 1.846 \times 10^{-5} \quad (15.84)$$

The film coefficients above act on the extended surface of the air side, that is the area of the fins and the tubes. Therefore, the fin efficiency must also be considered in calculating the overall thermal resistance on the outside. Gardner (1945) gives the derivation of Equation 15.85, used as a curve fit to find the fin efficiency as a function of film coefficient. This equation is based on circular fins of constant thickness. To model a coil with flat fins, an effective diameter – that of circular fins with the same fin area – is used. Equations 15.86 through 15.89 define variables used in Equation 15.85. The overall efficiency of the surface is shown by Equation 15.90. Note that the efficiency is found by the same equations for the wet surface using the wet surface film coefficient.

$$\eta_{fin} = \frac{-2\rho}{f_{ai}(1 + \rho)} \left[\frac{I_1(u_b)K_1(u_e) - K_1(u_b)I_1(u_e)}{I_0(u_b)K_1(u_e) + K_0(u_b)I_1(u_e)} \right] \quad (15.85)$$

$$f_{ai} = \frac{(D_{fin} - D_{tube})}{2} \sqrt{\frac{2f_o}{k_{fin}\delta_{fin}}} \quad (15.86)$$

$$\rho = \frac{D_{tube}}{D_{fin}} \quad (15.87)$$

$$u_e = \frac{f_{ai}}{1 - \rho} \quad (15.88)$$

$$u_b = u_e \rho \quad (15.89)$$

$$\eta_o = 1 - (1 - \eta_{fin}) \frac{A_{fins}}{A_{s,total}} \quad (15.90)$$

The definition of overall outside thermal resistance is given in Equation 15.91 as a function of fin efficiency and film coefficient. For a wet coil surface the resistance must be defined differently because the heat transfer equations are based on enthalpy rather than temperature differences, as shown in Equation 15.92.

$$R_o = \frac{1}{f_o \eta_o A_{s,total}} \quad (15.91)$$

$$R_{o,w} = \frac{C_{p,a}/bb}{f_{o,w} \eta_{o,w} A_{s,total}} \quad (15.92)$$

Equation 15.93 gives the last two overall components of thermal resistance. They represent the metal tube wall and internal fouling. The fouling factor, due to deposits of dirt and corrosion of the tube inside surfaces, is assumed to be $5 \times 10^{-5} \text{ m}^2\text{-K/W}$. All components of thermal resistance are added in series to produce the overall heat transfer coefficients shown in Equations 15.94 and 15.95.

$$R_{mf} = \frac{\delta_{tube}}{k_{tube} A_i} + \frac{Fl}{A_i} \quad (15.93)$$

$$U A_{dry} = \frac{A_{dry}}{A_{s,total}} \left[\frac{1}{R_i + R_{mf} + R_o} \right] \quad (15.94)$$

$$U_c A_w = \frac{A_w}{A_{s,total}} \left[\frac{1/bb}{R_i + R_{mf} + R_{o,w}} \right] \quad (15.95)$$

15.2.2.3 Solution Method of Model

The complicated equations derived above were implemented in a successive substitution solution procedure to calculate the coil performance based on the input parameters. The MODSIM implementation of a cooling coil, the TYPE12 subroutine, was the motivation for this approach; the method used there has been retained with modifications for the uncontrolled coil model. Clark (1985) contains notes about the MODSIM routine.

In the general case, the cooling coil is only partially wet. For an uncontrolled coil, Equation 15.68 is used to find the water temperature at the boundary. Several simple equations in the loop adjust the boundary point until the dry surface temperature at the boundary is equal to the dewpoint

of the inlet air. For the controlled coil, Equations 15.69 and 15.70 give two calculations of the boundary temperature, and the water flow rate and boundary position are adjusted until the two equations agree.

Special cases occur when the coil is all wet or all dry. The coil is solved as if it were all wet before the general case is attempted. If the wet surface temperatures at the coil inlet and outlet are both below the dewpoint, no further solution is required. However, to ensure a continuous solution as flow variables are changed, when the surface is all dry or when it is wet with only the dry surface equations yielding a surface temperature below the dewpoint at the water outlet, the general solution is used to calculate the unknowns. In the solution of the controlled coil the outlet air enthalpy, given some resulting dehumidification, must correspond to the enthalpy at the specified outlet air temperature.

15.2.2.4 Application of Cooling Coil Model to Heating Coils

The implementation of detailed heating coil models in IBLAST was another important aspect of the system/plant integration. The same kind of loops exist to provide hot water to the heating coils from the boilers as exist to supply the cooling coils with chilled water from the chillers. Some simplifications can be made, however, since the enthalpy change of the air flowing over a heating coil is entirely sensible. There is no condensation in a heating coil. In order to allow heating and cooling coils to be specified using the same geometric parameters, a heating coil simulation was developed from the cooling coil model described above by eliminating the wet surface analysis.

In addition, it was concluded that, since much simpler and less computationally expensive heating coil simulations are possible, an option was provided in IBLAST for a heating coil design using only the UA value of the coil, the product of heat transfer coefficient and coil area. This model was largely based on the TYPE10 subroutine implemented in MODSIM. The equations used to model the performance of the TYPE10 heating coil are as follows:

$$\begin{aligned} T_{a,out} &= T_{a,in} + (T_{w,in} - T_{a,in}) \varepsilon \left(\frac{\min(C_{p,a}\dot{m}_a, C_{p,w}\dot{m}_w)}{C_{p,a}\dot{m}_a} \right) \\ T_{w,out} &= T_{w,in} - (T_{a,out} - T_{a,in}) \left(\frac{C_{p,a}\dot{m}_a}{C_{p,w}\dot{m}_w} \right) \end{aligned} \quad (15.96)$$

where the coil effectiveness is given by:

$$\varepsilon = 1 - \exp \left(\frac{\left\{ \exp \left[- \left(\frac{\min\{C_{p,a}\dot{m}_a, C_{p,w}\dot{m}_w\}}{\max\{C_{p,a}\dot{m}_a, C_{p,w}\dot{m}_w\}} \right) \{NTU\}^{0.78} \right] - 1 \right\}}{\left(\frac{\min\{C_{p,a}\dot{m}_a, C_{p,w}\dot{m}_w\}}{\max\{C_{p,a}\dot{m}_a, C_{p,w}\dot{m}_w\}} \right) \{NTU\}^{-.22}} \right) \quad (15.97)$$

The parameter NTU is the number of transfer units and is defined as a function of the UA value of the coil as follows:

$$NTU = \frac{UA}{\min(C_{p,a}\dot{m}_a, C_{p,w}\dot{m}_w)} \quad (15.98)$$

15.2.3 Hot-Water-Based Air Heating Coil

15.2.3.1 Overview

The input object Coil:Heating:Water provides a model that uses an NTU–effectiveness model of a static heat exchanger. The model is an inlet – outlet model: given the inlet conditions and flow rates

and the UA, the effectiveness is calculated using the formula for the effectiveness of a cross-flow heat exchanger with both fluid streams unmixed. The effectiveness then allows the calculation of the outlet conditions from the inlet conditions.

The inputs to the model are: (1) the current inlet temperatures and flow rates of the air and water fluid streams and (2) the UA of the coil. Note that the UA is fixed in this model and is not a function of the flow rates.

There are 2 alternative user inputs for the component: the user may input the design water volumetric flow rate and the UA directly; or the user may choose to input the more familiar design heating capacity plus design inlet & outlet temperatures and let the program calculate the design UA. These alternative user inputs are fully described in the EnergyPlus Input Output Reference document.

15.2.3.2 Model Description

The air and water capacitance flows are defined as:

$$\dot{C}_{air} = c_{p,air} \cdot \dot{m}_{air} \quad (15.99)$$

$$\dot{C}_{water} = c_{p,water} \cdot \dot{m}_{water} \quad (15.100)$$

The minimum and maximum capacity flows are then:

$$\dot{C}_{min} = \min(\dot{C}_{air}, \dot{C}_{water}) \quad (15.101)$$

$$\dot{C}_{max} = \max(\dot{C}_{air}, \dot{C}_{water}) \quad (15.102)$$

The capacitance flow ratio is defined as:

$$Z = \dot{C}_{min} / \dot{C}_{max} \quad (15.103)$$

The number of transfer units (*NTU*) is:

$$NTU = UA / \dot{C}_{min} \quad (15.104)$$

The effectiveness is:

$$\varepsilon = 1 - \exp\left(\frac{e^{-NTU \cdot Z \cdot \eta} - 1}{Z \cdot \eta}\right) \quad (15.105)$$

where $\eta = NTU^{-0.22}$.

The outlet conditions are then:

$$T_{air,out} = T_{air,in} + \varepsilon \cdot \dot{C}_{min} \cdot (T_{water,in} - T_{air,in}) / \dot{C}_{air} \quad (15.106)$$

$$T_{water,out} = T_{water,in} - \dot{C}_{air} \cdot (T_{air,out} - T_{air,in}) / \dot{C}_{water} \quad (15.107)$$

The output of the coil in watts is:

$$\dot{Q}_{coil} = \dot{C}_{water} \cdot (T_{water,in} - T_{water,out}) \quad (15.108)$$

The UA value is recalculated for each timestep. A nominal UA, UA_0 , at the rating point is calculated by the program using the input for rated conditions and a search routine called root solver.

User input for the ratio of convective heat transfers at the nominal or rated operating point, “ r ,” is used in the model. This ratio is defined as:

$$r = \frac{\eta_f(hA)_{air}}{(hA)_{water}} \quad (15.109)$$

where:

η_f is the fin efficiency, (dimensionless)

h is the surface convection heat transfer coefficient

A is the surface area.

The value calculated for UA_0 is used with the input for r to characterize the convective heat transfer on the water sides at the nominal rating operation point using:

$$((hA)_w)_0 = UA_0 \left(\frac{r+1}{r} \right) \quad (15.110)$$

and on the air side at the nominal rating point using:

$$(\eta_f(hA)_a)_0 = r(hA)_{w,0} \quad (15.111)$$

Then, the following equations are used to calculate a new UA as a function of the flow rates and inlet temperatures at each timestep.

$$x_a = 1 + 4.769 \cdot 10^{-3} (T_{air,in} - T_{air,in,0}) \quad (15.112)$$

$$\eta_f(hA)_a = x_a \left(\frac{\dot{m}_a}{\dot{m}_{a,0}} \right)^{0.8} (\eta_f(hA)_a)_0 \quad (15.113)$$

$$x_w = 1 + \left(\frac{0.014}{1 + 0.014T_{water,in,0}} \right) (T_{water,in} - T_{water,in,0}) \quad (15.114)$$

$$(hA)_w = x_w \left(\frac{\dot{m}_w}{\dot{m}_{w,0}} \right)^{0.85} (hA)_{w,0} \quad (15.115)$$

$$UA = \left(\frac{1}{(hA)_w} + \frac{1}{\eta_f(hA)_a} \right)^{-1} \quad (15.116)$$

The above formulas are from the following reference, along with further references. The equation for x_w was modified from that published in Wetter (1999) to correct a small error.

15.2.4 Single-Speed Electric DX Air Cooling Coil

15.2.4.1 Overview

This model (object names Coil:Cooling:DX:SingleSpeed and Coil:Cooling:DX:TwoStageWithHumidityControlMode, with CoilPerformance:DX:Cooling) simulates the performance of an air-cooled or evaporative-cooled direct expansion (DX) air conditioner. The model uses performance information at rated conditions along with curve fits for variations in total capacity, energy input ratio and part-load fraction to determine the performance of the unit at part-load conditions (Henderson et al. 1992, ASHRAE 1993). Sensible/latent capacity splits are determined by the rated sensible heat ratio (SHR) and the apparatus dewpoint (ADP)/bypass factor (BF) approach. This approach is analogous to the NTU-effectiveness calculations used for sensible-only heat exchanger calculations, extended to a cooling and dehumidifying coil.

This model simulates the thermal performance of the DX cooling coil and the power consumption of the outdoor condensing unit (compressor, fan, crankcase heater and evap condenser water pump). The total amount of heat rejected by the condenser is also calculated and stored for use by other waste heat recovery models (e.g., Coil:Heating:Desuperheater). The performance of the indoor supply air fan varies widely from system to system depending on control strategy (e.g., constant fan vs. AUTO fan, constant air volume vs. variable air volume, etc.), fan type, fan motor efficiency and pressure losses through the air distribution system. Therefore, this DX system model does not account for the thermal effects or electric power consumption of the indoor supply air fan. EnergyPlus contains separate models for simulating the performance of various indoor fan configurations, and these models can be easily linked with the DX system model described here to simulate the entire DX air conditioner being considered (e.g., see AirLoopHVAC:Unitary:Furnace:HeatCool, AirLoopHVAC:UnitaryHeatCool, ZoneHVAC:WindowAirConditioner or AirLoopHVAC:UnitaryHeatPump:AirToAir).

15.2.4.2 Model Description

The user must input the total cooling capacity, sensible heat ratio (SHR), coefficient of performance (COP) and the volumetric air flow rate across the cooling coil at rated conditions. The capacity, SHR and COP inputs should be “gross” values, excluding any thermal or energy impacts due to the indoor supply air fan. The rated conditions are considered to be air entering the cooling coil at 26.7°C drybulb/19.4°C wetbulb and air entering the outdoor condenser coil at 35°C drybulb/23.9°C wetbulb. The rated volumetric air flow should be between 0.00004027 m³/s and 0.00006041 m³/s per watt of rated total cooling capacity (300 – 450 cfm/ton). The rated volumetric air flow to total cooling capacity ratio for 100% dedicated outdoor air (DOAS) application DX cooling coils should be between 0.00001677 (m³/s)/W (125 cfm/ton) and 0.00003355 (m³/s)/W (250 cfm/ton).

The user must also input five performance curves or performance tables that describe the change in total cooling capacity and efficiency at part-load conditions:

- 1) Total cooling capacity modifier curve or table (function of temperature)
 - 2) Total cooling capacity modifier curve or table (function of flow fraction)
 - 3) Energy input ratio (EIR) modifier curve or table (function of temperature)
 - 4) Energy input ratio (EIR) modifier curve or table (function of flow fraction)
 - 5) Part load fraction correlation curve or table (function of part load ratio)
- The total cooling capacity modifier curve (function of temperature) is a curve with two independent variables: wet-bulb temperature of the air entering the cooling coil, and dry-bulb

temperature of the air entering the air-cooled condenser coil (wet-bulb temperature if modeling an evaporative-cooled condenser). The output of this curve is multiplied by the rated total cooling capacity to give the total cooling capacity at the specific entering air temperatures at which the DX coil unit is operating (i.e., at temperatures different from the rating point temperatures). This curve is typically a biquadratic but any curve or table with two independent variables can be used.

Note: The data used to develop the total cooling capacity modifier curve (function of temperature) should represent performance when the cooling coil is ‘wet’ (i.e., coil providing sensible cooling and at least some dehumidification). Performance data when the cooling coil is ‘dry’ (i.e., not providing any dehumidification) should **not** be included when developing this modifier curve. This model automatically detects and adjusts for ‘dry coil’ conditions (see section “Dry Coil Conditions” below).

$$\text{TotCapTempModFac} = \text{Func}(T_{wb,i}, T_{c,i}) \quad (15.117)$$

where:

$T_{wb,i}$ are the “x” values or the wet-bulb temperature of the air entering the cooling coil (°C)

$T_{c,i}$ are the “y” values or the dry-bulb temperature of the air entering an air-cooled condenser or wet-bulb temperature of the air entering an evaporative-cooled condenser (°C).

- The total cooling capacity modifier curve (function of flow fraction) is a curve with one independent variable being the ratio of the actual air flow rate across the cooling coil to the rated air flow rate (i.e., fraction of full load flow). The output of this curve is multiplied by the rated total cooling capacity and the total cooling capacity modifier curve (function of temperature) to give the total cooling capacity at the specific temperature and air flow conditions at which the DX unit is operating. This curve is typically a quadratic but any curve or table with one independent variable can be used.

$$\text{TotCapFlowModFac} = \text{Func}(ff) \quad (15.118)$$

where:

$$ff = \text{flow fraction} = \left(\frac{\text{Actual air mass flow rate}}{\text{Rated air mass flow rate}} \right) = \text{x value} \quad (15.119)$$

Note: The actual volumetric air flow rate through the cooling coil for any simulation time step where the DX unit is operating must be between 0.00002684 m³/s and .00006713 m³/s per watt of rated total cooling capacity (200 - 500 cfm/ton). The simulation will issue a warning message if this air flow range is exceeded.

- The energy input ratio (EIR) modifier curve (function of temperature) is a curve with two independent variables: wet-bulb temperature of the air entering the cooling coil, and dry-bulb temperature of the air entering the air-cooled condenser coil (wet-bulb temperature if modeling an evaporative-cooled condenser). The output of this curve is multiplied by the rated EIR (inverse of the rated COP) to give the EIR at the specific entering air temperatures at which the DX coil unit is operating (i.e., at temperatures different from the rating point temperatures). This curve is typically a biquadratic but any curve or table with two independent variables can be used.

Note: The data used to develop the energy input ratio (EIR) modifier curve (function of temperature) should represent performance when the cooling coil is ‘wet’ (i.e., coil providing sensible cooling and at least some dehumidification). Performance data when the cooling coil is ‘dry’ (i.e., not providing any dehumidification) should **not** be included when developing this modifier curve. This model automatically detects and adjusts for ‘dry coil’ conditions (see section “Dry Coil Conditions” below).

$$\text{EIRTempModFac} = \text{Func}(T_{wb,i}, T_{c,i}) \quad (15.120)$$

where

$T_{wb,i}$ are the “x” values or the wet-bulb temperature of the air entering the cooling coil (°C)

$T_{c,i}$ are the “y” values or the dry-bulb temperature of the air entering an air-cooled condenser or wet-bulb temperature of the air entering an evaporative-cooled condenser (°C).

- The energy input ratio (EIR) modifier curve (function of flow fraction) is a curve with one independent variable being the ratio of the actual air flow rate across the cooling coil to the rated air flow rate (i.e., fraction of full load flow). The output of this curve is multiplied by the rated EIR (inverse of the rated COP) and the EIR modifier curve (function of temperature) to give the EIR at the specific temperature and air flow conditions at which the DX unit is operating. This curve is typically a quadratic but any curve or table with one independent variable can be used.

$$\text{EIRFlowModFrac} = \text{Func}(ff) \quad (15.121)$$

where:

$$ff = \text{flow fraction} = \left(\frac{\text{Actual air mass flow rate}}{\text{Rated air mass flow rate}} \right) = \text{x value} \quad (15.122)$$

- The part load fraction correlation (function of part load ratio) is a curve with one independent variable being part load ratio (sensible cooling load / steady-state sensible cooling capacity). The output of this curve is used in combination with the rated EIR and EIR modifier curves to give the “effective” EIR for a given simulation time step. The part load fraction (PLF) correlation accounts for efficiency losses due to compressor cycling. This curve is typically a linear, quadratic, or cubic but any curve or table with one independent variable can be used.

$$\text{PartLoadFrac} = \text{PLF} = \text{Func}(\text{PLR}) \quad (15.123)$$

where

$$\text{PLR} = \text{part load ratio} = \left(\frac{\text{actual sensible cooling load}}{\text{steady-state sensible cooling load}} \right) = \text{x values} \quad (15.124)$$

The part-load fraction correlation should be normalized to a value of 1.0 when the part load ratio equals 1.0 (i.e., no efficiency losses when the compressor(s) run continuously for the simulation time step). For PLR values between 0 and 1 ($0 < \text{PLR} < 1$), the following rules apply:

$$\begin{aligned} \text{PLF} &\geq 0.7 \\ \text{PLF} &\geq \text{PLR} \end{aligned} \quad (15.125)$$

If $\text{PLF} < 0.7$ a warning message is issued, the program resets the PLF value to 0.7, and the simulation proceeds. The runtime fraction of the coil is defined as PLR/PLF . If $\text{PLF} < \text{PLR}$, then a warning message is issued and the runtime fraction of the coil is limited to 1.0.

A typical part load fraction correlation for a conventional, single-speed DX cooling coil (e.g., residential or small commercial unit) would be:

$$\text{PLF} = 0.85 + 0.15(\text{PLR}) \quad (15.126)$$

All five part-load curves are accessed through EnergyPlus' built-in performance curve equation manager (curve: quadratic, curve:cubic and curve:biquadratic). It is not imperative that the user utilize all coefficients shown in Equations 15.117 through 15.123 if their performance equation has fewer terms (e.g., if the user's PartLoadFrac performance curve is linear instead of quadratic, simply enter the values for a and b, and set coefficient c equal to zero).

For any simulation time step, the total (gross) cooling capacity of the DX unit is calculated as follows:

$$\dot{Q}_{total} = \dot{Q}_{total,rated} (\text{TotCapTempModFac}) (\text{TotCapFlowModFac}) \quad (15.127)$$

In a similar fashion, the electrical power consumed by the DX unit (compressors plus outdoor condenser fans) for any simulation time step is calculated using the following equation:

$$\text{Power} = \left(\dot{Q}_{total} \right) (\text{EIR}) (\text{RTF}) \quad (15.128)$$

where:

\dot{Q}_{total} is the total cooling capacity as shown in Equation 15.127 (W)

$$\text{EIR} = \text{Energy input ratio} = \left(\frac{1}{\text{COP}_{rated}} \right) (\text{EIRTempModFac}) (\text{EIRFlowModFac}) \quad (15.129)$$

COP_{rated} is the coefficient of performance at rated conditions (user input)

$$\text{RTF} = \left(\text{PLR} / \text{PartLoadFrac} \right) = \text{runtime fraction of the cooling coil} \quad (15.130)$$

The total amount of heat rejected by the condenser is then calculated and stored for use by other waste heat recovery models (e.g., Coil:Heating:Desuperheater).

$$\dot{Q}_{cond} = \dot{Q}_{total} (1 + \text{EIR}) \quad (15.131)$$

where \dot{Q}_{cond} is the total amount of heat rejected by the condenser (W).

The crankcase heater is assumed to operate when the cooling coil's compressor is OFF and the outdoor dry-bulb temperature is below the maximum outdoor temperature for crankcase heater operation. The average crankcase heater power for the simulation time step is calculated as follows:

$$P_{crankcase} = \dot{Q}_{cap,crankcase} (1 - \text{RTF}) \quad (15.132)$$

where:

$P_{crankcase}$ is the DX cooling coil crankcase heater power (W)

$\dot{Q}_{cap,crankcase}$ is the crankcase heater capacity (W).

If this cooling coil is used as part of an air-to-air heat pump (Ref. AirLoopHVAC:UnitaryHeatPump:AirToAir), the crankcase heater defined for this DX cooling coil is disregarded and the associated output variable is omitted. Instead, the crankcase heater defined for the DX heating coil (Coil:Heating:DX:SingleSpeed) is enabled during the time that the compressor is not running for either heating or cooling. In this instance, RTF in the above equations would be the runtime fraction of the heat pump's heating coil or cooling coil, whichever is greater.

In addition to calculating the total cooling capacity provided by the DX air conditioner, it is important to properly determine the break down of total cooling capacity into its sensible (temperature) and latent (dehumidification) components. The model computes the sensible/ latent split using the rated SHR and the ADP/BF approach (Carrier et al. 1959). When the DX coil model is initially called during an EnergyPlus simulation, the rated total capacity and rated SHR are used to calculate the coil bypass factor (BF) at rated conditions. The rated total capacity and rated SHR are first used to determine the ratio of change in air humidity ratio to air dry-bulb temperature:

$$SlopeRated = \left(\frac{\omega_{in} - \omega_{out}}{T_{db,in} - T_{db,out}} \right)_{rated} \quad (15.133)$$

where:

ω_{in} is the humidity ratio of the air entering the cooling coil at rated conditions (kg/kg)

ω_{out} is the humidity ratio of the air leaving the cooling coil at rated conditions (kg/kg)

$T_{db,in}$ is the dry-bulb temperature of the air entering the cooling coil at rated conditions (°C)

$T_{db,out}$ is the dry-bulb temperature of the air leaving the cooling coil at rated conditions (°C).

Along with the rated entering air conditions, the algorithm then searches along the saturation curve of the psychrometric chart until the slope of the line between the point on the saturation curve and the inlet air conditions matches $SlopeRated$. Once this point, the apparatus dewpoint, is found on the saturation curve the coil bypass factor at rated conditions is calculated as follows:

$$BF_{rated} = \frac{h_{out,rated} - h_{ADP}}{h_{in,rated} - h_{ADP}} \quad (15.134)$$

where:

$h_{out,rated}$ is the enthalpy of the air leaving the cooling coil at rated conditions (J/kg)

$h_{in,rated}$ is the enthalpy of the air entering the cooling coil at rated conditions (J/kg)

h_{ADP} is the enthalpy of saturated air at the coil apparatus dewpoint (J/kg).

The coil bypass factor is analogous to the “ineffectiveness” $(1-\epsilon)$ of a heat exchanger, and can be described in terms of the number of transfer of unit (NTU).

$$BF = e^{-NTU} = e^{-\left(\frac{UA}{\dot{m} c_p}\right)} = e^{-A_o / \dot{m}} \quad (15.135)$$

For a given coil geometry, the bypass factor is only a function of air mass flow rate. The model calculates the parameter A_o in Equation 15.135 based on BF_{rated} and the rated air mass flow rate. With A_o known, the coil BF can be determined for non-rated air flow rates.

For each simulation time step when the DX air conditioner operates to meet a cooling load, the total cooling capacity at the actual operating conditions is calculated using Equation 15.127 and the

coil bypass factor is calculated based on Equation 15.135. The coil bypass factor is used to calculate the operating sensible heat ratio (SHR) of the cooling coil using Equations 15.136 and 15.137.

$$h_{ADP} = h_{in} - \frac{(\dot{Q}_{total} / \dot{m})}{1 - BF} \quad (15.136)$$

$$SHR = Min \left(\left(\frac{h_{Tin,wADP} - h_{ADP}}{h_{in} - h_{ADP}} \right), 1 \right) \quad (15.137)$$

where:

h_{in} is the enthalpy of the air entering the cooling coil (J/kg)

h_{ADP} is the enthalpy of air at the apparatus dewpoint condition (J/kg)

$h_{Tin,wADP}$ is the enthalpy of air at the entering coil dry-bulb temperature and humidity ratio at ADP (J/kg)

\dot{m} is the air mass flow rate (kg/s).

With the SHR for the coil at the current operating conditions, the properties of the air leaving the cooling coil are calculated using the following equations:

$$h_{out} = h_{in} - \frac{\dot{Q}_{total} \cdot PLR}{\dot{m}} \quad (15.138)$$

$$h_{Tin,\omega out} = h_{in} - (1 - SHR)(h_{in} - h_{out}) \quad (15.139)$$

$$\omega_{out} = PsyWFnTdbH(T_{in}, h_{Tin,\omega out}) \quad (15.140)$$

$$T_{db,out} = PsyTdbFnHW(h_{out}, \omega_{out}) \quad (15.141)$$

where:

h_{out} is the enthalpy of the air leaving the cooling coil (J/kg)

$h_{Tin,\omega out}$ is the enthalpy of air at the entering coil dry-bulb temperature and leaving air humidity ratio (J/kg)

ω_{out} is the leaving air humidity ratio (kg/kg)

$T_{db,out}$ is the leaving air dry-bulb temperature (°C)

$PsyWFnTdbH$ is an EnergyPlus psychrometric function, returns humidity ratio given dry-bulb temperature and enthalpy

$PsyTdbFnHW$ is an EnergyPlus psychrometric function, returns dry-bulb temperature given enthalpy and humidity ratio.

15.2.4.3 Dry Coil Conditions

If the model determines that the cooling coil is dry ($\omega_{in} < \omega_{ADP}$), then Equations 15.127 and 15.128 are invalid since they are functions of entering wet-bulb temperature. Under dry-coil conditions, coil performance is a function of dry-bulb temperature rather than wet-bulb temperature. In this case, the model recalculates the performance of the DX cooling unit using the calculation procedure described above but with $\omega_{in} = \omega_{dry}$, where ω_{dry} is the inlet air humidity ratio at the coil dry-out point (SHR = 1.0).

15.2.4.4 SHR Calculation Using User Specified SHR Modifier Curves

This alternative SHR calculation method is based on user specified *SHR* modifying curves for temperature and flow fractions. The modifying curves correct the rated *SHR* value for a given DX cooling coil entering air temperatures and air mass flow fraction. These *SHR* modifying curves are optional additional curve inputs to the DX cooling coil objects. These two curves are a biquadratic *SHR* modifier curve for temperature (*SHRFT*), and a quadratic *SHR* correction curve for flow fraction (*SHRFFF*).

- Biquadratic *SHR* modifier normalized curve for DX cooling coil entering air (outdoor) wet-bulb and dry-bulb temperatures. The coil entering conditions can be outdoor air or pretreated outdoor air.
- Quadratic *SHR* modifier curve for flow fraction.

The SHR is given by:

$$SHR = SHR_{rated} \cdot SHRFT(T_{wb,i}, T_{db,i}) \cdot SHRFFF(FF) \quad (15.142)$$

The cooling coil outlet air enthalpy is given by:

$$h_{out} = h_{in} - \frac{\dot{Q}_{total}}{\dot{m}} \quad (15.143)$$

The cooling coil outlet air enthalpy at the coil inlet air temperature and coil outlet humidity ratio is given by:

$$h_{T_{in}\omega_{out}} = h_{in} - (1.0 - SHR) \frac{\dot{Q}_{total}}{\dot{m}} \quad (15.144)$$

The DX cooling coil outlet air humidity ratio is calculated from the psychometric function as follows:

$$\omega_{out} = PsyWFnTdbH(T_{db,i}, h_{T_{in}\omega_{out}}) \quad (15.145)$$

The DX cooling coils leaving humidity ratio cannot exceed the DX coil entering air humidity ratio. And for dry air condition entering the cooling coil, the above equation may yield unrealistic (in some cases negative values) coil outlet humidity ratio. In this case the coil outlet air humidity is set a small value as follows:

$$\omega_{out} = MIN(0.000010, \omega_{in}) \quad (15.146)$$

The DX cooling coil outlet air dry-bulb temperature is determined as follows:

$$T_{db,out} = PsyTdbFnHW(h_{out}, \omega_{out}) \quad (15.147)$$

where:

SHRFT is the sensible heat ratio modifier normalized biquadratic curve as a function of coil entering air wet-bulb and dry-bulb temperatures, (-). The DX cooling coil entering air temperature can be the outdoor air condition or pretreated outdoor air when the DX cooling coil is placed after an exhaust heat recovery heat exchangers.

SHR_{FFF} is the sensible heat ratio modifier normalized quadratic curve as a function of air mass flow fraction. Flow fraction is the ratio of actual to rated mass flow rate of air through the DX cooling coil (-).

SHR_{rated} is the sensible heat ratio at rated condition (-).

15.2.4.5 Condenser Options: AirCooled vs. EvaporativelyCooled

As described previously, this model can simulate the performance of air-cooled or evaporative-cooled DX air conditioners. The following paragraphs describe three modeling options.

If the user wants to model an air-cooled condenser, they should simply specify AirCooled in the field Condenser Type. In this case, the Total Cooling Capacity Modifier Curve (function of temperature) and the Energy Input Ratio Modifier Curve (function of temperature) (Equations 15.117 and 15.120 above) will utilize the outdoor dry-bulb temperature.

If the user wishes to model an evaporatively-cooled condenser AND they have performance curves that are a function of the wet-bulb temperature of air entering the condenser coil, then the user should specify Condenser Type = EvaporativelyCooled and the evaporative condenser effectiveness value should be entered as 1.0. In this case, the Total Cooling Capacity Modifier Curve (function of temperature) and the Energy Input Ratio Modifier Curve (function of temperature) (Equations 15.117 and 15.120 above) will utilize the outdoor wet-bulb temperature.

If the user wishes to model an air-cooled condenser that has evaporative media placed in front of it to cool the air entering the condenser coil, then the user should specify Condenser Type = EvaporativelyCooled. The user must also enter the appropriate evaporative effectiveness for the media. In this case, the Total Cooling Capacity Modifier Curve (function of temperature) and the Energy Input Ratio Modifier Curve (function of temperature) will utilize the condenser inlet air temperature as calculated below:

$$T_{c,i} = (T_{wb,o}) + (1 - EvapCondEffectiveness) (T_{db,o} - T_{wb,o}) \quad (15.148)$$

where

$T_{c,i}$ is the temperature of the air entering the condenser coil (°C)

$T_{wb,o}$ is the wet-bulb temperature of the outdoor air (°C)

$T_{db,o}$ is the dry-bulb temperature of the outdoor air (°C).

In this case, the Total Cooling Capacity Modifier Curve (function of temperature) and the Energy Input Ratio Modifier Curve (function of temperature) input fields for this object should reference performance curves that are a function of outdoor dry-bulb temperature. Be aware that the evaporative media will significantly reduce the dry-bulb temperature of the air entering the condenser coil, so the Total Cooling Capacity and EIR Modifier Curves must be valid for the expected range of dry-bulb temperatures that will be entering the condenser coil.

If an evaporatively-cooled condenser is modeled, the power requirements for the water pump are calculated as follows:

$$P_{evapcondpump} = \dot{Q}_{cap,evapcondpump} (RTF) \quad (15.149)$$

where:

$P_{evapcondpump}$ is the DX cooling coil evap condenser pump electric power (W)

$\dot{Q}_{cap,evapcondpump}$ is the evaporative condenser pump rated power consumption (W).

Water consumption for the evaporative-cooled condenser is calculated using the difference in air humidity level across the evaporative media and the condenser air mass flow rate:

$$V_{water} = \frac{\dot{m}_{air} (\omega_{evapcond,out} - \omega_{evapcond,in})}{\rho_{water}} (RTF) (TimeStepSys) (3600.) \quad (15.150)$$

where:

V_{water} is the DX cooling coil evap condenser water consumption (m³)

\dot{m}_{air} is the evaporative condenser air mass flow rate (kg/s)

$\omega_{evapcond,in}$ is the humidity ratio of outdoor air entering the evap condenser (kg/kg)

$\omega_{evapcond,out}$ is the humidity ratio of air leaving the evap condenser (kg/kg)

ρ_{water} is the density of water at the outdoor dry-bulb temperature (kg/m³)

$TimeStepSys$ is the HVAC system simulation time step (hr).

15.2.4.6 Condenser Inlet Air Temperature

The air temperature entering the outdoor condenser is based on the weather data used during a simulation. This temperature is either taken directly from the weather data, or can be adjusted based on the height of the outdoor condenser. The input for Condenser Air Inlet Node Name can be used to control this optional feature. If this input is left blank, the air temperature entering the condenser is based solely on the weather data. If this input is not blank, then the node name specified must also be listed in an OutdoorAir:Node or OutdoorAir:NodeList object. When the node name is listed in an OutdoorAir:NodeList object, the air temperature entering the condenser is based solely on the weather data. When the node name is listed in an OutdoorAir:Node object, the height of the node determines the air temperature entering the outdoor condenser (see description of Local Outdoor Air Temperature Calculation in the Atmospheric Variation section of this document for further details).

15.2.4.7 Supply Air Fan Control: Cycling vs. Continuous

The DX cooling coil model simulates two specific supply air fan operation modes: cycling fan, cycling compressor or continuous fan, cycling compressor. The first operation mode is frequently referred to as “AUTO fan”, where the compressor(s) and supply air fan operate in unison to meet the zone cooling load, and cycle off together when the cooling load has been met. The second operation mode is often referred to as “fan ON”, where the compressor(s) cycle on and off to meet the zone cooling load but the supply air fan operates continuously regardless of compressor operation.

Since this DX heating coil can only be used in conjunction with a DX cooling coil (i.e. heat pumps), and these coils are used in AC equipment that specifies a fan operation mode schedule (e.g. AirLoopHVAC:UnitaryHeatPump:AirToAir), the fan operation mode schedule value determines the fan operation mode for each time step throughout the simulation. A fan operation mode schedule value of 0 specifies AUTO fan mode operation while values other than 0 (a 1 is usually used) specify fan ON operation. The use of a schedule allows the fan operation mode to change based on time-of-day or with changes in season.

The EnergyPlus methodology for determining the impact that HVAC equipment has on an air stream is to calculate the mass flow rate and air properties (e.g., enthalpy, dry-bulb temperature, humidity ratio) exiting the equipment. These exiting conditions are passed along as inlet conditions to the next component model in the air stream. Eventually the flow rate and properties of the air being supplied to the conditioned zone are used in the zone energy balance to determine the resulting

zone air temperature and humidity ratio. With this methodology, the determination of the air mass flow rate and air properties for the two different supply air fan operation modes is slightly different.

Cycling Fan Mode:

For the case of cycling fan/cycling compressor when humidity control is not specified, the conditions of the air leaving the cooling coil are the steady-state values calculated using Equations 15.138, 15.140, and 15.141 above. However the air mass flow rate passed along to the next component (and eventually to the conditioned zone) is the average air mass flow rate for the system simulation time step (determined by the cooling system; see ZoneHVAC:WindowAirConditioner, AirLoopHVAC:Unitary:Furnace:HeatCool, AirLoopHVAC:UnitaryHeatCool, or AirLoopHVAC:UnitaryHeatPump:AirToAir).

For the case of cycling fan/cycling compressor when humidity control is specified, the conditions of the air leaving the cooling coil are calculated as the average conditions during the fan operating period. When the compressor operates in tandem with the fan (i.e., compressor part-load ratio [PLR] is equal to the fan PLR), the outlet conditions are identical to the calculations described above. When the compressor operates for a shorter duration than the fan (i.e., the compressor PLR is less than the heating/fan PLR), the air properties leaving the cooling coil are calculated as the average conditions during the fan operating period. In this case the calculation of exiting air conditions is analogous to the calculations for continuous fan mode described below except that PLR in the equations represents the ratio of the compressor to the fan operating period. For cycling fan systems, the fan will only operate longer than the compressor, and therefore latent degradation may be modeled (user input), when humidity control is specified, a moisture load exists (i.e., the zone air humidistat senses a moisture load), and a heating load exists where the heating PLR is greater than the cooling PLR.

Continuous Fan Mode:

For the case of continuous fan/cycling compressor, the air mass flow rate is constant. However, the air properties leaving the cooling coil are calculated as the average conditions during the system simulation time step. The model assumes that the exiting air conditions are the steady-state values calculated using Equations 15.138, 15.140, and 15.141 above when the compressor(s) operate. For the remainder of the system simulation time step, it is assumed that the air exiting the DX coil has the same properties as the air entering the coil. For this supply air fan operating strategy, the leaving air properties are calculated as follows:

$$h_{out,ContFanCycComp} = h_{out} (PLR) + h_{in} (1 - PLR) \quad (15.151)$$

$$\omega_{out,ContFanCycComp} = \omega_{out} (PLR) + \omega_{in} (1 - PLR) \quad (15.152)$$

$$T_{db,out,ContFanCycComp} = PsyTdbFnHW(h_{out,ContFanCycComp}, \omega_{out,ContFanCycComp}) \quad (15.153)$$

15.2.4.8 Latent Capacity Degradation

The latent (dehumidification) capacity of a direct-expansion (DX) cooling coil is strongly affected by part-load, or cyclic, operation. This is especially true in applications where the supply air fan operates continuously while the cooling coil cycles on and off to meet the cooling load. During constant fan operation, moisture condenses on the cooling coil when the compressor operates, but part or all of the moisture that is held by the coil evaporates back into the airstream when the

cooling coil is deactivated (Figure 15.7). The net effect is that the amount of moisture removed from the air is degraded at part-load conditions as compared to steady-state conditions when the compressor operates continuously (Figure 15.8).

EnergyPlus is able to model latent capacity degradation based on algorithms developed by Henderson and Rengarajan (1996). The model is applicable to single-stage cooling units, like residential and small commercial air conditioners or heat pumps with less than 19 kW of nominal cooling capacity. The model inputs are described in the EnergyPlus Input/Output Reference for the object Coil:Cooling:DX:SingleSpeed. The model is enabled only if the four numerical inputs are defined (values greater than zero, see IO Reference).

The following discussion applies to both cycling fan and continuous fan operation when the fan operates for a longer period of time than the compressor and air continues to flow over the moisture laden cooling coil after compressor operation has terminated.

Figure 15.7: Transient Sensible and Latent Capacity of a Cooling Coil Over an Operating Cycle

Figure 15.9 graphically depicts the latent degradation concepts and defines several key model parameters. After the cooling coil starts to operate, the coil temperature is eventually reduced below the dewpoint temperature of the entering air. Moisture from the air then builds on the surface of the coil until time t_o has elapsed and the total moisture mass on the coil is M_o . After this time (t_o), moisture begins to fall from the coil and all of the latent capacity provided by the coil is “useful” since this condensate is collected and removed from the unit. When the coil cycles off and the supply air fan continues to operate, the initial moisture mass buildup on the coil (M_o) evaporates back into the supply air stream. If the cooling coil cycles back on before all of the moisture has evaporated, then the time until the first condensate removal (t_o) is shorter for this cooling cycle since the coil is already partially wetted.

Figure 15.8: Field Data Showing the Net Impact of Part-Load Operation on Sensible Heat Ratio

Figure 15.9 also shows several parameters that are used in the latent degradation model. The ratio of the coil's moisture holding capacity (M_o) and the steady-state latent capacity (\dot{Q}_L) is defined as t_{wet} : the nominal time for moisture to fall from the coil (ignoring transient effects at startup and starting with a dry coil). The ratio of the initial moisture evaporation rate (\dot{Q}_e) and the steady-state latent capacity (\dot{Q}_L) is defined as γ . Both t_{wet} and γ at the rated air volume flow rate and temperature conditions are required model inputs. Two other model inputs are the Maximum ON/OFF Cycling Rate (cycles per hour, N_{max}) and the time constant (τ , in seconds) for the cooling coil's latent capacity to reach steady state after startup. The development of the latent degradation model is fully described by Henderson and Rengarajan (1996). The model implemented in EnergyPlus is for their "linear decay" evaporation model.

During the simulation, all of the steady-state calculations described previously in Equations 15.117 through 15.137 are completed. The latent degradation model then modifies the steady-state sensible heat ratio for the coil as shown below. The value of t_{wet} at the current air volume flow rate and entering air conditions is first calculated based on the rated value of t_{wet} entered by the user:

$$t_{wet} = \text{Minimum} \left(t_{wet,rated} \left(\frac{\dot{Q}_{latent,rated}}{\dot{Q}_{latent}} \right), t_{wet,max} \right) \quad (15.154)$$

where:

t_{wet} is the nominal time for condensate removal to begin at the current airflow and entering air conditions, starting with a dry coil (sec)

Figure 15.9: Concepts of Moisture Buildup and Evaporation

$t_{wet,rated}$ is the nominal time for condensate removal to begin at the coil's rated airflow and entering air conditions, starting with a dry coil (sec)

$\dot{Q}_{latent,rated}$ is the cooling coil latent capacity at the rated airflow and temperature conditions (W)

\dot{Q}_{latent} is the cooling coil latent capacity at the current airflow and temperature conditions (W)

$t_{wet,max}$ is the maximum allowed value for t_{wet} (9999.0 sec).

Likewise, the value of γ at the current air volume flow rate and entering air conditions is calculated based on the rated value of γ entered by the user:

$$\gamma = \gamma_{rated} \left(\frac{\dot{Q}_{latent,rated}}{\dot{Q}_{latent}} \right) \left(\frac{T_{db,i} - T_{wb,i}}{T_{db,rated} - T_{wb,rated}} \right) \quad (15.155)$$

where:

γ is the ratio of the initial moisture evaporation rate from the cooling coil (when the compressor first turns off, in Watts) and the coil's steady-state latent capacity (Watts) at the current air volume flow rate and entering air conditions

γ_{rated} is equal to γ at the rated air flow and entering air conditions

$T_{db,i}$ is the dry-bulb temperature of the air entering the cooling coil (°C)

$T_{wb,i}$ is the wet-bulb temperature of the air entering the cooling coil (°C)

$T_{db,rated}$ is the dry-bulb temperature of air entering the cooling coil at rated conditions (26.7°C)

$T_{wb,rated}$ is the wet-bulb temperature of air entering the cooling coil at rated conditions (19.4°C).

The cooling coil on and off times are then calculated based on the maximum number of cycles per hour and the calculated run-time fraction for the coil.

$$t_{on} = \frac{3600}{4N_{max}(1 - X)} \quad (15.156)$$

$$t_{off} = \frac{3600}{4N_{max}X} \quad (15.157)$$

where:

t_{on} is the duration of cooling coil on-cycle (sec)

N_{max} is the maximum on/off cycles per hour (cph)

X is the cooling coil runtime fraction (-)

t_{off} is the duration of cooling coil off-cycle (sec).

For cycling fan systems, the duration of the heating coil on and off cycles are also calculated. When the heating coil operates for a longer duration of time than the cooling coil, latent degradation can also occur. For this case, the off-cycle time (i.e., the amount of time the fan operates longer than the cooling coil) is recalculated and based on the difference between the heating coil on-cycle time and the cooling coil on-cycle time. t_{on} and t_{off} for the heating coil are calculated in the same manner as shown above except that the heating run-time fraction is used for the calculations. This model assumes that the cycling rate of the cooling and heating coils are the same. In addition, since the heating coil cycling rate may be different than the cooling coil (based on run-time fractions), the heating coil may also turn on again before the next cooling coil on-cycle. The following equations are used when the heating coil operates for a longer time period than does the cooling coil.

$$t_{on,heating} = \frac{3600}{4N_{max}(1 - X_{heating})} \quad (15.158)$$

$$t_{off,heating} = \frac{3600}{4N_{max}(X_{heating})} \quad (15.159)$$

$$t_{on,heating} = t_{on,heating} + MAX(0, MIN(t_{on,heating}, ((t_{on} + t_{off}) - (t_{on,heating} + t_{off,heating})))) \quad (15.160)$$

$$t_{off} = MIN(t_{off}, t_{on,heating} - t_{on}) \quad (15.161)$$

where:

$t_{on,heating}$ is the duration of heating coil on-cycle (sec)

$X_{heating}$ is the heating coil runtime fraction (-)

$t_{off,heating}$ is the duration of heating coil off-cycle (sec).

The equation for calculating the time t_o when moisture first begins to fall from the cooling coil is shown below, and is solved iteratively by EnergyPlus:

$$t_o^{j+1} = \gamma t_{off} - \left(\frac{\gamma^2}{4t_{wet}} \right) t_{off}^2 - \tau \left(e^{\frac{t_o^j}{\tau}} - 1 \right), \quad t_{off} \leq \left(\frac{2t_{wet}}{\gamma} \right) \quad (15.162)$$

where:

t_o is the time where condensate removal begins (sec)

τ is the latent capacity time constant at start-up (sec)

j is the iteration number.

The part-load latent heat ratio of the cooling coil is then calculated with t_o , t_{on} and τ , which is in turn used to calculate the “effective” sensible heat ratio of the cooling including part-load latent degradation effects.

$$\frac{LHR}{LHR_{ss}} = Maximum \left(\left(\frac{t_{on} - t_o}{t_{on} + \tau \left(e^{\left(\frac{-t_{on}}{\tau} \right)} - 1 \right)} \right), 0.0 \right) \quad (15.163)$$

$$SHR_{eff} = 1 - (1 - SHR_{ss}) \left(\frac{LHR}{LHR_{ss}} \right) \quad (15.164)$$

where:

LHR is the part-load latent heat ratio

LHR_{ss} is the latent heat ratio at steady-state conditions ($1 - SHR_{ss}$ with SHR_{ss} from Equation 15.137)

SHR_{eff} is the part-load sensible heat ratio ($SHR_{ss} \leq SHR_{eff} \leq 1.0$)

SHR_{ss} is the steady-state sensible heat ratio (from Equation 15.137).

With the “effective” SHR for the coil at the current operating conditions, including the impacts of latent degradation, Equations 15.138 through 15.141 are then used to calculate the properties of the air leaving the cooling coil when it operates. Finally, Equations 15.151 through 15.153 are used to calculate the average leaving air conditions (average when the coil is on and off) for the simulation time step.

15.2.4.9 Basin Heater For Single-Speed DX Coil

Calculations are also made to estimate the electric power input to the DX coil basin heater. A schedule may be used to disable the basin heater during regular maintenance periods or other time periods (e.g., during summer). If a schedule is not provided, the basin heater is assumed to be available the entire simulation time period. The basin heater operates when it is scheduled on, the outdoor air dry-bulb temperature is below the basin heater setpoint temperature, and the DX coil is not active. The user is required to enter a basin heater capacity (watts per degree Kelvin) and a heater setpoint temperature (°C) if they want to model basin heater electric power.

$$P_{basinheater} = \max(0.0, CAP_{basinheater} (T_{setpoint,basin} - T_{db,outdoor}) (1 - RTF)) \quad (15.165)$$

$$E_{basinheater} = (P_{basinheater})(TimeStepSys)3600 \quad (15.166)$$

where:

$P_{basinheater}$ is the DX coil basin heater electric power (W)

$E_{basinheater}$ is the DX coil basin heater electric consumption (J)

$T_{setpoint,basin}$ is the basin heater setpoint temperature (°C)

$T_{db,outdoor}$ is the outdoor air dry-bulb temperature (°C)

$CAP_{basinheater}$ is the basin heater capacity (W/K)

RTF is the run time fraction of DX cooling coil.

15.2.4.10 Special Calculations for Coil:Cooling:DX:TwoStageWithHumidityControlMode with CoilPerformance:DX:Cooling

The multimode DX coil uses 1 to 4 set of performance specifications which all feed into the main DX coil model as described above. The multimode DX coil may have 1 or 2 capacity stages and may have 1 enhanced dehumidification mode in addition to its “normal” or base mode performance. Any mode may specify that a portion of the total airflow is bypassed.

15.2.4.10.1 Bypass Operation

When a mode has coil bypass, the non-bypassed air flow fraction is used to model the DX coil performance as described above. Then the bypassed air stream is mixed with the conditioned air stream and these conditions are placed on the coil outlet node.

15.2.4.10.2 Multi-Stage Operation

Multi-stage control is modeled with the DX coil. If 2-stage operation has been specified, stage 1 is assumed to operate first and continue to operate if stage 2 is required. If latent degradation is active, only one of the stages will be degraded. If stage 1 operates for less than the full time step, then latent degradation is applied. If stage 2 operates, then stage 1 is running for the full time step and latent degradation is applied only to the portion of the latent load which is attributed to stage 2 operation.

15.2.4.10.3 Enhanced Dehumidification Mode

If enhanced dehumidification mode is available, this is controlled by the parent object of the DX coil, such as DXSystem:AirLoop. A dehumidification mode flag is passed to the coil model which is used to select a different set of performance specifications from a CoilPerformance:DX:Cooling input object. Then the simulation of the DX coil proceeds as described above including any bypass or multi-stage operation.

15.2.4.10.4 Subcool Reheat Mode

When 3 operation modes are entered in the Coil:Cooling:DX:CurveFit:Performance object with a parent as Coil:Cooling:DX, the coil is considered as a Subcool Reheat Coil and can perform normal DX coil operation alone, and combined sensible cooling and dehumidification simultaneously with combination of normal mode and subcool or reheat mode. Load sensible heat ratio (LoadSHR) ($\text{Zone Sensible Load} / (\text{Zone Sensible Load} + \text{Zone Latent Load})$) determines which mode operates.

The zone sensible and latent loads determine the coil delivered energy between system supply node and controlled zone node. Due to fan heat and outdoor air introduction, the coil inlet node conditions are not equal to ones at the controlled zone node. In other words, the requested coil output sensible heat ratio (CoilSHR) ($\text{Sensible Coil output} / (\text{Sensible Coil Output} + \text{Latent Coile Output})$) will be different from LoadSHR. The given LoadSHR needs to be converted into coil sensible heat ratio (CoilSHR), so that coil requested sensible and latent energy can be delivered correctly to control zone temperature and humidity ratio simultaneously.

CoilSHR calculation procedure

1. Get full system sensible and latent outputs in normal mode as SenSysOutput and LatSysOutput.

2. Since system outputs are proportional to part load ratio (PLR), sensible (SenPLR) and latent (LatPLR) part load ratios can be calculated below

$$\text{SenPLR} = \text{SenLoad} / \text{SenSysOutput}$$

$$\text{LatPLR} = \text{LatLoad} / \text{LatSysOutput}$$

3. At the same time, coil sensible and latent outputs across the coil are obtained in Step 2 as SenCoilOutput and LatCoilOutput.

4. If coil sensible and latent outputs are also proportional to the part load ratios, sensible (SenCoil) and latent (LatCoil) coil load at given part load ratios are calculated as

$$\text{SenCoil} = \text{SenPLR} * \text{SenCoilOutput}$$

$$\text{LatCoil} = \text{LatPLR} * \text{LatCoilOutput}$$

It should be pointed out that coil outputs at $\text{PLR} = 0$ are zero. In other words, both linear functions have zero value of the constant term.

5. Coil sensible heat ratio (CoilSHR) can be calculated as

$$\text{CoilSHR} = \text{SenCoil} / (\text{SenCoil} + \text{LatCoil})$$

After getting CoilSHR, coil performance can be calculated as follows

Simulation logic

1. No latent control

Perform normal operation with $\text{SHR}_{\text{Normal}}$ (See Coil:Cooling:DX:SingleSpeed object)

2. Latent control

- a. If $\text{CoilSHR} \geq \text{SHR}_{\text{Normal}}$

Perform normal operation to meet sensible load, adjusted by PLR for a single capacity equipment

$$\text{SenLoad} = \text{SenOut} * \text{PLR}$$

- b. Else if $\text{SHR}_{\text{Normal}} > \text{CoilSHR}$ And $\text{CoilSHR} \geq \text{SHR}_{\text{Sub}}$

Perform combination between normal and subcooling operation

$$\text{CoilSHR} = \text{SHR}_{\text{Sub}} * r_{\text{Sub}} + \text{SHR}_{\text{Normal}} * (1 - r_{\text{Sub}})$$

$$\text{SenLoad} = [\text{SenOut}_{\text{Sub}} * r_{\text{Sub}} + \text{SenOut}_{\text{Normal}} * (1 - r_{\text{Sub}})] * \text{PLR}$$

c. Else if $\text{SHR}_{\text{Sub}} > \text{CoilSHR}$ And $\text{CoilSHR} \geq \text{SHR}_{\text{Reheat}}$

Perform combination between normal and reheat operation

$$\text{CoilSHR} = \text{SHR}_{\text{Reheat}} * r_{\text{Reheat}} + \text{SHR}_{\text{Normal}} * (1 - r_{\text{Sub}})$$

$$\text{SenLoad} = [\text{SenOut}_{\text{Sub}} * r_{\text{Sub}} + \text{SenOut}_{\text{Normal}} * (1 - r_{\text{Sub}})] * \text{PLR}$$

Else

Performreheatg operation

$$\text{SenLoad} = \text{SenOut}_{\text{Reheat}} * \text{PLR}$$

End If

where

$\text{SHR}_{\text{Normal}}$ = Gross sensible heat ratio in normal mode

SHR_{Subl} = Gross sensible heat ratio in subcool mode

$\text{SHR}_{\text{Reheatl}}$ = Gross sensible heat ratio in reheat mode

r_{Sub} = Subcooling mode ratio between subcooling and normal operation

r_{Reheat} = Reheat mode ratio between hot gas reheat and normal operation

15.2.4.11 Standard Rating of Single-Speed DX Cooling Coils

For small single-speed direct expansion (DX) cooling coils, the industry standard ratings of Standard Rating Cooling Capacity and Seasonal Energy Efficiency Ratio (SEER) are calculated according to ANSI/AHRI Standard 210/240 (AHRI 2008). These ratings apply to unitary air conditioners and air-source unitary heat pumps with air-cooled condensers with standard rating cooling capacities under 19 kW (<65,000 Btu/hr). For larger DX cooling coils, the industry standard ratings of Standard Rating Cooling Capacity, Energy Efficiency Ratio (EER), and Integrated Energy Efficiency Ratio (IEER) are calculated according to ANSI/AHRI Standard 340/360 (AHRI 2007). These ratings apply to unitary air conditioners and air-source unitary heat pumps with standard rating cooling capacities from 19 kW to below 73.2 kW (65,000 Btu/hr to <250,000 Btu/hr).

For the Coil:Cooling:DX:SingleSpeed object in EnergyPlus, these standard ratings are not direct inputs to the model. However, these standard ratings can be calculated using user-entered information for the Coil:Cooling:DX:SingleSpeed object. Since users sometimes lump the performance of several smaller DX cooling units into a single larger cooling coil object for simulation purposes, EnergyPlus outputs the Standard Rating Cooling Capacity, SEER, EER, and IEER regardless of the magnitude of the standard rating cooling capacity of the coil. It is up to the user to determine which standard ratings are applicable to the cooling coil(s) they are modeling. These standard rating values are provided in the eplusout.eio output file (Ref. [OutputDetailsAndExamples.pdf](#)) and also in the predefined tabular output reports (Output:Table:SummaryReports object, Equipment Summary). Currently, the standard ratings are only calculated and output for single-speed DX cooling coils with air-cooled condensers. If the single-speed DX coling coil is specified with an evaporatively-cooled condenser, then no standard ratings are output from EnergyPlus at this time.

Note: The standard ratings described in this section require that the DX cooling coil model be evaluated at specific operating conditions (i.e., specific wet-bulb temperatures for air entering the cooling coil and dry-bulb temperatures for air entering the air-cooled [outdoor] condenser). If the cooling coil performance curves can not be evaluated at the required test conditions, then a standard rating value calculated at the curves limit will be output and a warning message will

written to eplusout.err. For example, if the curve object (Curve:Biquadratic) for Total Cooling Capacity Function of Temperature Curve has a minimum value of 21°C for dry-bulb temperature entering the air-cooled condenser coil, the IEER calculation requires that EER_D be calculated at 18.3°C – so, this would result in IEER calculated at user specified curve limit as an output and a warning message in the eplusout.err file.

The standard rating cooling capacity (AHRI 2007, AHRI 2008) is calculated as follows:

$$\dot{Q}_{StandardRating} = \dot{Q}_{Total,Rated} (TotCapTempModFac_{Rated}) (TotCapFlowModFac_{Rated}) - \left(FanPowerPerVolFlowRate \cdot \dot{V}_{Rated} \right) \quad (15.167)$$

where:

$\dot{Q}_{StandardRating}$ is the standard Rating (Net) Cooling Capacity (W)

$\dot{Q}_{Total,Rated}$ is the rated Total (Gross) Cooling Capacity, user input (W)

$TotCapTempModFac_{Rated}$ is the total Cooling Capacity Function of Temperature Curve evaluated with 19.44°C wet-bulb temperature air entering the cooling coil and 35.0°C dry-bulb temperature air entering the air-cooled (outdoor) condenser (dimensionless)

$TotCapFlowModFac_{Rated}$ is the total Cooling Capacity Function of Flow Fraction Curve evaluated at a flow fraction of 1.0 (dimensionless)

$FanPowerPerVolFlowRate$ is the rated Evaporator Fan Power Per Volume Flow Rate, user input (W/(m³/s))

\dot{V}_{Rated} is the rated Air Volume Flow Rate, user input (m³/s).

The Rated Evaporator Fan Power Per Volume Flow rate is a user-entered value, with a default of 773.3 W/(m³/s) if the user leaves this input field blank. The default value is taken from ANSI/AHRI Standards 210/240 and 340/360 where it is defined for systems which do not have a cooling coil fan furnished as part of the system (e.g., a DX cooling coil mounted in the ductwork downstream of a gas furnace where the furnace contains the fan used for air distribution across the gas heating coil and the downstream DX cooling coil). The test conditions in ANSI/AHRI Standards 210/240 and 340/360 vary the external static pressure (i.e., pressure drop associated with ductwork and other devices external to the indoor fan/coil section) seen by the supply air fan based on the standard rating cooling capacity. Note, however, that external static pressure in actual installations is typically much higher. Further details regarding indoor fan power per volume flow rate can be found in Walker and Lutz (2005) and Walker (2007), including differences between Permanent Split Capacitor (PSC) and Brushless Permanent Magnet (BPM) fan motors. Especially at the low external static pressures defined in the ANSI/AHRI Standards, BPM motors (e.g., Electronically Commutated Motors (ECMs)) can draw significantly less power (e.g., 50-75% less) than PSC motors.

The seasonal energy efficiency ratio (SEER) is calculated as follows:

$$SEER = PLF_{0.5} \cdot EER_{TestB} \quad (15.168)$$

$$EER_{TestB} = \frac{\dot{Q}_{Total,Net,TestB}}{Power_{Total,TestB}} \quad (15.169)$$

$$\begin{aligned}\dot{Q}_{Total,Net,TestB} &= \dot{Q}_{Total,Rated} (TotCapTempModFac_{TestB}) (TotCapFlowModFac_{Rated}) \\ &\quad - \left(FanPowerPerVolFlowRate \cdot \dot{V}_{Rated} \right)\end{aligned}\quad (15.170)$$

$$\begin{aligned}Power_{Total,TestB} &= \dot{Q}_{Total,Rated} (TotCapTempModFac_{TestB}) (TotCapFlowModFac_{Rated}) \cdot EIR_{TestB} \\ &\quad + \left(FanPowerPerVolFlowRate \cdot \dot{V}_{Rated} \right)\end{aligned}\quad (15.171)$$

$$EIR_{TestB} = \frac{1}{COP_{rated}} (EIRTempModFac_{TestB}) (EIRFlowModFac_{Rated}) \quad (15.172)$$

where:

$PLF_{0.5}$ is the part load fraction correlation curve evaluated at a part load ratio (PLR) of 0.5 (dimensionless)

EER_{TestB} is the energy efficiency ratio with 19.44°C wet-bulb temperature air entering the cooling coil, 27.78°C dry-bulb temperature air entering the air-cooled (outdoor) condenser, and rated air volume flow through the cooling coil (W/W)

$\dot{Q}_{Total,Net,TestB}$ is the net total cooling capacity with 19.44°C wet-bulb temperature air entering the cooling coil, 27.78°C dry-bulb temperature air entering the air-cooled (outdoor) condenser, and rated air volume flow through the cooling coil (W)

$TotCapTempModFac_{TestB}$ is the total cooling capacity function of temperature curve evaluated with 19.44°C wet-bulb temperature air entering the cooling coil and 27.78°C dry-bulb temperature air entering the air-cooled (outdoor) condenser (dimensionless)

$Power_{Total,TestB}$ is the total electric power (compressors, condenser fans and evaporator fan) with 19.44°C wet-bulb temperature air entering the cooling coil, 27.78°C dry-bulb temperature air entering the air-cooled (outdoor) condenser, and rated air volume flow through the cooling coil (W)

COP_{rated} is the Coefficient of Performance at rated conditions, user input (W/W)

$EIRTempModFac_{TestB}$ is the Energy Input Ratio function of temperature curve evaluated with 19.44°C wet-bulb temperature air entering the cooling coil and 27.78°C dry-bulb temperature air entering the air-cooled (outdoor) condenser (dimensionless)

$EIRFlowModFac_{Rated}$ is the Energy Input Ratio function of flow fraction curve evaluated at a flow fraction of 1.0 (dimensionless).

Energy Efficiency Ratio (EER) is another standard rating (AHRI 2007), and it is defined as the ratio of the total cooling capacity to the total power input at any given set of rating conditions, expressed in W/W (or Btu/W-h). For this class of air-cooled DX cooling coils, EER is calculated at rated test conditions as follows:

$$EER = \frac{\dot{Q}_{Standard\ Rating}}{Power_{Total,Rated}} \quad (15.173)$$

$$\begin{aligned}Power_{Total,Rated} &= \dot{Q}_{Total,Rated} (TotCapTempModFac_{Rated}) (TotCapFlowModFac_{Rated}) \cdot EIR_{Rated} \\ &\quad + \left(FanPowerPerVolFlowRate \cdot \dot{V}_{Rated} \right)\end{aligned}\quad (15.174)$$

$$EIR_{Rated} = \left(\frac{1}{COP_{Rated}} \right) (EIR_{TempModFac_{Rated}})(EIR_{FlowModFac_{Rated}}) \quad (15.175)$$

where:

EER is the Energy Efficiency Ratio (W/W)

$Power_{Total,Rated}$ is the total electric power (compressors, condenser fans and evaporator fan) with 19.44°C wet-bulb temperature air entering the cooling coil, 35.0°C dry-bulb temperature air entering the air-cooled (outdoor) condenser, and air flow rate across the evaporator at the Rated Air Volume Flow Rate (W).

$TotCapTempModFac_{Rated}$ is the total cooling capacity function of temperature curve evaluated with 19.44°C wet-bulb temperature air entering the cooling coil and 35.0°C dry-bulb temperature air entering the air-cooled (outdoor) condenser (dimensionless)

$EIR_{TempModFac_{Rated}}$ is the Energy Input Ratio function of temperature curve evaluated with 19.44°C wet-bulb temperature air entering the cooling coil and 35.0°C dry-bulb temperature air entering the air-cooled (outdoor) condenser (dimensionless).

The Integrated Energy Efficiency Ratio (IEER) is intended to be a measure of merit for the cooling coil's part-load efficiency. IEER replaced Integrated Part-Load Value (IPLV) as the part-load performance metric in Std. 340/360 as of January 1, 2010. Full details regarding the IEER calculation are available in ANSI/AHRI Std. 340/360 (AHRI 2007). A summary of the IEER calculations made by EnergyPlus for single-speed air-cooled DX cooling coils is provided below:

$$IEER = (0.02 \cdot EER_A) + (0.617 \cdot EER_B) + (0.238 \cdot EER_C) + (0.125 \cdot EER_D) \quad (15.176)$$

where,

EER_A is the EER at 100% net capacity at AHRI standard rating conditions (same as EER calculation shown above)

EER_B is the EER at 75% net capacity and reduced outdoor air temperature

EER_C is the EER at 50% net capacity and reduced outdoor air temperature

EER_D is the EER at 25% net capacity and reduced outdoor air temperature.

$$EER_{B-D} = \frac{LF \cdot \dot{Q}_{Total,Net,PartLoad}}{Power_{Total,PartLoad}} \quad (15.177)$$

$$Power_{Total,PartLoad} = LF (C_D \cdot Power_{CompCondFan,PartLoad}) + \left(FanPowerPerVolFlowRate \cdot \dot{V}_{Rated} \right) \quad (15.178)$$

$$Power_{CompCondFan,PartLoad} = \dot{Q}_{Total,Rated} (TotCapTempModFac_{PartLoad}) \cdot (TotCapFlowModFac_{Rated}) \cdot EIR_{PartLoad} \quad (15.179)$$

$$EIR_{PartLoad} = \left(\frac{1}{COP_{Rated}} \right) (EIR_{TempModFac_{PartLoad}})(EIR_{FlowModFac_{Rated}}) \quad (15.180)$$

where:

$\dot{Q}_{Total,Net,PartLoad}$ is the net total cooling capacity with 19.44°C wet-bulb temperature air entering the cooling coil rated air volume flow through the cooling coil (W). The dry-bulb temperature of air entering the air-cooled condenser varies (B = 27.5°C, C = 20.0°C, D = 18.3°C).

$Power_{Total,PartLoad}$ is the total electric power (compressors, condenser fans and evaporator fan) with 19.44°C wet-bulb temperature air entering the cooling coil and air flow rate across the evaporator at the Rated Air Volume Flow Rate (W). The dry-bulb temperature of air entering the air-cooled condenser varies (B = 27.5°C, C = 20.0°C, D = 18.3°C).

$Power_{CompCondFan,PartLoad}$ is the electric power of the compressor and condenser fan at the various part-load ratios, with 19.44°C wet-bulb temperature air entering the cooling coil and rated supply air volume flow rate (W). The dry-bulb temperature of air entering the air-cooled condenser varies per the part-load ratio (B = 27.5°C, C = 20.0°C, D = 18.3°C).

$EIRTempModFac_{PartLoad}$ is the Energy Input Ratio function of temperature curve evaluated with 19.44°C wet-bulb temperature air entering the cooling coil and dry-bulb temperature of air entering the air-cooled condenser corresponding to the reduced part-load ratio (B = 27.5°C, C = 20.0°C, D = 18.3°C) (dimensionless).

C_D is the degradation coefficient to account for cycling of the compressor = $1.13 - 0.13LF$

LF is the fractional “on” time at the desired load point.

The load factor (LF) is the fractional “on” time for the desired reduced load points (75%, 50%, or 25%) calculated from the following equation:

$$LF = \frac{\left(\frac{\% \text{ Load}}{100}\right) \cdot \dot{Q}_{StandardRating}}{\dot{Q}_{Total,Net,PartLoad}} \quad (15.181)$$

where %Load is the part-load operating points, i.e., 75% (B), 50% (C), 25% (D).

The calculations for $\dot{Q}_{Total,Net,PartLoad}$ and $Power_{Total,PartLoad}$ are calculated in nearly the same way as $\dot{Q}_{Total,Net,TestB}$ and $Power_{Total,TestB}$ are calculated for SEER (defined above). The only difference is that these cooling capacity and power values, used for calculating $EER_B/EER_C/EER_D$ for IEER, are calculated for a series of dry-bulb temperatures of air entering the air-cooled condenser (B = 27.5°C, C = 20.0°C, D = 18.3°C) and part-load performance degradation correction is also applied to the condensing unit electric power calculation.

15.2.4.12 ANSI/ASHRAE 127 - Standard Ratings of Single-Speed DX Cooling Coils

For computer and data processing room unitary air conditioners single-speed direct expansion (DX) cooling coils, the standard ratings net total cooling capacity and total cooling electric power inputs are calculated according to ANSI/AHRI Standard 127 (ASHRAE 2012). These ratings apply to unitary air conditioners with air-cooled. If the single-speed DX cooling coil is specified with an evaporatively-cooled condenser, then no standard ratings are output from EnergyPlus at this time. These standard ratings are not direct inputs to the model. However, these standard ratings can be calculated using user-entered information for the Coil:Cooling:DX:SingleSpeed object. These standard rating values are provided in the eplusout.eio output file and also in the predefined tabular output reports (Output:Table:SummaryReports object, Equipment Summary).

Note: The standard ratings described in this section require that the DX cooling coil model be evaluated at sixteen different test conditions (i.e., specific wet-bulb temperatures for air entering the cooling coil and dry-bulb temperatures for air entering the air-cooled [outdoor] condenser) for each

of the four standard tests and four application classes (ASHRAE – 2012). The four test conditions: A, B, C and D are provided in the ANSI/ASHRAE Standard 127. And the test conditions are different for each application classes described in the standard. In total sixteen performance data of net cooling capacity and total electric power inputs are reported. The total cooling electric power includes the supply fan power.

Rated Cooling Tests					
	Application Class	A	B	C	D
Tdb, Indoor	Class 1	23.9°C(75.0°F)	23.9°C(75.0°F)	23.9°C(75.0°F)	23.9°C(75.0°F)
	Class 2	29.4°C(85.0°F)	29.4°C(85.0°F)	29.4°C(85.0°F)	29.4°C(85.0°F)
	Class 3	35.0°C(95.0°F)	35.0°C(95.0°F)	35.0°C(95.0°F)	35.0°C(95.0°F)
	Class 4	40.5°C(105°F)	40.5°C(105°F)	40.5°C(105°F)	40.5°C(105°F)
Tdp, Indoor		35.0°C(95.0°F)	26.7°C(80.0°F)	18.3°C(65.0°F)	4.4°C(40.0°F)
Tdb, Outdoor		35.0°C(95.0°F)	26.7°C(80.0°F)	18.3°C(65.0°F)	4.4°C(40.0°F)

The standard rating net total cooling capacity is calculated as follows:

$$\dot{Q}_{StandardRating} = \dot{Q}_{TotalRated} (\text{TotCapTempModFac}_{Rated}) (\text{TotCapFlowModFac}_{Rated}) - \left(\text{FanPowerPerVolFlowRate} \cdot \dot{V}_{Rated} \right) \quad (15.182)$$

where:

$\dot{Q}_{StandardRating}$ is the standard rating (net) cooling capacity (W)

$\dot{Q}_{Total,Rated}$ is the rated Total (Gross) Cooling Capacity, user input (W)

$\text{TotCapTempModFac}_{Rated}$ is the total cooling capacity function of temperature curve evaluated at wet-bulb temperature of air entering the cooling coil and dry-bulb temperature of air entering the air-cooled (outdoor) condenser (dimensionless)

$\text{TotCapFlowModFac}_{Rated}$ is the total cooling capacity function of flow fraction curve evaluated at a flow fraction of 1.0 (dimensionless)

$\text{FanPowerPerVolFlowRate}$ is the rated evaporator fan power per volume flow rate, user input (W/(m³/s))

\dot{V}_{Rated} is the rated air volume flow rate, user input (m³/s).

The standard rating net total cooling electric power input is calculated as follows:

$$\text{Power}_{Total} = \left[\dot{Q}_{Total,Rated} (\text{TotCapTempModFac}) (\text{TotCapFlowModFac}_{Rated}) \right] \cdot \text{EIR} + (\text{FanPowerPerVolFlowRate} \cdot \dot{V}_{Rated}) \quad (15.183)$$

$$\frac{\text{EIRTempModFacEIRFlowModFac}_{Rated}}{COP_{Rated}} \quad (15.184)$$

where:

EER is the Energy efficiency ratio at wet-bulb temperature of air entering the cooling coil, dry-bulb temperature of air entering the air-cooled (outdoor) condenser, and rated air volume flow through the cooling coil (W/W)

TotCapTempModFac is the total cooling capacity function of temperature curve evaluated at the test condition of wet-bulb temperature of air entering the cooling coil and dry-bulb temperature of air entering the air-cooled (outdoor) condenser (dimensionless)

Power_{Total} is the total electric power (compressors, condenser fans and evaporator fan) at the test conditions of wet-bulb temperature of air entering the cooling coil, and dry-bulb temperature of air entering the air-cooled (outdoor) condenser, and rated air volume flow through the cooling coil (W)

COP_{Rated} is the Coefficient of Performance at rated conditions, user input (W/W)

EIRTempModFac is the Energy Input Ratio function of temperature curve evaluated at the test condition of wet-bulb temperature of air entering the cooling coil and dry-bulb temperature of air entering the air-cooled (outdoor) condenser (dimensionless)

EIRFlowModFac_{Rated} is the Energy Input Ratio function of flow fraction curve evaluated at a flow fraction of 1.0 (dimensionless).

15.2.4.13 Basin Heater For Two-Stage DX Coil

Basin heater for the object Coil:Cooling:DX:TwoStageWithHumidityControlMode operates in the same manner as for Coil:Cooling:DX:SingleSpeed. Refer to the “Basin Heater For Single-Speed DX Coil” description above.

If the number of capacity stages is equal to 1 and the CondenserType for that stage is Evap-Cooled, then the basin heater power is calculated for (1 - RunTimeFractionStage1) of DX coil.

If the number of capacity stages is greater than 1, then

1. If the CondenserType for stage 1 is EvapCooled, then the basin heater power is calculated for (1 - RunTimeFractionStage1) of DX coil
2. Elseif the CondenserType for stage 2 is EvapCooled, then the basin heater power is calculated for (1 - RunTimeFractionStage2) of DX coil.

15.2.5 Multi-Speed Electric DX Air Cooling Coil

15.2.5.1 Overview

This model (object name Coil:Cooling:DX:MultiSpeed) simulates the performance of an air-to-air direct expansion (DX) cooling system. The main difference compared to the other cooling coil models, such as Coil:Cooling:DX:SingleSpeed, is that this cooling coil allows modeling of two to four discrete compressor speeds. Each speed has a set of corresponding performance information at rated conditions along with curve fits for variations in total capacity, SHR, energy input ratio and part-load fraction to determine the performance of the unit at part-load conditions (DOE 1982). The full load supply airflow rate is dependent on the speed number and provided by its parent object (Ref. AirLoopHVAC:UnitaryHeatPump:AirToAir:MultiSpeed). The part-load impact on coil energy use is automatically applied to the lowest speed. A choice is provided to determine whether part-load impacts on coil energy use are applied when the coil is operating at speeds greater than speed 1.

This model simulates the thermal performance of the indoor DX cooling coil, and the power consumption of the outdoor unit (multispeed compressor, fans, and crankcase heaters). The performance of the indoor supply air fan varies widely from system to system depending on control strategy (e.g., constant fan vs. AUTO fan), fan type, fan motor efficiency and pressure losses through the air distribution system. Therefore, this DX system model does not account for the thermal effects or electric power consumption of the indoor supply air fan. EnergyPlus contains separate models for simulating the performance of various indoor fan configurations, and these models can be easily linked with the DX system model described here to simulate the entire DX system being considered. For the time being, this coil model can only be called by the parent object AirLoopHVAC:UnitaryHeatPump:AirToAir:MultiSpeed.

When the model determines performance at Speed 1 (the lowest speed) or cycling between OFF and Speed 1, its performance is almost the same as the performance for the Coil:Cooling:DX:SingleSpeed model. However, the outlet conditions are calculated slightly differently. Therefore, the Coil:Cooling:DX:SingleSpeed model may be considered as a subset of the model described here. When the multispeed coil model determines performance at higher

speeds (above 1), the model linearly interpolates the performance at two consecutive speeds (n-1 and n) as needed to meet the cooling load, with the fraction of time at each speed established by the speed ratio.

When single mode operation is specified at higher speeds (above 1), defined in the UnitarySystemPerformance:Multispeed object, a child object of AirLoopHVAC:UnitarySystem, its performance is almost the same as the performance for the Coil:Cooling:DX:SingleSpeed model at different flow rate and capacity with given speed number. No linear interpolation is performed between two adjacent speeds. The highest speed which does not exceed the sensible load is used for each HVAC timestep. This operation does not apply to speed 1 operation and the case when the sensible load is above the highest sensible capacity.

15.2.5.2 Model Inputs

The model inputs are also very similar to the inputs of the Coil:Cooling:DX:SingleSpeed object. The main difference is that this multispeed model requires a set of fields at each speed, such as rated capacity, rated SHR, rated COP, two capacity modifiers, two energy input ratio modifiers, part-load correction, and latent degradation inputs. The inputs also include waste heat fraction at the rated conditions and modifier as a function of temperature to calculate recoverable waste heat for heat recovery, which are not available in the similar Coil:Cooling:DX:SingleSpeed object

15.2.5.3 Speed 1 Operation

The calculation procedures in this model, including defrost and crankcase heater, are identical to the Coil:Heating:DX:SingleSpeed object (Ref: Coil:Heating:DX:SingleSpeed) with one exception: outlet node condition calculation when the supply air fan operates continuously (i.e., supply air fan operating mode schedule value is not equal to 0; Ref. AirLoopHVAC:UnitaryHeatPump:AirToAir:MultiSpeed).

The following procedure provides the detailed description of the exception.

- Total delivered cooling capacity

The total delivered cooling capacity for speed 1 operating at the cycling ratio needed to meet the requested cooling load is:

$$Q_{coil,cycling} = \dot{m}_{Speed1} * CycRatio * (h_{inlet} - h_{outlet,full}) \quad (15.185)$$

where:

$Q_{coil,cycling}$ is the delivered total cooling capacity for Speed 1 operating at a specific cycling ratio (W)

\dot{m}_{Speed1} is the air mass flow rate through cooling coil at Speed 1 as set by the parent object (kg/s)

$h_{outlet,full}$ is the specific enthalpy of the coil outlet air during full-load operation at Speed 1 (no cycling) (J/kg)

h_{inlet} is the specific enthalpy of the coil inlet air (J/kg)

$CycRatio$ is the cycling ratio at Speed 1, ratio of requested heating load to the full-load capacity of the coil at Speed 1 (dimensionless).

It is assumed that the coil provides no cooling capacity when the coil is OFF, even if the supply air fan continues to operate.

- Outlet air specific enthalpy

The average specific enthalpy of the coil outlet air is then calculated based on the total delivered cooling capacity and the average air mass flow rate entering the coil:

$$h_{outlet,average} = h_{inlet} - \frac{Q_{coil,cycling}}{\dot{m}_{inlet}} \quad (15.186)$$

where

$h_{outlet,average}$ is the averaged specific enthalpy at the coil outlet (J/kg)

h_{inlet} is the specific enthalpy at the coil inlet (J/kg)

$Q_{coil,cycling}$ is the total capacity at full load (W)

\dot{m}_{inlet} is the mass flow rate at the inlet to the coil as established by the parent object (Ref. AirLoopHVAC:UnitaryHeatPump:AirToAir:MultiSpeed, Mass Flow Rate Calculation). This flow rate is the average value determined by the parent object, accounting for the specified flow rate when the cooling coil is ON and the specified flow rate when the cooling coil is OFF for the time step being simulated.

- Sensible capacity

The minimum humidity ratio (HR_{min}) is based on humidity ratios between inlet and full load outlet as:

$$HR_{min} = Minimum(HR_{inlet}, HR_{full}) \quad (15.187)$$

where

HR_{inlet} is the humidity ratio at the inlet (kg/kg)

HR_{full} is the full load humidity ratio at the outlet (kg/kg).

The coil sensible capacity may be calculated as:

$$Q_{coil,sens} = \dot{m}_{Speed1} * CycRatio * [h_{inlet}(T_{inlet}, HR_{min}) - h_{outlet,full}(T_{outlet,full}, HR_{min})] \quad (15.188)$$

where:

$Q_{coil,sens}$ is the delivered sensible cooling capacity (W)

$h_{outlet,full}$ is the full load specific enthalpy at the coil outlet as a function of outlet dry-bulb temperature at the full load, and the minimum humidity ratio (J/kg)

h_{inlet} is the specific enthalpy at the coil inlet (J/kg).

- Latent capacity

The latent capacity is the difference between total and sensible capacities

$$Q_{coil,latent} = Q_{coil,cycling} - Q_{coil,sens} \quad (15.189)$$

where $Q_{coil,latent}$ is the delivered latent cooling capacity (W).

- Average outlet air humidity ratio

The averaged outlet HR can be calculated as:

$$HR_{outlet,average} = HR_{inlet} - \frac{Q_{coil,latent}}{\lambda \dot{m}_{inlet}} \quad (15.190)$$

where λ is the heat of vaporization as a function of HR_{min} and $CycRatio * T_{outlet,full} + (1 - CycRatio) * T_{inlet}$ (J/kg).

- Average outlet air temperature

Using the above averaged outlet humidity ratio and specific enthalpy, the averaged outlet temperature can be calculated using the psych function of `PsyTdbFnHW`.

The main reason using the above approach is that outlet conditions are calculated in the same way in low and high speed operation.

The crankcase heater defined for this DX cooling coil is enabled during the time that the compressor is not running for either heating or cooling. The crankcase heater power use from either heating or cooling is reported in the heating coil (`Coil:Heating:DX:MultiSpeed`).

15.2.5.4 Higher Speed Operation

This section describes how higher speed operation is simulated. When the required sensible load is less than the full load sensible capacity at Speed n (Speed Number > 1), the following calculations are performed:

- Bypass factor at Speed n-1 and Speed n

$$BypassFactor_n = f(RatedBypassFactor_n, RatedFlowRate_n, ActualFowRate_n) \quad (15.191)$$

$$BypassFactor_{n-1} = f(RatedBypassFactor_{n-1}, RatedFlowRate_{n-1}, ActualFowRate_{n-1}) \quad (15.192)$$

where:

$BypassFactor_i$ is the bypass factor at actual flow rate conditions at Speed i (dimensionless)

$RatedBypassFactor_i$ is the bypass factor at the rated conditions at Speed i (dimensionless)

$RatedFowRate_i$ is the air mass flow rate at the rated conditions at Speed i (kg/s)

$ActualFowRate_i$ is the actual air mass flow rate at Speed i (kg/s)

i is Speed n or Speed n-1.

The bypass factor at Speed n is a function of the bypass factor at the rated conditions, rated airflow rate, and actual flow rate at Speed n. The calculation is performed by a function, called `AdjustCBF` in the `DXCoil` module.

- Total capacity at Speed n-1 and Speed n

$$TotCap_{n-1} = f(RatedCap_{n-1}, TotCapTempModFac_{n-1}, TotCapFlowModFac_{n-1}, BypassFactor_{n-1}) \quad (15.193)$$

$$TotCap_n = f(RatedCap_n, TotCapTempModFac_n, TotCapFlowModFac_n, BypassFactor_n) \quad (15.194)$$

where

TotCap_i is the total cooling capacity at given temperatures and flow rates at Speed i (W)

RatedCap_i is the cooling capacity at the rated conditions at Speed i (W)

TotCapTempModFac_i is the total cooling capacity modifier as a function of indoor wet-bulb temperature and outdoor air dry-bulb temperature at Speed i

TotCapFlowModFac_i is the total cooling capacity modifier as a function of the ratio of the actual flow rate across the cooling coil to the rated airflow rate at Speed i

i is Speed n or Speed n-1.

The calculation is performed by a subroutine, called CalcTotCapSHR in the DXCoil module.

- EIR at Speed n-1 and Speed n

$$EIR_{n-1} = RatedEIR_{n-1} * EIRTempModFac_{n-1} * EIRFlowModFac_{n-1} \quad (15.195)$$

$$EIR_n = RateEIR_n * EIRTempModFac_n * EIRFlowModFac_n \quad (15.196)$$

where:

EIR_i is the energy input ratio at given temperatures and flow rates at Speed i (W)

RatedEIR_i is the energy input ratio at the rated conditions at Speed i (W)

EIRTempModFac_i is the energy input ratio modifier as a function of indoor and outdoor air dry-bulb temperature at Speed i

EIRFlowModFac_i is the energy input ratio modifier as a function of ratio of the actual flow rate across the heating coil to the rated airflow rate at Speed i

i is n or n-1.

- Full load outlet conditions at Speed n-1 and Speed n

The calculation procedure of full load outlet conditions at Speed n-1 and Speed n is the same as the calculation procedure used in the Coil:Cooling:DX:SingleSpeed model (Ref. Coil:Cooling:DX:SingleSpeed). The difference is that the outlet conditions at Speed n-1 are calculated based on the total cooling capacity and mass flow rate at Speed n-1, while the outlet conditions at Speed n are calculated based on the total cooling capacity and mass flow rate at Speed n.

- Effective total cooling capacity

$$Q_{coil,SpeedRatio} = (SpeedRatio)\dot{m}_{Speed,n}(h_{inlet} - h_{outlet,FullSpeed\ n}) + (1 - SpeedRatio)\dot{m}_{Speed,n-1}(h_{inlet} - h_{outlet,FullSpeed\ n-1}) \quad (15.197)$$

where:

$Q_{coil,SpeedRatio}$ is the delivered sensible cooling capacity at a given speed ratio between two consecutive speeds (W)

$\dot{m}_{Speed,n}$ is the air mass flow rate through cooling coil at Speed n as set by the parent object (kg/s)

$\dot{m}_{Speed,n-1}$ is the air mass flow rate through cooling coil at Speed 1 as set by the parent object (kg/s)

h_{inlet} is the specific enthalpy at the coil inlet (J/kg)

$h_{outlet,FullSpeed\ n}$ is the full load specific enthalpy at the coil outlet at Speed n (J/kg)

$h_{outlet,FullSpeed\ n-1}$ is the full load specific enthalpy at the coil outlet at Speed n-1 (J/kg).

- Average outlet air specific enthalpy

$$h_{outlet,average} = h_{inlet} - \frac{Q_{coil,SpeedRatio}}{\dot{m}_{inlet}} \quad (15.198)$$

where:

$h_{outlet,average}$ is the averaged specific enthalpy at the coil outlet (J/kg)

h_{inlet} is the specific enthalpy at the coil inlet (J/kg)

\dot{m}_{inlet} is the mass flow rate at the inlet to the coil as established by the parent object (Ref. AirLoopHVAC:UnitaryHeatPump:AirToAir:MultiSpeed, Mass Flow Rate Calculation). This flow rate is the average value determined by the parent object, accounting for the specified flow rate when the heating coil is at Speed n and the specified flow rate when the heating coil is at Speed n-1 for the time step being simulated.

- Effective sensible cooling capacity

The minimum humidity ratio (HR_{min}) is calculated as:

$$HR_{min} = Minimum[HR_{inlet}, (SpeedRatio)HR_{full,n} + (1.0 - SpeedRatio)HR_{full,n-1}] \quad (15.199)$$

The effective sensible cooling capacity is expressed as:

$$Q_{coil,sens} = \dot{m}_{Speed,n}(SpeedRatio)[h_{inlet}(T_{inlet}, HR_{min}) - h_{outlet,FullSpeed,n}(T_{outlet,n}, HR_{min})] + \dot{m}_{Speed,n-1}(1 - SpeedRatio)[h_{inlet}(T_{inlet}, HR_{min}) - h_{outlet,FullSpeed,n-1}(T_{outlet,n-1}, HR_{min})] \quad (15.200)$$

where:

$Q_{coil,sens}$ is the effective sensible cooling capacity (W)

$h_{outlet,FullSpeed,n}$ is the full load specific enthalpy at the coil outlet at Speed n as a function of outlet dry-bulb temperature at the full load, and the minimum humidity ratio (J/kg)

$h_{outlet,FullSpeed,n-1}$ is the full load specific enthalpy at the coil outlet at Speed n-1 as a function of outlet dry-bulb temperature at the full load, and the minimum humidity ratio (J/kg)

h_{inlet} is the specific enthalpy at the coil inlet (J/kg).

- Average outlet air humidity ratio and temperature

The effective latent cooling capacity is the difference between the total and sensible capacity:

$$Q_{coil,latent} = Q_{coil,SpeedRatio} - Q_{coil,sens} \quad (15.201)$$

where $Q_{coil,latent}$ is the effective latent cooling capacity (W).

The average outlet air HR can be calculated as:

$$HR_{outlet,average} = HR_{inlet} - \frac{Q_{coil,latent}}{\lambda \dot{m}_{inlet}} \quad (15.202)$$

where λ is the heat of vaporization as a function of HR_{min} and $SpeedRatio * T_{outlet,n} + (1 - SpeedRatio) * T_{outlet,n-1}$ (J/kg).

At the given averaged outlet humidity ratio and specific enthalpy, the averaged outlet temperature can be calculated using the psych function of `PsyTdbFnHW`.

- Calculate combined energy input

When the input for the field 'Apply Part Load Fraction to Speeds Greater than 1' is No in the object (equivalent to a single compressor), the combined energy output is calculated as follows:

$$CoolingPower = (TotCap_n)(EIR_n)(SpeedRatio) + (TotCap_{n-1})(EIR_{n-1})(1.0 - SpeedRatio) \quad (15.203)$$

When the input for the field 'Apply Part Load Fraction to Speeds Greater than 1' is Yes in the object (equivalent to multiple compressors), the combined energy output is calculated as follows:

$$CoolingPower = (TotCap_n)(EIR_n)(RTF) + (TotCap_{n-1})(EIR_{n-1})(1.0 - RTF) \quad (15.204)$$

where $CoolingPower$ is the power used (W) and RTF is the run time fraction at Speed n .

- Latent degradation

When the supply fan operation mode is `ContinuousFanWithCyclingCompressor` and the input of the `Apply Latent Degradation to Speeds Greater than 1` is Yes, the latent degradation is included at Speed n . The calculation procedure is the same as one in the `Coil:Cooling:DX:SingleSpeed` object. The difference is that the rated values and run time fraction at Speed n are used. The adjusted SHR is used to calculate full load outlet conditions at Speed n .

It is expected to have less latent degradation at Speed n than Speed 1. Therefore, smaller values of the latent degradation inputs at Speed n than those at Speed 1 are recommended.

- Crankcase heater

There is no power need at higher speed operation.

15.2.5.5 Higher Speed Operation with Single Mode Operation

This section describes how higher speed operation is simulated with single mode operation. When the required sensible load is less than the full load sensible capacity at Speed n (Speed Number > 1), its performance is almost the same as the performance for the Coil:Cooling:DX:SingleSpeed model at different flow rate and capacity with given Speed n . No linear interpolation is performed between two adjacent speeds.

15.2.5.6 Waste heat calculation

The waste heat generated by this coil object is calculated as:

$$\dot{Q}_{WasteHeat} = (Fraction)(TempModifier)(CoolingPower) \quad (15.205)$$

where Fraction is the rated waste heat fraction of the energy input and TempModifier is the waste heat modifier as a function of indoor and outdoor air dry-bulb temperature.

15.2.5.7 Basin Heater For Multi-Speed DX Coil

Basin heater for the object Coil:Cooling:DX:MultiSpeed operates in the same manner as for Coil:Cooling:DX:SingleSpeed. Refer to the Basin Heater For Single-Speed DX Coil description above.

15.2.5.8 Standard Rating of Multi-Speed DX Cooling Coils

For multi-speed direct expansion cooling coils, the industry standard ratings of Standard Rating Seasonal Energy Efficiency Ratio (SEER) are calculated according to ANSI/AHRI Standard 210/240 (AHRI 2008). These standard ratings can be calculated using the user-entered information for the Coil:Cooling:DX:MultiSpeed object. According to Standard 210/240, the Standard Rating SEER applies to air-to-air unitary heat pumps and air conditions with rated cooling capacities under 19,000 Watts ($< 65,000$ Btu/h). The Cooling Mode Test Conditions for Units Having two-capacity Compressor standard tests A_2 , B_2 , B_1 , and F_1 are also provided in Table 15.6. Cooling Mode Test Conditions for Units Having a Two-Capacity Compressor. The equations required to calculate the net cooling capacity and SEER value are described next.

15.2.5.9 Standard Rating Cooling Capacity

The standard net cooling capacity of multi-speed DX cooling coil is reported at the maximum speed and full load A2 test condition only. The Standard Rating (Net) Cooling Capacity calculation is the same as single speed DX cooling coil procedure when calculated at maximum speed. The procedure for calculating the Standard Rating Cooling Capacity is given by:

$$\dot{Q}_{StandardRating} = \dot{Q}_{T,CRated}^{k=2} \cdot CAPFT_{TestA2}^{k=2} \cdot CAPFF_{TestA2}^{k=2} \quad (15.206)$$

$$\dot{Q}_{StandardRatingNet} = \dot{Q}_{StandardRating} - FanPower_{CRated} \quad (15.207)$$

$$FanPower_{CRated} = FanPowerPerVolFlowRate^{k=2} \cdot \dot{V}_{CRated}^{k=2} \quad (15.208)$$

where:

$\dot{Q}_{StandardRating\ Net}$ is the total standard (**net**) cooling capacity (W) of the air-conditioning or heat pump equipment in cooling mode determined from ANSI/AHRI Standard 210/240 and A2 test conditions shown in Table 15.6. The standard cooling test conditions for air-cooled condenser are: indoor coil entering air dry-bulb and wet-bulb temperatures 26.7°C/19.4°C and outdoor coil entering air dry-bulb and wet-bulb temperatures 35.0°C/23.9°C

$\dot{Q}_{StandardRating}$ is the total standard cooling capacity (W) of the air-conditioning or heat pump equipment determined from ANSI/AHRI Standard 210/240 and A2 test conditions shown in Table 15.6. The standard cooling test conditions for air-cooled are: indoor coil entering air dry-bulb and wet-bulb temperatures 26.7°C/19.4°C and outdoor coil entering air dry-bulb and wet-bulb temperatures 35.0°C/23.9°C

$\dot{Q}_{T,CRated}^{k=2}$ is the rated total cooling capacity at maximum speed, user input (W)

$CAPFT_{TestA2}^{k=2}$ is the user-specified bi-quadratic curve evaluated at the indoor coil entering air wet-bulb temperature (19.4°C) and outdoor coil entering air dry-bulb temperature (35.0°C) for air-cooled condenser per A2 test condition as specified in Table 15.6 (dimensionless)

$CAPFFF_{TestA2}^{k=2}$ is the user-specified quadratic or cubic curve modifying the total cooling capacity as function of flow fraction, (dimensionless). This curve is evaluated at a flow fraction of 1.0.

$FanPower_{Rated}$ is the supply air fan power at rated conditions at high (maximum) compressor speed (W)

$\dot{V}_{CRated}^{k=2}$ is the rated air volume flow rate at high (maximum) compressor speed, user input (m³/s)

$FanPowerPerVolFlowRate^{k=2}$ is the rated indoor coil fan power per volume flow rate is a user-entered value, with a default of 773.3 W/(m³/s) if the user leaves this input field blank. The default value is taken from ANSI/ASHRAE Standard 210/240 -2008 where it is defined for systems which do not have an indoor coil fan furnished as part of the system. See the description given below how this value is calculated, user input (W/(m³/s)).

The Rated Evaporator (Indoor Coil) Fan Power Per Volume Flow rate is a user-entered value, with a default of 773.3 W/(m³/s) if the user leaves this input field blank. The default value is taken from ANSI/ASHRAE Standard 210/240-2008 where it is defined for systems which do not have an Indoor Coil (Evaporator) fan furnished as part of the system. The test conditions in ANSI/AHRI Standard 210/240 vary the external static pressure (i.e., pressure drop associated with ductwork and other devices external to the indoor fan/coil section) seen by the supply air fan based on the standard rating cooling capacity.

15.2.5.10 Seasonal Energy Efficiency Ratio (SEER) for Multi-Speed DX Coil

The SEER value for multi-speed compressor air conditioner or air-to-air heat pumps per AHRI/ANSI Std. 210/240 – 2008 is calculated as follows:

$$SEER = \frac{\sum_{j=1}^8 \frac{q_c(T_j)}{N}}{\sum_{j=1}^8 \frac{e_c(T_j)}{N}} \quad (15.209)$$

where:

$q_c(T_j)/N$ is the ratio of space cooling capacity provided by the unit during periods of the space cooling season when the outdoor temperature fell within the range represented by bin temperature T_j to the total number of hours in the cooling season (N), (W)

$e_c(T_j)/N$ is the ratio of the electrical energy consumed by the unit during periods of the space cooling season when the outdoor temperature fell within the range represented by bin temperature T_j to the total number of hours in the cooling season (N), W.

j is the bin number, dimensionless. For cooling season, j ranges from 1 to 8.

T_j is the outdoor air bin temperature ($^{\circ}\text{C}$). Outdoor temperatures are “binned” such that calculations are only performed based one temperature within the bin. Bins of 2.8°C with 8 cooling season bin temperatures being 19.44°C , 22.22°C , 25.0°C , 27.78°C , 30.56°C , 33.33°C , 36.11°C , 38.89°C .

For multi-speed compressor the SEER value is weighted average performance at different outdoor air temperature bins. The eight outdoor air temperature bins and the corresponding weight are provided in Table 15.7. Distribution of Fractional Hours with in Cooling Season Temperature Bins.

The steady-state cooling capacity delivered and the electric power inputs when the DX coil is operating at minimum compressor speed ($k = 1$), and outdoor air temperature T_j , are determined by linear interpolation using the values of B1 and F1 tests as follows:

$$\dot{Q}_c^{k=1}(T_j) = \dot{Q}_c^{k=1}(19.44) + \frac{\dot{Q}_c^{k=1}(27.78) - \dot{Q}_c^{k=1}(19.44)}{27.78 - 19.44} (T_j - 19.44) \quad (15.210)$$

$$\dot{E}_c^{k=1}(T_j) = \dot{E}_c^{k=1}(19.44) + \frac{\dot{E}_c^{k=1}(27.78) - \dot{E}_c^{k=1}(19.44)}{27.78 - 19.44} (T_j - 19.44) \quad (15.211)$$

The steady-state cooling capacities and electric power inputs at the minimum speed and test condition B_1 and F_1 are calculated from the minimum (low) speed performance curves as follows:

$$\dot{Q}_c^{k=1}(27.78) = \dot{Q}_{T,CRated}^{k=1} \cdot CAPFT_{TestB1}^{k=1} \cdot CAPFFF_{TestB1}^{k=1} - FanPower_{CRated}^{k=1} \quad (15.212)$$

$$\dot{E}_c^{k=1}(27.78) = \left[\frac{\dot{Q}_c^{k=1}(27.78)}{COP_{CRated}^{k=1}} \right] \cdot EIRFT_{TestB1}^{k=1} \cdot EIRFFF_{TestB1}^{k=1} + FanPower_{CRated}^{k=1} \quad (15.213)$$

$$\dot{Q}_c^{k=1}(19.44) = \dot{Q}_{T,CRated}^{k=1} \cdot CAPFT_{TestF1}^{k=1} \cdot CAPFFF_{TestF1}^{k=1} - FanPower_{CRated}^{k=1} \quad (15.214)$$

$$\dot{E}_c^{k=1}(19.44) = \left[\frac{\dot{Q}_c^{k=1}(19.44)}{COP_{CRated}^{k=1}} \right] \cdot EIRFT_{TestF1}^{k=1} \cdot EIRFFF_{TestF1}^{k=1} + FanPower_{CRated}^{k=1} \quad (15.215)$$

$$FanPower_{CRated}^{k=1} = FanPowerPerVolFlowRate^{k=1} \cdot \forall_{CRated}^{k=1} \quad (15.216)$$

where:

$\dot{Q}_{T,CRated}^{k=1}$ is the rated total cooling capacity at minimum compressor speed specified by users (W)

$COP_{CRated}^{k=1}$ is the rated gross COP at minimum compressor speed specified by users (-)

$CAPFT_{TestB1}^{k=1}$ is the cooling capacities modifier curve for temperature at minimum compressor speed and B1 test condition (-)

$CAPFFF_{TestB1}^{k=1}$ is the cooling capacities modifier curve for flow fraction at minimum compressor speed and B1 test condition (-)

$EIRFT_{TestB1}^{k=1}$ is the EIR modifier curve for temperature at minimum compressor speed and B1 test condition (-)

$EIRFFF_{TestB1}^{k=1}$ is the EIR modifier curve for flow fraction at minimum compressor speed and B1 test condition (-)

$CAPFT_{TestF1}^{k=1}$ is the cooling capacities modifier curve for temperature at minimum compressor speed and F1 test condition (-)

$CAPFFF_{TestF1}^{k=1}$ is the cooling capacities modifier curve for flow fraction at minimum compressor speed and F1 test condition (-)

$EIRFT_{TestF1}^{k=1}$ is the EIR modifier curve for temperature at minimum compressor speed and F1 test condition (-)

$EIRFFF_{TestF1}^{k=1}$ is the EIR modifier curve for flow fraction at minimum compressor speed and F1 test condition (-)

$FanPower_{CRated}^{k=1}$ is the the rated supply air fan power when the unit is operating at minimum compressor speed (W)

$V_{CRated}^{k=1}$ is the rated cooling supply air volume flow rate at minimum compressor speed specified by users (-)

$FanPowerPerVolFlowRate^{k=1}$ is the rated indoor coil fan power per volume flow rate at low (minimum) compressor speed specified value by the user (W/(m³/s)).

The steady-state cooling capacity delivered and the electric power inputs when the DX cooling coil is operating at maximum (high) compressor speed ($k = 2$), and outdoor air temperature T_j , are determined as follows:

$$\dot{Q}_c^{k=2}(T_j) = \dot{Q}_c^{k=2}(27.78) + \frac{\dot{Q}_c^{k=2}(35.0) - \dot{Q}_c^{k=2}(27.78)}{35.0 - 27.78} (T_j - 27.78) \quad (15.217)$$

$$\dot{E}_c^{k=2}(T_j) = \dot{E}_c^{k=2}(27.78) + \frac{\dot{E}_c^{k=2}(35.0) - \dot{E}_c^{k=2}(27.78)}{35.0 - 27.78} (T_j - 27.78) \quad (15.218)$$

The steady-state cooling capacities and electric power input at the maximum speed and test condition A_2 and B_2 are determined from the maximum (high) speed performance curves as follows:

$$\dot{Q}_c^{k=2}(35.0) = \dot{Q}_{T,CRated}^{k=2} \cdot CAPFT_{TestA2}^{k=2} \cdot CAPFFF_{TestA2}^{k=2} - FanPower_{CRated}^{k=2} \quad (15.219)$$

$$\dot{E}_c^{k=2}(35.0) = \left[\frac{\dot{Q}_c^{k=2}(35.0)}{COP_{CRated}^{k=2}} \right] \cdot EIRFT_{TestA2}^{k=2} \cdot EIRFFF_{TestA2}^{k=2} + FanPower_{CRated}^{k=2} \quad (15.220)$$

$$\dot{Q}_c^{k=2}(27.78) = \dot{Q}_{T,CRated}^{k=2} \cdot CAPFT_{TestB2}^{k=2} \cdot CAPFFF_{TestB2}^{k=2} - FanPower_{CRated}^{k=2} \quad (15.221)$$

$$\dot{E}_c^{k=2}(27.78) = \left[\frac{\dot{Q}_c^{k=2}(19.44)}{COP_{CRated}^{k=2}} \right] \cdot EIRFT_{TestB2}^{k=2} \cdot EIRFFF_{TestB2}^{k=2} + FanPower_{CRated}^{k=2} \quad (15.222)$$

$$FanPower_{CRated}^{k=2} = FanPowerPerVolFlowRate^{k=2} \cdot V_{CRated}^{k=2} \quad (15.223)$$

where:

$\dot{Q}_{T,CRated}^{k=2}$ is the rated total cooling capacity at maximum (high) compressor speed specified by users (W)

$COP_{CRated}^{k=2}$ is the rated gross COP at maximum (high) compressor speed specified by users (-)

$CAPFT_{TestA2}^{k=2}$ is the cooling capacity modifier curve for temperature at maximum (high) compressor speed and A_2 test condition (-)

$CAPFFF_{TestA2}^{k=2}$ is the cooling capacity modifier curve for flow fraction at maximum (high) compressor speed and A_2 test condition (-)

$EIRFT_{TestA2}^{k=2}$ is the EIR modifier curve for temperature at maximum (high) compressor speed and A_2 test condition (-)

$EIRFFF_{TestA2}^{k=2}$ is the EIR modifier curve for flow fraction at maximum (high) compressor speed and A_2 test condition (-)

$CAPFT_{TestB2}^{k=2}$ is the cooling capacity modifier curve for temperature at maximum (high) compressor speed and B_2 test condition (-)

$CAPFFF_{TestB2}^{k=2}$ is the cooling capacity modifier curve for flow fraction at maximum (high) compressor speed and B_2 test condition (-)

$EIRFT_{TestB2}^{k=2}$ is the EIR modifier curve for temperature at maximum (high) compressor speed and B_2 test condition (-)

$EIRFFF_{TestB2}^{k=2}$ is EIR modifier curve for flow fraction at maximum (high) compressor speed and B_2 test condition (-)

$FanPower_{CRated}^{k=2}$ is the the rated supply air fan power when the unit is operating at maximum (high) compressor speed (W)

$V_{CRated}^{k=2}$ is the rated supply air volume flow rate at maximum (high) compressor speed specified by users (-)

$FanPowerPerVolFlowRate^{k=2}$ is the the Rated Evaporator (Indoor Coil) Fan Power Per Volume Flow rate at maximum (high) compressor speed specified value by the user (W/(m³/s)).

The above steps show how the cooling capacity and electric power inputs are determined when the DX cooling coil is operating at minimum (low) and maximum (high) compressor speeds. But the unit may operate at minimum (low) speed capacity, cycle on-off, cycle between successive lower and higher compressor speed capacity, or operate at maximum (high) speed capacity depending on the building cooling load. The operating range of the DX cooling coil is determined based on the building cooling load for each binned outside air temperature. The building cooling load at an outdoor air temperature T_j , is calculated as follows:

$$BL(T_j) = \left(\frac{T_j - 18.3}{35.0 - 18.3} \right) \left(\frac{\dot{Q}_c^{k=2}(35.0)}{1.1} \right) \quad (15.224)$$

where:

$BL(T_j)$ is the building space cooling load corresponding to outdoor temperature of T_j (W)

$\dot{Q}_c^{k=2}(35.0)$ is the the cooling capacity determined from the standard A2 test (W).

The temperatures 35.0°C and 18.3°C in the building load calculation equation represent the outdoor design air temperature, and zero-load base temperature, respectively (ANSI/ASHRAE, 2008). 1.1 is a sizing factor.

The cooling capacity delivered and the electric power inputs calculations when the DX cooling coil is cycling on-off, operating at minimum (low) compressor speed, cycling between successive minimum (low) and maximum (high) compressor speed, or operating at maximum (high) compressor speed are described next.

Case 1: The steady state cooling capacity when the unit is operating at or below the minimum (low) speed compressor capacity, i.e., when the building cooling load is less or equal to the minimum (low) compressor speed capacity, is calculated as follows:

$$\dot{Q}_c^{k=1}(T_j) \geq BL(T_j) \quad (15.225)$$

$$\frac{q_c(T_j)}{N} = \left[X^{k=1}(T_j) \cdot \dot{Q}_c^{k=1}(T_j) \right] \cdot \frac{n_j}{N} \quad (15.226)$$

$$\frac{e_c(T_j)}{N} = \left[\frac{X^{k=1}(T_j)}{PLF_j} \dot{E}_c^{k=1}(T_j) \right] \cdot \frac{n_j}{N} \quad (15.227)$$

$$X^{k=1}(T_j) = \frac{BL(T_j)}{\dot{Q}_c^{k=1}(T_j)} \quad (15.228)$$

$$PLF_j = 1 - C_D^c [1 - X^{k=1}(T_j)] \quad (15.229)$$

where:

$X(T_j)$ is the cooling mode load factor or part-load ratio for temperature bin j (-)

n_i/N is the fractional bin hours for the cooling season; the ratio of the number of hours during the cooling season when the outdoor temperature fell within the range represented by bin temperature T_j to the total number of hours in the cooling season (-). (see Table 15.7)

C_D^c is the cooling coefficient of degradation, default value is 0.25.

Case 2: The unit cycles between successive the minimum (low) and maximum (high) compressor speed capacity to meet the building cooling load at outdoor air temperature T_j . That is, the cooling building load is between the units successive minimum (low) and maximum (high) compressor speed capacities:

$$\dot{Q}_c^{k=1}(T_j) < BL(T_j) < \dot{Q}_c^{k=2}(T_j) \quad (15.230)$$

$$\frac{q_c(T_j)}{N} = \left[X^{k=1}(T_j) \cdot \dot{Q}_c^{k=1}(T_j) + (1 - X^{k=1}(T_j)) \cdot \dot{Q}_c^{k=2}(T_j) \right] \cdot \frac{n_j}{N} \quad (15.231)$$

$$\frac{e_c(T_j)}{N} = \left[X^{k=1}(T_j) \cdot \dot{E}_c^{k=1}(T_j) + (1 - X^{k=1}(T_j)) \cdot \dot{E}_c^{k=2}(T_j) \right] \cdot \frac{n_j}{N} \quad (15.232)$$

$$X^{k=1}(T_j) = \frac{\dot{Q}_c^{k=2}(T_j) - BL(T_j)}{\dot{Q}_c^{k=2}(T_j) - \dot{Q}_c^{k=1}(T_j)} \quad (15.233)$$

Case 3: The steady-state cooling capacity when the unit is operating continuously at maximum (high) compressor speed capacity at outdoor air temperature T_j . That is the building cooling load is greater or equal to the available capacity at maximum (high) compressor speed:

$$BL(T_j) \geq \dot{Q}_c^{k=2}(T_j) \quad (15.234)$$

For units when operating continuously at maximum (high) compressor speed ($k = 2$) at temperature T_j , the delivered cooling capacity and electric power inputs are calculated as follows:

$$\frac{q_c(T_j)}{N} = \left[\dot{Q}_c^{k=2}(T_j) \right] \cdot \frac{n_j}{N} \quad (15.235)$$

$$\frac{e_c(T_j)}{N} = \left[\dot{E}_c^{k=2}(T_j) \right] \cdot \frac{n_j}{N} \quad (15.236)$$

Table 15.6: Cooling Mode Test Conditions for Units Having a Two-Capacity Compressor

Test Description	Air Entering Indoor Unit Temperature (°F/°C)		Air Entering Outdoor Unit Temperature (°F/°C)		Compressor Capacity	Cooling Air Volume Rate
	Dry Bulb	Wet Bulb	Dry Bulb	Wet Bulb		
A2 Test-required (steady, wet coil)	80.0/26.7	67.0/19.4	95.0/35.0	75.0/23.9	High	Cooling Full-load
B2 Test-required (steady, wet coil)	80.0/26.7	67.0/19.4	82.0/27.8	65.0/18.3	High	Cooling Full-load
B1 Test-required (steady, wet coil)	80.0/26.7	67.0/19.4	82.0/27.8	65.0/18.3	Low	Cooling Minimum
C2 Test-optional (steady, dry coil)	80.0/26.7		82.0/27.8		High	Cooling Full-load
D2 Test-required (cyclic, dry coil)	80.0/26.7		82.0/27.8		High	
C1 Test-optional (steady, dry coil)	80.0/26.7		82.0/27.8		Low	Cooling Minimum
D1 Test-optional (cyclic, dry coil)	80.0/26.7		82.0/27.8		Low	
F1 Test-optional (steady, dry coil)	80.0/26.7	67.0/19.4	67.0/19.4	53.5/11.9	High	Cooling Minimum

15.2.5.11 Energy Management System Coil Speed Override

The cooling coil speed level and cycling/speed ratio can be actuated by EMS at run-time. When EMS is used to overwrite the “Unitary System DX Coil Speed Value”, the speed levels are set based on EMS values rather than speed levels determined by the Non-EMS EnergyPlus control logic. The EMS override coil speed value is a continuous number below maximum coil speed level allowed. With any EMS override coil speed value, if the input value is a integer, the speed level is set as the exact speed value input, with the cycling or speed ratio = 1.0. Otherwise, if the floating point part is greater than zero, the speed level is calculated as the closest integer greater than the EMS speed value, and the cycling/speed ratio is set as the floating point part of the EMS speed value. For example, if EMS overrides coil speed value = 1.2, the speed level number is set as 2 with a speed ratio at 0.2.

15.2.5.12 References

See the references for the single speed DX cooling coil earlier in this document.

15.2.6 Two-Speed Electric DX Air Cooling Coil

15.2.6.1 Overview

The input object Coil:Cooling:DX:TwoSpeed provides a model that is meant to represent either a 2 speed (fan and compressor) DX cooling unit (compressor, evaporator, condenser) or a variable speed DX cooling unit in which the variation of compressor speed and air flow rate is nearly linear as a function of cooling part load. In EnergyPlus Coil:Cooling:DX:TwoSpeed is used as the cooling coil in packaged variable volume systems (PVAV). The model is based upon the single speed DX unit Coil:Cooling:DX:SingleSpeed. Basically the model for Coil:Cooling:DX:TwoSpeed employs a separate single speed model at high speed (full load) and low speed (minimum load) and interpolates

between these 2 states to obtain the needed cooling output. Below minimum load the unit cycles on/off, just like the single speed unit.

15.2.6.2 Inputs and Data

The input is similar to that for Coil:Cooling:DX:SingleSpeed except there needs to be two complete sets of performance data. The user inputs a rated total cooling capacity, rated SHR, rated COP, and rated air volumetric flow rate for the high speed and low speed states. Performance curves – cooling capacity as a function of entering air wet-bulb temperature and outside dry-bulb temperature (wet-bulb if there is an evaporatively cooled condenser), EIR as a function of the same two temperatures – must be defined and referenced for both high and low speed states. The performance characteristics of the evaporative condenser, if present, also need to be given at high and low speed states: effectiveness, air volumetric flow rate, and pump power consumption. The full list of inputs is given in the Input/Output Reference document.

The data for Coil:Cooling:DX:TwoSpeed is stored in the array structure *DXCoil* in the program module *DXCoils*

15.2.6.3 Calculation

Calculation is performed in routine *CalcMultiSpeedDXCoil* in module *DXCoils*. The inputs to the calculation are the coil index (denoting a specific coil with its particular performance parameters), the speed ratio, and the cycling ratio. The speed ratio is an artificial parameter between 0 and 1. If the speed ratio (*SR*) is greater than zero, the performance of the unit will be:

$$SR \cdot HighSpeedPerformance + (1 - SR) \cdot LowSpeedPerformance \quad (15.237)$$

Here *HighSpeedPerformance* means the electricity consumption, cooling output, and outlet conditions of the unit if the unit were operating at high speed (full load). Similarly *LowSpeed Performance* means the electricity consumption, cooling output, and outlet conditions if the unit were operating at low speed (minimum non-cycling load). The calculations for each state are the same as for the single speed, cycling DX unit Coil:Cooling:DX:SingleSpeed.

If the speed ratio is zero and the cycling ratio is > 0 , the unit will be in cycling mode. The unit will be on for *cycling ratio* fraction of the time step, off for the remainder of the time step. While on, the unit will perform according to the low speed performance parameters.

15.2.6.4 Simulation and Control

Coil:Cooling:DX:TwoSpeed is not used by itself; it is used as part of an encompassing component or system that provides control for the unit. In setting up a PVAV system, for instance, Coil:Cooling:DX:TwoSpeed is part of the component CoilSystem:Cooling:DX, which controls Coil:Cooling:DX:TwoSpeed. When used in the CoilSystem:Cooling:DX component, the simulation allows for either temperature *or* temperature and dehumidification control based on a dehumidification control selection in the CoilSystem:Cooling:DX component. If None is selected the simulation runs the DX unit to satisfy a supply air temperature setpoint. It typically varies the speed ratio in an iterative solution process to establish the operating point that will give the desired unit outlet air temperature. If CoolReheat is selected, the simulation first runs the DX unit to satisfy a supply air temperature setpoint. However, in this case if the

DX unit outlet air humidity ratio is above the humidity ratio setpoint, the simulation will increase the speed and/or cycling ratio to meet the desired unit outlet air humidity ratio. The humidity ratio setpoint is specified through the use of a humidistat (ref. ZoneControl:Humidistat) and a setpoint manager (ref. SetpointManager:SingleZone:Humidity:Maximum, SetpointManager:MultiZone:MaximumHumidity:Average, SetpointManager:MultiZone:Humidity:Maximum or SetpointManager:OutdoorAirPretreat). When used with the CoilSystem:Cooling:DX component, the dehumidification control type Multimode is not allowed.

15.2.6.5 Basin Heater For Two-Speed DX Coil

Basin heater for the object Coil:Cooling:DX:TwoSpeed operates in the same manner as for Coil:Cooling:DX:SingleSpeed. Refer to the “Basin Heater For Single-Speed DX Coil” description above.

15.2.6.6 Standard Ratings

The Coil:Cooling:DX:TwoSpeed object includes industry standard ratings of Standard Rating Cooling Capacity, Energy Efficiency Ratio (EER), and Integrated Energy Efficiency Ratio (IEER) which are calculated according to ANSI/AHRI Standard 340/360-2007 with Addenda 1 and 2 (AHRI 2007). These ratings apply to unitary air conditioners with air-cooled condensers with standard rated cooling capacities from 19 kW (65,000 Btu/h) to below 220 kW (760,000 Btu/h).

For the Coil:Cooling:DX:TwoSpeed object in EnergyPlus, these standard ratings are not direct inputs to the model. However, these standard ratings can be calculated using user-entered information for the Coil:Cooling:DX:TwoSpeed object. These standard rating values are provided in the eplusout.eio output file (Ref. OutputDetailsAndExamples.pdf) and also in the predefined tabular output reports (Output:Table:SummaryReports object, Equipment Summary report, DX Cooling Coil table and VAV DX Cooling Standard Rating Details table). Currently, the standard ratings are only calculated and output for Packaged VAV cooling coils with air-cooled condensers and variable-air-volume fans. If the two-speed DX cooling coil is specified with an evaporatively-cooled condenser or along with a constant volume fan, then no standard ratings are output from EnergyPlus at this time.

The standard rating cooling capacity is calculated as follows:

$$\dot{Q}_{StandardRating} = \dot{Q}_{Total,Rated} TotCapTempModFac_{Rated} TotCapFlowModFac_{Rated} - FanHeatCorrection \quad (15.238)$$

where:

$\dot{Q}_{StandardRating}$ is the standard rating (net) cooling capacity (W)

$\dot{Q}_{Total,Rated}$ is the rated total (gross) cooling capacity, user input (W)

$TotCapTempModFac_{Rated}$ is the total cooling capacity function of temperature curve evaluated with 19.4°C wet-bulb temperature air entering the cooling coil and 35.0°C dry-bulb temperature air entering the air-cooled (outdoor) condenser (dimensionless)

$TotCapFlowModFac_{Rated}$ is the total cooling capacity function of flow fraction curve evaluated at a flow fraction of 1.0 (dimensionless)

$FanHeatCorrection$ is the rate that air is heated by the supply fan (W).

FanHeatCorrection is calculated in one of two ways depending on the user's input for the field called Unit Internal Static Air Pressure. If this field was left blank, then the fan heat is calculated using:

$$FanHeatCorrection = \dot{V}_{RatedHighSpeed} * 773.3 \quad (15.239)$$

where:

$\dot{V}_{RatedHighSpeed}$ is the rated air volume flow rate at high speed, user input (m³/s).

The value of 773.3 W/(m³/s) (365 W/1000cfm) is specified by ANSI/AHRI 340/360 for indoor-coil-only units that are not provided with a supply fan.

If an internal static pressure is provided, then the fan heat is modeled by evaluating the full model for Fan:VariableVolume. This is different that the ratings calculated for single-speed DX equipment which does not use data from an associated fan object. The program detects the VAV fan associated with the two-speed coil and uses the input data for that fan but with a different total air pressure rise. The total pressure is the sum of the internal pressure and the external pressure (i.e., pressure drop associated with ductwork and other devices external to the indoor fan/coil section). The test conditions in ANSI/AHRI Standard 340/360 vary the (minimum) external static pressure seen by the supply air fan based on the standard rating cooling capacity (see Table # 5 in ANSI/AHRI Standard 340/360). For the part load test points the supply air flow is reduced and the external pressure varies with the square of the flow ratio (see Note 1 in Table # 6 in ANSI/AHRI Standard 340/360-2007 with Addenda 1 and 2). The entire VAV fan model in EnergyPlus is evaluated at the specified air flow rate and the total static pressure for rating and the fan heat is calculated using

$$FanHeatCorrection = Enthalpy_{leavingFan} - Enthalpy_{enteringFan} \quad (15.240)$$

Energy Efficiency Ratio (EER) is another standard rating (AHRI 2007), and it is defined as the ratio of the total cooling capacity to the total power input at any given set of rating conditions, expressed in W/W (or Btu/W-h). For this class of air-cooled DX cooling coils, EER is calculated at rated test conditions as follows:

$$EER = \frac{\dot{Q}_{StandardRating}}{Power_{Total,Rated}} \quad (15.241)$$

$$Power_{Total,Rated} = \dot{Q}_{Total,Rated} TotCapTempModFac_{Rated} TotCapFlowModFac_{Rated} EIR_{Rated} + FanPowerCorr \quad (15.242)$$

$$EIR_{Rated} = \left(\frac{1}{COP_{Rated}} \right) (EIRTempModFac_{Rated}) (EIRFlowModFac_{Rated}) \quad (15.243)$$

where:

EER is the Energy Efficiency Ratio (W/W)

$Power_{Total,Rated}$ is the total electric power (compressors, condenser fans and evaporator fan) with 19.4°C wet-bulb temperature air entering the cooling coil, 35.0°C dry-bulb temperature air entering the air-cooled (outdoor) condenser, and air flow rate across the evaporator at the rated high speed air flow rate.

Similar to the fan heat correction, the fan power correction is calculated in one of two ways depending on the input for internal static pressure. If no internal static is provided, fan power is calculated using:

$$FanPowerCorrection = \dot{V}_{RatedHighSpeed} * 773.3 \quad (15.244)$$

If the internal static pressure is provided, then the entire VAV fan model in EnergyPlus is evaluated at the rated high speed air flow rate and the total static pressure for rating and then the fan power calculated by the fan model is used for the fan power correction.

$TotCapTempModFac_{Rated}$ is the total cooling capacity function of temperature curve evaluated with 19.44°C wet-bulb temperature air entering the cooling coil and 35.0°C dry-bulb temperature air entering the air-cooled (outdoor) condenser (dimensionless)

$EIRTempModFac_{Rated}$ is the Energy Input Ratio function of temperature curve evaluated with 19.44°C wet-bulb temperature air entering the cooling coil and 35.0°C dry-bulb temperature air entering the air-cooled (outdoor) condenser (dimensionless).

The Integrated Energy Efficiency Ratio (IEER) is intended to be a measure of merit for the cooling coil's part-load efficiency. IEER replaced Integrated Part-Load Value (IPLV) as the part-load performance metric in Std. 340/360 as of January 1, 2010. Full details regarding the IEER calculation are available in ANSI/AHRI Std. 340/360 (AHRI 2007). A summary of the IEER calculations made by EnergyPlus for two-speed air-cooled DX cooling coils is provided below:

$$IEER = (0.02 \cdot EER_A) + (0.617 \cdot EER_B) + (0.238 \cdot EER_C) + (0.125 \cdot EER_D) \quad (15.245)$$

where:

EER_A is the EER at 100% net capacity at AHRI standard rating conditions (same as EER calculation shown above but in Btu/h)

EER_B is the EER at 75% net capacity and reduced outdoor air temperature Btu/h

EER_C is the EER at 50% net capacity and reduced outdoor air temperature Btu/h

EER_D is the EER at 25% net capacity and reduced outdoor air temperature Btu/h.

The following table summarizes the test points.

Table 15.8: Test points for Two-Speed DX Coil Ratings

Point	Net Capacity	Coil inlet wetbulb	Coil inlet drybulb	Condenser inlet drybulb	Supply air flow rate
A	100%	19.4°C	26.7°C	35.0°C	Rated High speed flow rate
B	75%	19.4°C	26.7°C	27.5°C	Root solver result where
C	50%	19.4°C	26.7°C	20.0°C	coil leaving drybulb
D	25%	19.4°C	26.7°C	18.3°C	matches Point A

The units are assumed to be VAV and Standard 340/360 is applied as for VAV indoor supply fan. Because the standard stipulates “the airflow rate at part load should be adjusted to maintain the full load measured leaving dry-bulb temperature,” the part load rating test points “B”,

“C”, and “D” are evaluated by using the entire DX coil model calculations to obtain the supply air conditions leaving the coil and iterating on supply air flow rate to find the supply air flow rate. The numerical method called root solver is used to find the supply flow rate at each of the part load test points. Once the supply air flow rate is known, the two-speed DX coil model results are used to determine EER at the part load test points.

When evaluating the two-speed DX coil model, the speed ratio and cycling ratio are specified based on the desired or target net capacity. When the low speed net capacity is lower than the target part load net capacity, the speed ratio is calculated using:

$$SpeedRatio = \frac{DesiredNetCapacity - LowSpeedNetCapacity}{HighSpeedNetCapacity - LowSpeedNetCapacity} \quad (15.246)$$

When the low speed net capacity is higher than a target part load net capacity then the unit must cycle to meet the lower load. The speed ratio is then set to 0.0 (minimum unloading) and the cycling ratio is calculated using:

$$CyclingRatio = \frac{DesiredNetCapacity}{LowSpeedNetCapacity} \quad (15.247)$$

The results for EER, COP, and supply air mass flow rate at the part load test points are reported to the EIO file and a predefined table report called VAV DX Cooling Standard Rating Details.

15.2.6.7 Energy Management System Coil Speed Level Override

The heating coil speed level and cycling/speed ratio can be actuated by EMS at run-time. When EMS is used to overwrite the “Unitary System DX Coil Speed Value”, the speed levels are set based on EMS values rather than speed levels determined by the Non-EMS EnergyPlus control logic. The EMS override coil speed value is a continuous number below maximum coil speed level allowed. With any EMS override coil speed value, if the input value is a integer, the speed level is set as the exact speed value input, with the cycling or speed ratio = 1.0. Otherwise, if the floating point part is greater than zero, the speed level is calculated as the closest integer greater than the EMS speed value, and the cycling/speed ratio is set as the floating point part of the EMS speed value. For example, if EMS overrides coil speed value = 1.2, the speed level number is set as 2 with a speed ratio at 0.2.

15.2.6.8 References

See the references for the single speed DX cooling coil earlier in this document.

15.2.7 Variable Speed DX Cooling Coil

15.2.7.1 Overview

The Coil:Cooling:DX:VariableSpeed object will simulate the performance of a DX cooling coil used in combination with a variable-speed unitary air conditioner and air-to-air heat pump. It fits into the parent objects of AirLoopHVAC:UnitaryHeatCool, ZoneHVAC:PackagedTerminalAirConditioner, AirLoopHVAC:UnitaryHeatPump:AirToAir and ZoneHVAC:PackagedTerminalHeatPump, etc.

The rated conditions for obtaining the capacities, COPs and SHR are indoor dry-bulb temperature at 26.67°C (80°F), wet bulb temperature at 19.44°C (67°F), and the source side entering air temperature at 35°C (95°F).

Variable-speed cooling coils lead to varied dehumidification behaviors, that the Bypass Factor (BF) is not only dependent on the indoor air flow rate, but also on the refrigerant mass flow rate, i.e. the compressor speed. The methods of calculating Bypass factor and Sensible Heat Transfer Ratio at each speed are the same as the water source variable-speed cooling coil (object name Coil:Cooling:WaterToAirHeatPump:VariableSpeedEquationFit).

15.2.7.2 Model Description

The Coil:Cooling:DX:VariableSpeed object is modeled in a manner similar to Coil:Cooling:WaterToAirHeatPump:VariableSpeedEquationFit. Of course, rather than referencing a water-cooled condenser, the new coil object references to outdoor air-cooled condenser, and has the air entering temperature in place of the condenser water entering temperature.

It shall be noted for the total cooling capacity and flow rate inputs, two fields are autosizable, which are Rated Total Cooling Capacity at Selected Nominal Speed Level and Rated Volumetric Air Flow Rate at Selected Nominal Speed Level. They are used to scale the performances of an actual unit and correlate with the actual loop flow. Except the two fields, all other total cooling capacity and flow rate inputs at individual speed levels should be directly obtained from Reference Unit catalog.

The Rated Total Cooling Capacity at Selected Nominal Speed Level contains the rated total cooling capacity to match the building sensible or latent cooling load. The rated cooling capacity is used to determine a capacity scaling factor, as compared to the Reference Unit catalog capacity at the nominal speed level.

$$\text{Capacity Scale Factor} = \frac{\text{Rated Total Cooling Capacity}}{\text{Reference Unit Total Cooling Capacity@Nominal Speed Level}} \quad (15.248)$$

And then, this scaling factor is used to determine capacities at rated condition for other speed levels, as below,

$$\begin{aligned} \text{Rated Total Cooling Capacity@Speed Level (x)} = \\ \text{Capacity Scale Factor} \times \text{Reference Unit Total Cooling Capacity@Speed Level(x)} \end{aligned} \quad (15.249)$$

The Rated Volumetric Air Flow Rate is used to determine an internal scaling factor, and calculate the air flow rates in the parent objects, as follows:

$$\text{Air Flow Scale Factor} = \frac{\text{Rated Volumetric Air Flow Rate}}{\text{Reference Unit Vol Air Flow Rate@Nominal Speed Level} \times \text{CapacityScaleFactor}} \quad (15.250)$$

And the loop volumetric air flow rates in the parent objects are calculated as below:

$$\begin{aligned} \text{Loop Volumetric Air Flow Rate@Speed Level (x)} = \\ \text{Air Flow Scale Factor} \times \text{Reference Unit Vol Air Flow Rate@Speed Level(x)} \times \text{Capacity Scale Factor} \end{aligned} \quad (15.251)$$

If the volumetric air flow rate at one speed level is higher than the flow rate allowed by the fan in the parent object, the flow rate will be set back to the fan flow rate.

If Air Flow Scale Factor equals to unity, the loop air flow rate become the design flow rates of the original unit (after scaled by the rated total cooling capacity). The Rated Volumetric Air Flow Rate is introduced here to correlate with the actual flow rate in the air loop, in case that these differ from the design specifications. Certainly, it is recommended that the Rated Volumetric Air Flow Rate is selected in the way that Air Flow Scale Factor is unity, so as to get more accurate results from the performance curves.

If the condenser is evaporatively cooled, it is necessary to know the condenser air flow rate, so as to calculate the water evaporation rate. We will have fields for specifying the Reference Unit condenser volumetric air flow rates at individual speed levels, and these inputs are optional. If the condenser air flow rates are not inputted by the user, default values of condenser volumetric air flow rate as a function of the rated total cooling capacity will be used. Condenser air flow rates of the simulated unit are calculated as below,

$$\begin{aligned} \text{Condenser Volumetric Air Flow Rate@Speed Level (x)} = \\ \text{Reference Unit Condenser Vol Air Flow Rate@Speed Level(x)} \times \\ \text{Capacity Scale Factor} \end{aligned} \quad (15.252)$$

15.2.7.3 Performance Curves

This object includes 4 curve objects at each individual speed level.

- 1) Total cooling capacity modifier curve (function of temperature)
- 2) Total cooling capacity modifier curve (function of air flow fraction)
- 3) Energy input ratio (EIR) modifier curve (function of temperature)
- 4) Energy input ratio (EIR) modifier curve (function of air flow fraction)

The flow fraction modifier curves are used as a placeholder, to account for off-design flow rates if needed. If the manufacturer doesn't provide the off-design performances, we can simply use a default modification multiplier of 1.0.

At the lowest speed, there will be one additional performance curve to correlate the part-load condition, i.e.

- 5) Part load fraction correlation (function of part load ratio)

More information on each of these curves is given below.

- 1) Total cooling capacity modifier curve (function of temperature)

The total cooling capacity modifier as a function of temperature curve (CAP-FT) is a biquadratic curve with two independent variables: wet-bulb temperature of the air entering the cooling coil and the condenser entering air temperature. The output of this curve is multiplied by the rated total cooling capacity at the speed, to give the total cooling capacity at the specific entering air WB and condenser inlet air DB at which the DX unit is operating (i.e., at temperatures different from the rating point temperatures).

Note: The data used to develop the total cooling capacity modifier curve (function of temperature) should represent performance when the cooling coil is ‘wet’ (i.e., coil providing sensible cooling and at least some dehumidification). Performance data when the cooling coil is ‘dry’ (i.e., not providing any dehumidification) should not be included when developing this modifier curve. This model automatically detects and adjusts for ‘dry coil’ conditions.

$$\text{TotCapTempModFac} = a + b * \text{WB}_i + c * \text{WB}_i^2 + d * \text{DB}_o + e * \text{DB}_o^2 + f * \text{WB}_i * \text{DB}_o \quad (15.253)$$

where:

WB_i is the wet-bulb temperature of the air entering the indoor cooling coil ($^{\circ}\text{C}$)

DB_o is the dry-bulb temperature of the air entering the condenser coil ($^{\circ}\text{C}$)

a-f is the regression curve-fit coefficients.

2) Total cooling capacity modifier curve (function of air flow fraction)

The total cooling capacity modifier curve (function of air flow fraction) is a cubic curve with the independent variable being the ratio of the actual air flow rate across the cooling coil to the design air flow rate (i.e., fraction of design flow at the speed).

$$\text{TotCapAirFlowModFac} = a + b * \text{ff}_a + c * \text{ff}_a^2 + d * \text{ff}_a^3 \quad (15.254)$$

where:

ff_a is the actual air mass flow rate/design air mass flow rate, at one speed level

a-d are the regression curve fit coefficients. If no data for correction is available, the user can simply use $a = 1.0$ and set the other coefficients to 0.0.

$$\begin{aligned} \text{DesignAirMassFlowRate@SpeedLevel}(x) = \\ \text{ReferenceUnitAirMassFlowRate@SpeedLevel}(x) \times \text{CapacityScaleFactor} \end{aligned} \quad (15.255)$$

3) Energy input ratio (EIR) modifier curve (function of temperature)

The energy input ratio modifier curve as a function of temperature (EIR-FT) is a biquadratic curve with two independent variables: wet-bulb temperature of the air entering the cooling coil and the condenser entering air temperature. The output of this curve is multiplied by the rated EIR (inverse of the rated COP) at the speed level, to give the EIR at the specific entering air temperatures at which the DX unit is operating (i.e., at temperatures different from the rating point temperatures).

$$\text{EIRTempModFac} = a + b * \text{WB}_i + c * \text{WB}_i^2 + d * \text{DB}_o + e * \text{DB}_o^2 + f * \text{WB}_i * \text{DB}_o \quad (15.256)$$

where a-f are regression curve fit coefficients.

4) Energy input ratio (EIR) modifier curve (function of air flow fraction)

$$\text{EIRAirFlowModFac} = a + b * \text{ff}_a + c * \text{ff}_a^2 + d * \text{ff}_a^3 \quad (15.257)$$

where a-d are regression curve fit coefficients. If no data is available for correction, the user can simply use $a = 1.0$ and set the other coefficients to 0.0.

5) Part load fraction correlation (function of part load ratio)

This field defines the name of a quadratic or cubic performance curve (Ref: Performance Curves) that parameterizes the variation of electrical power input to the unit as a function of the part load ratio (PLR, Sensible or Latent Load/Steady-State Sensible or Latent Capacity for Speed 1). The description of the part load fraction correlation for the variable-speed DX cooling coil is similar to the variable-speed DX heating coil.

15.2.7.4 Lowest Speed Operation

The lowest speed operation of the variable-speed DX cooling coil is similar to the single speed DX cooling coil. The total (gross) cooling capacity of the variable-speed DX coil is calculated as follows:

$$\begin{aligned} Q_{\text{total},1} = & \text{Rated Total Cooling Capacity@Speed Level (1)} * \\ & \text{TotCapTempModFac}_1 * \text{TotCapAirFlowModFac}_1 \end{aligned} \quad (15.258)$$

And the EIR is calculated as:

$$\text{EIR}_1 = \frac{1.0}{\text{Reference Unit COP@Speed(1)}} \text{EIRTempModFac}_1 * \text{EIRAirFlowModFac}_1 \quad (15.259)$$

And the power consumption excluding the indoor fan is:

$$\text{Power}_1 = Q_{\text{total},1} * \text{EIR}_1 * \text{RTF} \quad (15.260)$$

At the lowest speed, the dehumidification calculation is exactly the same as the single speed DX coil. That is to use the rated SHR and the design air flow rate at the lowest speed to calculate rated bypass factor of $\text{BF}_{\text{rated},1}$, and the corresponding effective surface area of $A_{o,1}$. With $A_{o,1}$ known, the coil BF can be adjusted for non-rated air flow rates.

The part load ratio for sensible cooling is:

$$\text{PLR} = \text{SensibleCoolingLoad} / (Q_{\text{total},1} * \text{SHR}_1) \quad (15.261)$$

For latent cooling:

$$\text{PLR} = \text{LatentCoolingLoad} / [Q_{\text{total},1} * (1.0 - \text{SHR}_1)] \quad (15.262)$$

15.2.7.5 Higher Speed Operation

At the speed level between the lowest and the highest, there is no part-load loss. A parameter of speed ratio (SpeedRatio) is used to define the capacity partition between Speed x-1 and Speed x.

The design air flow rate at the speed ratio are given as following:

$$\begin{aligned} \text{DesignAirFlowRateSpeedRatio} = & \text{Reference Unit Air Mass Flow Rate@Speed Level (x - 1)} * \\ & \text{CapacityScaleFactor} * (1 - \text{SpeedRatio}) + \\ & \text{Reference Unit Air Mass Flow Rate@Speed Level (x)} * \\ & \text{CapacityScaleFactor} * \text{SpeedRatio} \end{aligned} \quad (15.263)$$

The fraction of air flow is given by $ff_{a,x-1} = ff_{a,x} = \text{actual air mass flow rate} / \text{DesignAirFlowRateSpeedRatio}$.

The total cooling capacities and EIRs at Speed x-1 and Speed x are calculated:

$$\begin{aligned} Q_{\text{total},x-1} = & \text{Rated Total Cooling Capacity@Speed Level (x - 1)} * \\ & \text{TotCapTempModFac}_{x-1} * \text{TotCapAirFlowModFac}_{x-1} \end{aligned} \quad (15.264)$$

$$\begin{aligned} Q_{\text{total},x} = & \text{Rated Total Cooling Capacity@Speed Level (x)} * \\ & \text{TotCapTempModFac}_x * \text{TotCapAirFlowModFac}_x \end{aligned} \quad (15.265)$$

$$\text{EIR}_{x-1} = \frac{1.0}{\text{Reference Unit COP@Speed(x - 1)}} \text{EIRTempModFac}_{x-1} * \text{EIRAirFlowModFac}_{x-1} \quad (15.266)$$

$$\text{EIR}_x = \frac{1.0}{\text{Reference Unit COP@Speed (x)}} \text{EIRTempModFac}_x * \text{EIRAirFlowModFac}_x \quad (15.267)$$

The total cooling capacity at the corresponding speed ratio is:

$$Q_{\text{total,SpeedRatio}} = (1.0 - \text{SpeedRatio}) * Q_{\text{total},x-1} + \text{SpeedRatio} * Q_{\text{total},x} \quad (15.268)$$

and the power consumption, excluding the indoor fan, is:

$$\text{Power}_{\text{SpeedRatio}} = (1.0 - \text{SpeedRatio}) * Q_{\text{total},x-1} * \text{EIR}_{x-1} + \text{SpeedRatio} * Q_{\text{total},x} * \text{EIR}_x \quad (15.269)$$

The net heat discharged from the condenser is:

$$Q_{\text{cond,SpeedRatio}} = \text{Power}_{\text{SpeedRatio}} + Q_{\text{total,SpeedRatio}} \quad (15.270)$$

and the effective surface area in the correlations of BF factor is calculated as below:

$$A_{o,\text{SpeedRatio}} = (1 - \text{SpeedRatio}) * A_{o,x-1} + \text{SpeedRatio} * A_{o,x} \quad (15.271)$$

Using $A_{o,\text{SpeedRatio}}$ in the same BF and SHR calculation procedure as the single speed DX cooling coil, we can get $\text{BF}_{\text{SpeedRatio}}$ and $\text{SHR}_{\text{SpeedRatio}}$. The sensible cooling capacity is calculated using:

$$Q_{\text{sensible,SpeedRatio}} = Q_{\text{total,SpeedRatio}} * \text{SHR}_{\text{SpeedRatio}} \quad (15.272)$$

If the variable-speed DX cooling coil used to match the sensible cooling load, then:

$$Q_{\text{sensible,SpeedRatio}} = \text{SensibleLoad} \quad (15.273)$$

If it intends to match the latent cooling load, then:

$$Q_{\text{total,SpeedRatio}} * (1.0 - \text{SHR}_{\text{SpeedRatio}}) = \text{LatentLoad} \quad (15.274)$$

If the speed reaches the highest level, the speed ratio becomes 1.0, and Speed n represents the highest speed.

15.2.7.6 Evaporatively Cooled Condenser

If using evaporative pre-cooling pad upstream of the condenser, the user must also enter the appropriate evaporative effectiveness for the media at each compressor speed, so as to correlate variation of the effectiveness as a function of compressor speed, i.e. the variation of condenser air flow rate. The evaporative effectiveness is interpolated between speed levels as:

$$\text{Effectiveness}_{\text{SpeedRatio}} = (1.0 - \text{SpeedRatio}) * \text{Effectiveness}_{x-1} + \text{SpeedRatio} * \text{Effectiveness}_x \quad (15.275)$$

The interpolated effectiveness at the speed ratio is used to calculate the air temperature reduction across the evaporative cooling pad, and the decreased air temperature entering the condenser coil is used in place of the ambient temperature as:

$$T_{c,i} = T_{wb,o} + (1.0 - \text{Effectiveness}_{\text{SpeedRatio}}) * (T_{db,o} - T_{wb,o}) \quad (15.276)$$

where:

$T_{c,i}$ is the condenser entering air temperature (°C)

$T_{wb,o}$ is the outdoor air wet bulb temperature (°C)

$T_{db,o}$ is the outdoor air dry bulb temperature (°C).

The water consumption rate is calculated based on the interpolated condenser air flow rate at the speed ratio, i.e. the condenser flow rate at the speed ratio is:

$$\dot{m}_{\text{condair,SpeedRatio}} = (1.0 - \text{SpeedRatio}) * \dot{m}_{\text{condair},x-1} + \text{SpeedRatio} * \dot{m}_{\text{condair},x} \quad (15.277)$$

15.2.8 Electric Air Heating Coil

The electric air heating coil (object name: Coil:Heating:Electric) is a simple capacity model with a user-input efficiency. In many cases, this efficiency for the electric coil will be 100%. This coil only has air nodes to connect it in the system. The coil can be used in the air loop simulation or in the zone equipment as a reheat coil. Depending on where it is used determines if this coil is temperature or capacity controlled. If used in the air loop simulation it will be controlled to a specified temperature on the setpoint node by the SetpointManager. If it is used in zone equipment,

it will be controlled from the zone thermostat by meeting the zone demand. See Input Output Reference for additional information.

For a coil that is controlled to meet the zone demand, it will meet the zone demand unless this demand exceeds the capacity of the coil specified by the user. The following code section demonstrates the simulation of the electric air heating coil.

```
! Control output to meet load QCoilReq
IF((AirMassFlow > 0.0 .AND. HeatingCoil(CoilNum)%NominalCapacity > 0.0) .and. &
  (GetCurrentScheduleValue(HeatingCoil(CoilNum)%SchedPtr) > 0.0) .and. &
  (QCoilReq > 0.0) .and. (TempSetPoint == 0.0)) THEN
  !check to see if the Required heating capacity is greater than the user! specified capacity.
  IF(QCoilReq > HeatingCoil(CoilNum)%NominalCapacity) Then
    QCoilCap = HeatingCoil(CoilNum)%NominalCapacity
  Else
    QCoilCap = QCoilReq
  End IF
  TempAirOut = TempAirIn + QCoilCap/CapacitanceAir
  HeatingCoilLoad = QCoilCap
!The HeatingCoilLoad is the change in the enthalpy of the Heating
  HeatingCoil(CoilNum)%ElecUseLoad = HeatingCoilLoad/Effic
```

For a temperature setpoint coil, the delta temperature from the coil inlet temperature to the setpoint is determined and the capacity of the coil is calculated and is met if that demand is less than the user specified capacity. The following code section demonstrates this.

```
! Control coil output to meet a setpoint temperature.
Else IF((AirMassFlow > 0.0 .AND. HeatingCoil(CoilNum)%NominalCapacity > 0.0) .and. &
  (GetCurrentScheduleValue(HeatingCoil(CoilNum)%SchedPtr) > 0.0) .and. &
  (QCoilReq == 0.0) .and. &
  (ABS(TempSetPoint-TempAirIn) > TempControlTol) ) THEN
  QCoilCap = CapacitanceAir*(TempSetPoint - TempAirIn)
  ! check to see if setpoint above entering temperature. If not, set
  ! output to zero.
  IF(QCoilCap ≤ 0.0) THEN

15.2.9 Fuel-fired Air Heating Coil

The fuel-powered heating coil (object name: Coil:Heating:Fuel) is a simple capacity model with user inputted burner efficiency. The default for the burner efficiency is 80%. This coil only has air nodes to connect it in the system. The coil can be used in the air loop simulation or in the zone equipment as a reheat coil. Depending on where it is used determines if this coil is temperature or capacity controlled. If used in the air loop simulation it will be controlled to a specified temperature scheduled from the SetpointManager. If it is used in zone equipment, it will be controlled from the zone thermostat by meeting the zone demand. The fuel coil has additional features that can add a part load correction and a parasitic fuel or electric load.

The parasitic electric load associated with the gas coil operation, such as an inducer fan, etc. This will be modified by the PLR (or coil runtime fraction if a part-load fraction correlation is provided in the next input field) to reflect the time of operation in a simulation time step.

The parasitic fuel load associated with the gas coil's operation (Watts), such as a standing pilot light. The model assumes that this parasitic load is consumed only for the portion of the simulation time step where the gas heating coil is not operating.

15.2.9.1 Field: Part Load Fraction Correlation (function of part load ratio)

The part load correction defines the name of a quadratic or cubic performance curve (Ref: Performance Curves) that parameterizes the variation of fuel consumption rate by the heating coil as a function of the part load ratio (PLR, sensible heating load/nominal capacity of the heating coil). For any simulation time step, the nominal fuel consumption rate (heating load/burner efficiency) is divided by the part-load fraction (PLF) if a part-load curve has been defined. The part-load curve accounts for efficiency losses due to transient coil operation.

The part-load fraction correlation should be normalized to a value of 1.0 when the part load ratio equals 1.0 (i.e., no efficiency losses when the heating coil runs continuously for the simulation time step). For PLR values between 0 and 1 ($0 \leq \text{PLR} < 1$), the following rules apply:

PLF \geq 0.7 and PLF \geq PLR

If $\text{PLF} < 0.7$ a warning message is issued, the program resets the PLF value to 0.7, and the simulation proceeds. The runtime fraction of the heating coil is defined a PLR/PLF . If $\text{PLF} < \text{PLR}$, then a warning message is issues and the runtime fraction of the coil is limited to 1.0.

A typical part load fraction correlation for a conventional gas heating coil (e.g., residential furnace) would be:

$$\text{PLF} = 0.8 + 0.2 \cdot \text{PLR} \quad (15.278)$$

For a better understanding of how the coil meets the temperature setpoint in the air loop or the zone demand as zone equipment, see Coil:Electric:Heating for additional information. Also see Input Output Reference for additional input information.

15.2.10 Multi-Stage Electric and Gas Air Heating Coil

15.2.10.1 Overview

These models (object names Coil:Heating:Electric:MultiStage and Coil:Heating:Gas:MultiStage) simulate the performance of multi stage electric and gas heating systems with two to four discrete air

flow stages. Each stage has a set of user inputted gas burner efficiency, Nominal capacity, and Parasitic electric load (for gas coil only). The full load supply airflow rate is dependent on the stage number and is set by its parent object (Ref: AirLoopHVAC:UnitaryHeatPump:AirToAir:MultiSpeed). The part-load impact on coil energy use is automatically applied to the lowest stage.

When the model determines performance at Stage 1 (the lowest stage) or cycling between OFF and Stage 1, its performance is almost the same as the performance for the Coil:Heating:Electric and Coil:Heating:Fuel models. However, the outlet conditions are calculated slightly differently. Therefore, the Coil:Heating:Electric and Coil:Heating:Fuel model may be considered as subsets of the multistage model described here. When the multistage coil model determines performance at higher stages (above 1), the model linearly interpolates the performance at two consecutive stages (n-1 and n) as needed to meet the heating load, with the fraction of time at each speed established by the speed ratio. For the time being, this coil model can only be called by the parent object AirLoopHVAC:UnitaryHeatPump:AirToAir:MultiSpeed.

15.2.10.2 Model Inputs

The model inputs are also very similar to the inputs of the Coil:Heating:Electric and Coil:Heating:Fuel objects. The main difference is that this multistage model requires a set of fields at each speed, such as nominal capacity, and efficiency.

15.2.10.3 Stage 1 Operation

The following procedure provides the detailed description of the exception.

- Total delivered heating capacity

The total delivered heating capacity for Stage 1 operating at the cycling ratio needed to meet the requested heating load is:

$$Q_{coil,cycling} = \dot{m}_{Speed\ 1} (CycRatio) (h_{inlet} - h_{outlet,full}) \quad (15.279)$$

where:

$Q_{coil,cycling}$ is the delivered sensible heating capacity for Stage 1 operating at a specific cycling ratio (W)

$\dot{m}_{Speed\ 1}$ is the air mass flow rate through heating coil at Speed 1 as set by the parent object (kg/s)

$h_{outlet,full}$ is the specific enthalpy of the coil outlet air during full-load operation at Stage 1 (no cycling) (J/kg)

h_{inlet} is the specific enthalpy of the coil inlet air (J/kg)

$CycRatio$ is the cycling ratio at Stage 1, ratio of requested heating load to the full-load capacity of the coil at Stage 1 (dimensionless).

It is assumed that the coil provides no heating capacity when the coil is OFF, even if the supply air fan continues to operate.

- Outlet air specific enthalpy

The average specific enthalpy of the coil outlet air is then calculated based on the delivered sensible heating capacity and the average air mass flow rate entering the coil:

$$h_{outlet,average} = h_{inlet} - \frac{Q_{coil,cycling}}{\dot{m}_{inlet}} \quad (15.280)$$

where:

$h_{outlet,average}$ is the average specific enthalpy at the coil outlet (J/kg)

\dot{m}_{inlet} is the mass flow rate at the inlet to the coil as established by the parent object (Ref. AirLoopHVAC:UnitaryHeatPump:AirToAir:MultiStage, Mass Flow Rate Calculation). This flow rate is the average value determined by the parent object, accounting for the specified flow rate when the heating coil is ON and the specified flow rate when the heating coil is OFF for the time step being simulated.

- Outlet air temperature

The heating coil's outlet air humidity ratio equals the inlet air humidity ratio since the coil does not change the moisture content of the air. So the average outlet air temperature is calculated based on the inlet air humidity ratio and the average outlet air enthalpy using the psychrometric function `PsyTdbFnHW`.

The main reason for using the above approach is that outlet air conditions are calculated in the same way for all operating Stages.

15.2.10.4 Higher Stage Operation

This section describes how higher Stage operation is simulated. When the required sensible load is less than the full load sensible capacity at Stage n (Stage Number > 1), the following calculations are performed:

- Total delivered heating capacity at Stage n-1 and Stage n

$$TotCap_{n-1} = MSNominalCap_{n-1} \quad (15.281)$$

$$TotCap_n = MSNominalCap_n \quad (15.282)$$

where:

$TotCap_i$ is the total delivered heating capacity at given temperatures and flow rates at Stage i (W)

$MSNominalCap_i$ is the heating capacity at the rated conditions at Stage i (W)

i is Stage n or Stage n-1.

- Full load outlet air specific enthalpy at Stage n-1 and Stage n

$$h_{outlet,full\ Speed\ n} = h_{inlet} - (MSNominalCap_n / \dot{m}_{inlet}) \quad (15.283)$$

$$h_{outlet,full\ Speed\ n-1} = h_{inlet} - (MSNominalCap_{n-1} / \dot{m}_{inlet}) \quad (15.284)$$

where:

$h_{outlet,full\ Speed\ n}$ is the specific enthalpy of the coil outlet air during full-load operation at Stage n (no cycling) (J/kg)

$h_{outlet,full\ Speed\ n-1}$ is the specific enthalpy of the coil outlet air during full-load operation at Stage n-1 (no cycling) (J/kg).

- Effective total heating capacity

$$Q_{coil,SpeedRatio} = (SpeedRatio) \dot{m}_{Speed\ n} (h_{inlet} - h_{outlet,full\ Speed\ n}) + (1 - SpeedRatio) \dot{m}_{Speed\ n-1} (h_{inlet} - h_{outlet,full\ Speed\ n-1}) \quad (15.285)$$

where:

$Q_{coil,SpeedRatio}$ is the delivered sensible heating capacity at a given Stage ratio between two consecutive Stages (W)

$\dot{m}_{Speed\ n}$ is the air mass flow rate through heating coil at Stage n as set by the parent object (kg/s)

$\dot{m}_{Speed\ n-1}$ is the air mass flow rate through heating coil at Stage 1 as set by the parent object (kg/s).

- Average outlet air enthalpy

$$h_{outlet,average} = h_{inlet} - \frac{Q_{coil,SpeedRatio}}{\dot{m}_{inlet}} \quad (15.286)$$

where:

$h_{outlet,average}$ is the average specific enthalpy at the coil outlet (J/kg)

h_{inlet} is the specific enthalpy of the coil inlet air (J/kg)

\dot{m}_{inlet} is the mass flow rate at the inlet to the coil as established by the parent object (Ref. AirLoopHVAC:UnitaryHeatPump:AirToAir:MultiStage, Mass Flow Rate Calculation). This flow rate is the average value determined by the parent object, accounting for the specified flow rate when the heating coil is at Stage n and the specified flow rate when the heating coil is at Stage n-1 for the time step being simulated.

- Average outlet air temperature

The heating coil's outlet air humidity ratio equals the inlet air humidity ratio since the coil does not change the moisture content of the air. So the average outlet air temperature is calculated based on the inlet air humidity ratio and the average outlet air enthalpy using the psychrometric function `PsyTdbFnHW`.

- Full load energy inputs at Stage n-1 and Stage n

$$HeatingPower_n = MSNominalCap_n / MSEfficiency_n \quad (15.287)$$

$$HeatingPower_{n-1} = MSNominalCap_{n-1} / MSEfficiency_{n-1} \quad (15.288)$$

where:

$MSEfficiency_n$ is the efficiency at stage n

$MSEfficiency_{n-1}$ is the efficiency at stage n-1.

- Calculate combined energy input

$$\text{HeatingPower} = \text{HeatingPower}_n(\text{SpeedRatio}) + \text{HeatingPower}_{n-1}(1.0 - \text{SpeedRatio}) \quad (15.289)$$

where HeatingPower is the power used (W).

15.2.11 Single-Speed Electric Heat Pump DX Air Heating Coil

15.2.11.1 Overview

This model (object name Coil:Heating:DX:SingleSpeed) simulates the performance of an air-to-air direct expansion (DX) heating system. The model uses performance information at rated conditions along with curve fits for variations in total capacity, energy input ratio and part-load fraction to determine the performance of the unit at part-load conditions (DOE 1982). Adjustment factors are applied to total capacity and input power to account for frost formation on the outdoor coil.

This model simulates the thermal performance of the indoor DX heating coil, and the power consumption of the outdoor unit (compressors, fans, crankcase heaters and defrost heaters). The performance of the indoor supply air fan varies widely from system to system depending on control strategy (e.g., constant fan vs. AUTO fan, constant air volume vs. variable air volume, etc.), fan type, fan motor efficiency and pressure losses through the air distribution system. Therefore, this DX system model does not account for the thermal effects or electric power consumption of the indoor supply air fan. EnergyPlus contains separate models for simulating the performance of various indoor fan configurations, and these models can be easily linked with the DX system model described here to simulate the entire DX system being considered (e.g., see AirLoopHVAC:UnitaryHeatPump:AirToAir).

15.2.11.2 Model Inputs

The user must input the total heating capacity, coefficient of performance (COP) and the volumetric airflow rate across the heating coil at rated conditions. The capacity and COP inputs should be “gross” values, excluding any thermal or energy impacts due to the indoor supply air fan. The rating condition is considered to be outdoor air at 8.33°C dry-bulb and 6.11°C wet-bulb temperatures (i.e., air entering the outdoor coil), with air entering the indoor DX heating coil at 21.11°C dry-bulb and 15.55°C wet-bulb temperatures. The rated volumetric air flow across the DX heating coil should be between 0.00004027 m³/s and 0.00006041 m³/s per watt of rated total heating capacity (300 – 450 cfm/ton).

Depending on the defrost strategy that is selected, the user must also input up to six performance curves that describe the change in total heating capacity and efficiency at part-load conditions, and efficiency during reverse-cycle defrosting:

- The total heating capacity modifier curve (function of temperature) can be a function of both the outdoor and indoor air dry-bulb temperature or only the outdoor air dry-bulb temperature. User has the choice of a bi-quadratic curve with two independent variables or a quadratic curve as well as a cubic curve with a single independent variable. The bi-quadratic curve is recommended if sufficient manufacturer data is available as it provides sensitivity to the indoor air dry-bulb temperature and a more realistic output. The output of

this curve is multiplied by the rated total heating capacity to give the total heating capacity at specific temperature operating conditions (i.e., at an outdoor or indoor air temperature different from the rating point temperature).

$$TotCapTempModFac = a + b(T_{db,o}) + c(T_{db,o})^2 \quad (15.290)$$

or

$$TotCapTempModFac = a + b(T_{db,o}) + c(T_{db,o})^2 + d(T_{db,o})^3 \quad (15.291)$$

or

$$TotCapTempModFac = a + b(T_{db,i}) + c(T_{db,i})^2 + d(T_{db,o}) + e(T_{db,o})^2 + f(T_{db,i})(T_{db,o}) \quad (15.292)$$

where:

$T_{db,i}$ is the dry-bulb temperature of the air entering the indoor coil (°C)

$T_{db,o}$ is the dry-bulb temperature of the air entering the outdoor coil (°C).

- The total heating capacity modifier curve (function of flow fraction) is a quadratic or cubic curve with the independent variable being the ratio of the actual air flow rate across the heating coil to the rated air flow rate (i.e., fraction of full load flow). The output of this curve is multiplied by the rated total heating capacity and the total heating capacity modifier curve (function of temperature) to give the total heating capacity at the specific temperature and air flow conditions at which the coil is operating.

$$TotCapFlowModFac = a + b(ff) + c(ff)^2 \quad (15.293)$$

or

$$TotCapFlowModFac = a + b(ff) + c(ff)^2 + d(ff)^3 \quad (15.294)$$

where:

$$ff = \text{flow fraction} = \left(\frac{\text{Actual air mass flow rate}}{\text{Rated air mass flow rate}} \right) \quad (15.295)$$

Note: The actual volumetric airflow rate through the heating coil for any simulation time step where the DX unit is operating should be between 0.00002684 m³/s and .00008056 m³/s per watt of rated total heating capacity (200 - 600 cfm/ton). The simulation will issue a warning message if this airflow range is exceeded.

- The energy input ratio (EIR) modifier curve (function of temperature) can be a function of both the outdoor and indoor air dry-bulb temperature or only the outdoor air dry-bulb temperature. User has the choice of a bi-quadratic curve with two independent variables or a quadratic curve as well as a cubic curve with a single independent variable. The bi-quadratic curve is recommended if sufficient manufacturer data is available as it provides sensitivity to the indoor air dry-bulb temperature and a more realistic output. The output of this curve is multiplied by the rated EIR (inverse of the rated COP) to give the EIR at specific temperature operating conditions (i.e., at an outdoor or indoor air temperature different from the rating point temperature).

$$EIRTempModFac = a + b(T_{db,o}) + c(T_{db,o})^2 \quad (15.296)$$

or

$$EIRTempModFac = a + b(T_{db,o}) + c(T_{db,o})^2 + d(T_{db,o})^3 \quad (15.297)$$

or

$$EIRTempModFac = a + b(T_{db,i}) + c(T_{db,i})^2 + d(T_{db,o}) + e(T_{db,o})^2 + f(T_{db,i})(T_{db,o}) \quad (15.298)$$

- The energy input ratio (EIR) modifier curve (function of flow fraction) is a quadratic or cubic curve with the independent variable being the ratio of the actual air flow rate across the heating coil to the rated air flow rate (i.e., fraction of full load flow). The output of this curve is multiplied by the rated EIR (inverse of the rated COP) and the EIR modifier curve (function of temperature) to give the EIR at the specific temperature and air flow conditions at which the coil is operating.

$$EIRFlowModFac = a + b(ff) + c(ff)^2 \quad (15.299)$$

or

$$EIRFlowModFac = a + b(ff) + c(ff)^2 + d(ff)^3 \quad (15.300)$$

- The part-load fraction correlation (function of part-load ratio) is a quadratic or cubic curve with the independent variable being part-load ratio (sensible heating load / steady-state heating capacity). The output of this curve is used in combination with the rated EIR and EIR modifier curves to give the “effective” EIR for a given simulation time step. The part-load fraction (PLF) correlation accounts for efficiency losses due to compressor cycling.

$$PartLoadFrac = PLF = a + b(PLR) + c(PLR)^2 \quad (15.301)$$

or

$$PartLoadFrac = a + b(PLR) + c(PLR)^2 + d(PLR)^3 \quad (15.302)$$

where:

$$PLR = \text{part - load ratio} = \left(\frac{\text{sensible heating load}}{\text{steady - state sensible heating capacity}} \right) \quad (15.303)$$

The part-load fraction correlation should be normalized to a value of 1.0 when the part load ratio equals 1.0 (i.e., no efficiency losses when the compressor(s) run continuously for the simulation time step). For PLR values between 0 and 1 ($0 < = PLR < 1$), the following rules apply: $PLF > = 0.7$ and $PLF > = PLR$.

If $PLF < 0.7$ a warning message is issued, the program resets the PLF value to 0.7, and the simulation proceeds. The runtime fraction of the coil is defined a PLR/PLF . If $PLF < PLR$, then a warning message is issued and the runtime fraction of the coil is limited to 1.0.

A typical part load fraction correlation for a conventional, single-speed DX heating coil (e.g., residential heat pump) would be: $PLF = 0.85 + 0.15(PLR)$.

- The defrost energy input ratio (EIR) modifier curve (function of temperature) is a bi-quadratic curve with two independent variables: outdoor air dry-bulb temperature and the heating coil entering air wet-bulb temperature. The output of this curve is multiplied by the heating coil capacity, the fractional defrost time period and the runtime fraction of the heating coil to give the defrost power at the specific temperatures at which the coil is operating. This curve is only required when a reverse-cycle defrost strategy is specified.

$$DefrostEIRTempModFac = a + b(T_{wb,i}) + c(T_{wb,i})^2 + d(T_{db,o}) + e(T_{db,o})^2 + f(T_{wb,i})(T_{db,o}) \quad (15.304)$$

where:

$T_{wb,i}$ is the wet-bulb temperature of the air entering the indoor heating coil (°C)

$T_{db,o}$ is the dry-bulb temperature of the air entering the outdoor coil (°C).

All six curves are accessed through EnergyPlus' built-in performance curve equation manager (curve:quadratic, curve:cubic and curve:biquadratic). It is not imperative that the user utilize all coefficients shown in the preceding Equations 15.290 through 15.304 in items (1) through (6) if their performance equation has fewer terms (e.g., if the user's PartLoadFrac performance curve is linear instead of quadratic or cubic, simply enter the appropriate values for the coefficients a and b, and set the remaining coefficients to zero).

The next input item for the Heating DX single speed coil is the supply air fan operation mode. Either the supply air fan runs continuously while the DX coil cycles on/off, or the fan and coil cycle on/off together. The next two inputs define the minimum outdoor dry-bulb temperature that the heat pump compressor will operate and the maximum outdoor dry-bulb temperature for defrost operation. Crankcase heater capacity and crankcase heater cutout temperature are entered in the following two inputs. The final four inputs cover the type of defrost strategy (reverse-cycle or resistive), defrost control (timed or on-demand), the fractional defrost time period (timed defrost control only), and the resistive defrost heater capacity if a resistive defrost strategy is selected.

15.2.11.3 Model Description

The general flow of the model is as follows:

1. If the outdoor air dry-bulb temperature is below the specified minimum temperature for compressor operation or the DX heating coil is not scheduled to operate, simply pass through the heating coil inlet air conditions as the coil outlet conditions, set power and heating rates equal to zero, and set crankcase heater power equal to the crankcase heater capacity value specified by the input file.
2. If the outdoor air dry-bulb temperature is above the specified minimum temperature for compressor operation and the DX heating coil is scheduled to operate, then:
 - (a) If the outdoor dry-bulb temperature is below the specified maximum outdoor dry-bulb temperature for defrost operation, calculate a heating capacity multiplier, input power multiplier and fractional defrost time period depending on the defrost strategy and defrost control type specified for the heating coil.
 - (b) Using the rated heating capacity and COP, the part-load curves specified for the DX heating coil, the defrost multipliers calculated above (if applicable), and the part-load ratio that is being requested of the heating coil, determine the following: heating coil exiting air conditions (dry-bulb temperature, humidity ratio and enthalpy), total DX coil heating rate, electric power during heating (compressors and outdoor fans), electric power during defrost, and crankcase heater power.

The following paragraphs give a detailed description of the model calculations that are performed when the DX heating coil is operating (i.e., scenario # 2 above).

15.2.11.4 Frost Adjustment Factors

Frost formation on the outdoor coil, and the need to periodically defrost this coil, has a significant impact on heating capacity and energy use by the DX heating system. If the outdoor air dry-bulb temperature is below the specified maximum temperature for defrost operation, then the model calculates adjustment factors for heating capacity and input power due to frost formation, and the fractional defrost time period, depending on the defrost strategy and defrost control type specified for the heating coil. This method of accounting for the impacts of frosting/defrost was taken from the model used in DOE-2.1E (ESTSC 2001, Miller and Jaster 1985).

The model first estimates the outdoor coil temperature according to a linear empirical relationship with outdoor air dry-bulb temperature as the independent variable.

$$T_{coil,out} = 0.82T_{db,o} - 8.589 \quad (15.305)$$

The difference between the outdoor air humidity ratio (from the weather file) and the saturated air humidity ratio at the estimated outdoor coil temperature is then calculated, and this value is used as an indication of frost formation on the outdoor coil.

$$\Delta\omega_{coil,out} = MAX[1.0E - 6, \omega_{outdoor} - \omega_{sat}(T_{coil,out}, OutBaroPress)] \quad (15.306)$$

Frost formation on the outdoor coil must be periodically removed. The fraction of compressor runtime when the coil is being defrosted is either entered by the user (for timed defrost) or

is calculated by the model (for on-demand defrost) using an empirical equation and $\Delta\omega_{coil,out}$. Adjustment factors to total heating coil capacity and input power due to frost formation on the outdoor coil are also calculated by empirical models with $\Delta\omega_{coil,out}$ or fractional defrost time period as the independent variable. The defrost time period fraction and adjustment factors due to frost formation on the outdoor coil vary depending on the defrost control type as shown below.

Timed Defrost:

$$\text{Fractional Defrost Time} = \text{time period specified by user} = t_{frac,defrost} \quad (15.307)$$

$$\text{Heating Capacity Multiplier} = 0.909 - 107.33 (\Delta\omega_{coil,out}) \quad (15.308)$$

$$\text{Input Power Multiplier} = 0.9 - 36.45 (\Delta\omega_{coil,out}) \quad (15.309)$$

On-Demand Defrost:

$$\text{Fractional Defrost Time} = \frac{1}{1 + \left(\frac{0.01446}{\Delta\omega_{coil,out}} \right)} = t_{frac,defrost} \quad (15.310)$$

$$\text{Heating Capacity Multiplier} = 0.875 (1 - t_{frac,defrost}) \quad (15.311)$$

$$\text{Input Power Multiplier} = 0.954 (1 - t_{frac,defrost}) \quad (15.312)$$

If the outdoor air dry-bulb temperature is above the specified maximum temperature for defrost operation, the fractional defrost time period is set to zero and the heating capacity/input power multipliers are set to unity.

15.2.11.5 Defrost Operation

If the fractional defrost time period is greater than zero for the simulation time step, then the model calculates the electrical power used during defrost. The method for calculating defrost power varies based on the defrost strategy specified (i.e., reverse-cycle or resistive). In the case of reverse-cycle defrost, the additional heating load due to defrost (indoor cooling during defrost) is also calculated so that it may be added to the existing heating load when calculating input power for the compressor(s) and outdoor coil fan(s).

Reverse-Cycle:

$$Q_{defrost} = 0.01 (t_{frac,defrost}) (7.222 - T_{db,o}) \left(\frac{Q_{total,rated}}{1.01667} \right) \quad (15.313)$$

$$P_{defrost} = \text{DefrostEIRTempModFac} \left(\frac{Q_{total,rated}}{1.01667} \right) (t_{frac,defrost}) (RTF) \quad (15.314)$$

Resistive:

$$Q_{defrost} = 0.0 \quad (15.315)$$

$$P_{defrost} = (Q_{cap,defrost}) (t_{frac,defrost}) (RTF) \quad (15.316)$$

where:

$Q_{defrost}$ is the additional indoor heating load due to reverse-cycle defrost (W)

$Q_{total,rated}$ is the total full-load heating capacity of the coil at rated conditions (W)

$P_{defrost}$ is the average defrost power for the simulation time step (W)

$Q_{cap,defrost}$ is the capacity of the resistive defrost heating element (W)

$DefrostEIRTempModFac$ is the energy input ratio modifier curve applicable during defrost

$$RTF = \left(\frac{PLR}{PartLoadFrac} \right) = \text{runtime fraction of the heating coil} \quad (15.317)$$

15.2.11.6 Heating Operation

For any simulation time step, the total heating capacity of the DX unit is calculated as follows:

$$Q_{total} = Q_{total,rated} (TotCapTempModFac) (TotCapFlowModFac) \quad (15.318)$$

If the outdoor air dry-bulb temperature is below the maximum temperature for defrost operation, then the total heating capacity is further adjusted due to outdoor coil frost formation based on the results of Equation 15.318 and Equation 15.308 or 15.311.

$$Q_{total} = Q_{total} (HeatingCapacityMultiplier) \quad (15.319)$$

In a similar fashion, the electrical power draw by the DX unit (compressors plus outdoor coil fans) for any simulation time step is calculated. For a reverse-cycle defrost strategy, the additional heating load ($Q_{defrost}$) generated during defrost operation is added to the heating load being requested by adjusting the part-load ratio. If a resistive defrost strategy is selected, $Q_{defrost} = 0$. The part-load fraction correlation for the heating coil (user input, Equation 15.301 or 15.302) is used in the calculation of electrical power draw to account for efficiency losses due to compressor cycling.

$$PLR = MIN \left(1.0, PLR + \left(\frac{Q_{defrost}}{Q_{total}} \right) \right) \quad (15.320)$$

$$PartLoadFrac = a + b(PLR) + c(PLR)^2 + d(PLR)^3 \quad (15.321)$$

$$P_{heating} = \frac{(Q_{total})(EIR)(PLR)}{PartLoadFrac} \times InputPowerMultiplier \quad (15.322)$$

where

$P_{heating}$ is the average compressor and outdoor fan power for the simulation time step (W)

Q_{total} is the total heating capacity from Equation 15.319 (W)

$$EIR = \text{Energy Input Ratio} = \left(\frac{1}{COP_{rated}} \right) (EIRTempModFac) (EIRFlowModFac) \quad (15.323)$$

COP_{rated} is the coefficient of performance at rated conditions (user input)

$InputPowerMultiplier$ is the power adjustment due to frost if applicable as in Equation 15.309 or 15.312.

The crankcase heater is assumed to operate when the heating coil's compressor is OFF, and the average crankcase heater power for the simulation time step is calculated as follows:

$$P_{crankcase} = Q_{cap,crankcase} (1 - RTF) \quad (15.324)$$

$$RTF = \left(\frac{PLR}{PartLoadFrac} \right) = \text{runtime fraction of the heating coil} \quad (15.325)$$

where:

$P_{crankcase}$ is the average crankcase heater power for the simulation time step (W)

$Q_{cap,crankcase}$ is the crankcase heater capacity (W).

If this heating coil is used as part of an air-to-air heat pump (Ref. AirLoopHVAC:UnitaryHeat-Pump:AirToAir), the crankcase heater defined for this DX heating coil is enabled during the time that the compressor is not running for either heating or cooling (and the crankcase heater power defined in the DX cooling coil object is disregarded in this case). In this instance, RTF in the above equations would be the runtime fraction of the heat pump's heating coil or cooling coil, whichever is greater.

The properties of the air leaving the heating coil at full-load operation are calculated using the following equations:

$$h_{outlet} = h_{inlet} + \frac{Q_{total}}{\dot{m}} \quad (15.326)$$

$$\omega_{outlet} = \omega_{inlet} \quad (15.327)$$

$$T_{db,outlet} = PsyTdbFnHW(h_{outlet}, \omega_{outlet}) \quad (15.328)$$

where:

h_{outlet} is the enthalpy of the air leaving the heating coil (J/kg)

ω_{outlet} is the leaving air humidity ratio (kg/kg)

$T_{db,outlet}$ is the leaving air dry-bulb temperature (°C)

$PsyTdbFnHW$ is an EnergyPlus psychrometric function, returns dry-bulb temp given enthalpy and humidity ratio.

15.2.11.7 Condenser Inlet Air Temperature

The air temperature entering the outdoor condenser is based on the weather data used during a simulation. This temperature is either taken directly from the weather data, or can be adjusted based on the height of the outdoor condenser. Since this DX heating coil can only be used in conjunction with a DX cooling coil, the input for Condenser Air Inlet Node Name in the DX cooling coil object can be used to control this optional feature. If this input is left blank, the air temperature entering the condenser is based solely on the weather data. If this input is not blank, then the node name specified must also be listed in an OutdoorAir:Node or OutdoorAir:NodeList object. When the node name is listed in an OutdoorAir:NodeList object, the air temperature entering the condenser is based solely on the weather data. When the node name is listed in an OutdoorAir:Node object, the height of the node determines the air temperature entering the outdoor condenser (see description of Local Outdoor Air Temperature Calculation in the Atmospheric Variation section of this document for further details).

15.2.11.8 Supply Air Fan Control: Cycling vs. Continuous

One of the inputs to the DX coil model is the supply air fan operation mode: cycling fan, cycling compressor (CyclingFanAndCompressor) or continuous fan, cycling compressor (ContinuousFan-WithCyclingCompressor). The first operation mode is frequently referred to as “AUTO fan”, where the compressor(s) and supply air fan operate in unison to meet the zone heating load, and cycle off together when the heating load has been met. The second operation mode is often referred to as “fan ON”, where the compressor(s) cycle on and off to meet the zone heating load but the supply air fan operates continuously regardless of compressor operation.

Since this DX heating coil can only be used in conjunction with a DX cooling coil (i.e. heat pumps), and these coils are used in AC equipment that specifies a fan operation mode schedule (e.g. AirLoopHVAC:UnitaryHeatPump:AirToAir), the selection made in the DX heating coil is currently ignored and the fan operation mode schedule value determines the fan operation mode for each time step throughout the simulation. A fan operation mode schedule value of 0 specifies AUTO fan mode operation while values other than 0 specify fan ON operation. The use of a schedule allows the fan operation mode to change based on time-of-day or with changes in season.

The EnergyPlus methodology for determining the impact that HVAC equipment has on an air stream is to calculate the mass flow rate and air properties (e.g., enthalpy, dry-bulb temperature, humidity ratio) exiting the equipment. These exiting conditions are passed along as inlet conditions to the next component model in the air stream. Eventually the flow rate and properties of the air being supplied to the conditioned zone are used in the zone energy balance to determine the resulting zone air temperature and humidity ratio.

With this methodology, the determination of the air mass flow rate and air properties for the two different supply air fan operation modes is slightly different. For the case of cycling fan/cycling compressor, the conditions of the air leaving the heating coil are the steady-state values calculated using Equations 15.326, 15.327, and 15.328 above. However the air mass flow rate passed along to the next component (and eventually to the conditioned zone) is the average air mass flow rate for the system simulation time step (determined by the heating system; see AirLoopHVAC:UnitaryHeatPump:AirToAir). For this fan control type, the heating coil part-load fraction (Equation 15.301 or 15.302) is also passed to Fan:OnOff (if used) to properly calculate the supply air fan power and associated fan heat.
