For the case of continuous fan/cycling compressor, the air mass flow rate is constant. However, the air properties leaving the heating coil are calculated as the average conditions during the system simulation time step. The model assumes that the exiting air conditions are the steady-state values calculated using Equations 15.326, 15.327, and 15.328 above when the compressor(s) operate. For the remainder of the system simulation time step, it is assumed that the air exiting the DX coil has the same properties as the air entering the coil. For this supply air fan operating strategy, the leaving air properties are calculated as follows:

$$h_{outlet,ContFanCycComp} = h_{outlet}(PLR) + h_{inlet}(1 - PLR) \quad (15.329)$$

$$\omega_{outlet,ContFanCycComp} = \omega_{outlet}(PLR) + \omega_{inlet}(1 - PLR) \quad (15.330)$$

$$T_{db,outlet,ContFanCycComp} = PsyTdbFnHW(h_{outlet,ContFanCycComp}, \omega_{outlet,ContFanCycComp}) \quad (15.331)$$

15.2.12 Single-Speed DX Heating Coil Standard Ratings

For single-speed direct expansion (DX) heating coils, the industry standard ratings of High Temperature Heating Standard (Net) Rating Capacity, Low Temperature Heating Standard (Net) Rating Capacity and Heating Seasonal Performance Factor (HSPF) are calculated according to ANSI/AHRI Standard 210/240 (AHRI 2008). The rated Energy Efficiency Ratio (EER) is not calculated for any DX heating coils at this time.

For the Coil:Heating:DX:SingleSpeed object in EnergyPlus, these standard ratings are not direct inputs to the model. However, these standard ratings can be calculated using user-entered information for the Coil:Heating:DX:SingleSpeed object. These standard rating values are provided in the eplusout.eio output file (Ref. OutputDetailsAndExamples.pdf) and also in the predefined tabular output reports (Output:Table:SummaryReports object, Equipment Summary). Currently, the standard ratings are only calculated and output for single-speed DX heating coils.

Note: The standard ratings described in this section require that the DX heating coil model be evaluated at specific operating conditions (i.e., specific temperatures for air entering the heating coil and for air entering the air-cooled [outdoor] condenser). If the heating coil performance curves can not be evaluated at the required test conditions, then a standard rating value will be calculated at user specified curve limit as an output and a warning message will be written to eplusout.err. For example, if the curve object (Curve:Biquadratic) for Total Heating Capacity Function of Temperature Curve has a minimum value of -5°C for dry-bulb temperature entering the condenser coil, the HSPF calculation requires that heating capacity and EIR be calculated at -8.33°C , so this would result in HSPF value calculated at -5°C as an output and a warning message in the eplusout.err file.

15.2.12.1 High Temperature Heating Standard (Net) Rating Capacity

The procedure for calculating the Standard Rating Heating Capacity is given by:

$$\dot{Q}_{HighStandardRating} = \dot{Q}_{total,Rated} (TotCapTempModFac_{Rated}) \quad (15.332)$$

$$\dot{Q}_{HighStandardRating,Net} = \dot{Q}_{HighStandardRating} + FanPower_{Rated} \quad (15.333)$$

where:

$\dot{Q}_{HighStandardRating,Net}$ is the total standard (net) heating capacity (W) of the air-source heat pump equipment in heating mode determined from ANSI/AHRI Standard 210/240 and test conditions shown in Table 15.9. The standard heating test conditions for air-cooled condenser are: indoor coil entering air dry-bulb 21.1°C and outdoor coil entering air dry-bulb 8.33°C

$\dot{Q}_{HighStandardRating}$ is the total standard heating capacity (W) of the air-source heat pump equipment in heating mode determined from ANSI/AHRI Standard 210/240 and test conditions shown in Table 15.10. The standard heating test conditions for air-cooled condenser are: indoor coil entering air dry-bulb 21.1°C and outdoor coil entering air dry-bulb 8.33°C

$\dot{Q}_{total,Rated}$ is the rated total heating capacity, user input (W)

$TotCapTempModFac_{Rated}$ is the user-specified bi-quadratic curve evaluated at the indoor coil entering air dry-bulb 21.1°C and outdoor coil entering air dry-bulb 8.33°C for air-cooled condenser as specified in Table 15.9 (dimensionless)

$FanPower_{Rated}$ is the supply air fan power at rated conditions, (W). The Rated Indoor Coil Fan Power Per Volume Flow rate is a user-entered value, with a default of 773.3 W/(m³/s) if the user leaves this input field blank. The default value is taken from ANSI/ASHRAE Standard 210/240-2008 where it is defined for systems which do not have an Indoor Coil fan furnished as part of the system. See the description given at the end of this section for how this value is calculated.

15.2.12.2 Low Temperature Heating Standard (Net) Rating Capacity

The procedure for calculating the Low Temperature Standard Rating Heating Capacity is given by:

$$\dot{Q}_{LowStandardRating} = \dot{Q}_{total,Rated} (TotCapTempModFac_{H3Test}) \quad (15.334)$$

$$\dot{Q}_{LowStandardRating,Net} = \dot{Q}_{LowStandardRating} + FanPower_{Rated} \quad (15.335)$$

where:

$\dot{Q}_{LowStandardRating,Net}$ is the total standard (net) heating capacity (W) of the air-source heat pump equipment in heating mode determined from ANSI/AHRI Standard 210/240 and test conditions shown in Table 15.10. The standard heating test conditions for air-cooled condenser are: indoor coil entering air dry-bulb 21.1°C and outdoor coil entering air dry-bulb -8.33°C

$\dot{Q}_{LowStandardRating}$ is the total standard heating capacity (W) of the air-source heat pump equipment in heating mode determined from ANSI/AHRI Standard 210/240 and test conditions shown in Table 15.9. The standard heating test conditions for air-cooled condenser are: indoor coil entering air dry-bulb 21.1°C and outdoor coil entering air dry-bulb -8.33°C

$\dot{Q}_{total,Rated}$ is the rated total heating capacity, user input (W)

$TotCapTempModFac_{H3Test}$ is the user-specified bi-quadratic curve evaluated at the indoor coil entering air dry-bulb 21.1°C and outdoor coil entering air dry-bulb -8.33°C for air-cooled condenser as specified in Table 15.10, (dimensionless).

$FanPower_{Rated}$ is the supply air fan power at rated conditions (W). The Rated Indoor Coil Fan Power Per Volume Flow rate is a user-entered value, with a default of 773.3 W/(m³/s) if the user leaves this input field blank. The default value is taken from ANSI/ASHRAE Standard 210/240-2008 where it is defined for systems which do not have an Indoor Coil fan furnished as part of the system. See the description given at the end of this section for how this value is calculated.

15.2.12.3 Heating Seasonal Performance Factor (HSPF)

Heating Seasonal Performance Factor (HSPF) is defined as the total space heating required during the space heating season, divided by the total electrical energy consumed by the heat pump system during the same season.

Calculations of HSPF of a heat pump having a single-speed compressor that was tested with a fixed speed indoor fan installed, a constant-air-volume-rate indoor fan installed, or with no indoor fan installed is given below.

$$HSPF = \frac{\sum_j^J \left[\frac{n_j}{N} \cdot BL(T_j) \right]}{\sum_j^J \left[\frac{e_h(T_j)}{N} \right] + \sum_j^J \left[\frac{RH(T_j)}{N} \right]} \cdot F_{def} \quad (15.336)$$

where:

$\frac{e_h(T_j)}{N}$ is the ratio of the electrical energy consumed by the heat pump during periods of the space heating season when the outdoor temperature fell within the range represented by bin temperature T_j to the total number of hours (N) in the heating season (W)

$\frac{RH(T_j)}{N}$ = The ratio of the electrical energy used for resistive space heating during periods when the outdoor temperature fell within the range represented by bin temperature T_j to the total number of hours (N) in the heating season (W)

T_j is the outdoor bin temperature (°C). Outdoor temperatures are “binned” such that calculations are only performed based one temperature within the bin. Bins of 2.78°C are used

$\frac{n_j}{N}$ is the fractional bin hours for the heating season; the ratio of the number of hours during the heating season when the outdoor temperature fell within the range represented by bin temperature T_j to the total number of hours in the heating season, dimensionless. Obtain $\frac{n_j}{N}$ values from Table 17 of AHRI Std. 210/240-2008 (Table 15.10 below).

j is the bin number (dimensionless)

J is, for each generalized climatic region, the total number of temperature bins (dimensionless). Referring to Table 15.10, J is the highest bin number (j) having a nonzero entry for the fractional bin hours for the generalized climatic region of interest.

F_{def} is the demand defrost credit described in section 3.9.2 of AHRI Std. 210/240-2008 (dimensionless). For simplification, assigned a value of 1 for timed defrost control and a value of 1.03 for demand defrost control.

$BL(T_j)$ is the building space conditioning load corresponding to an outdoor temperature of T_j ; the heating season building load also depends on the generalized climatic region’s outdoor design temperature and the design heating requirement (W).

Building heating load can be evaluated by using the following equation:

$$BL(T_j) = \frac{(18.33 - T_j)}{(18.33 - T_{OD})} \cdot C \cdot DHR \quad (15.337)$$

where:

T_{OD} is the outdoor design temperature (°C). An outdoor design temperature is specified for each generalized climatic region in Table 17 of AHRI Std. 210/240-2008 (Table 15.10 below).

C is 0.77, a correction factor which tends to improve the agreement between calculated and measured building loads (dimensionless)

DHR is the Design Heating Requirement (W). This is the amount of heating required to maintain a given indoor temperature at a particular outdoor design temperature.

For a single speed heat pump with a fixed speed indoor fan installed, a constant-air-volume-rate indoor fan installed, or with no indoor fan installed, the minimum and maximum design heating requirements for each generalized climatic region can be calculated as follows:

$$DHR_{min} = \left\{ \begin{array}{l} \dot{Q}_h(8.33) \cdot (1.8) \cdot \left(\frac{18.33 - T_{OD}}{60.0} \right), \text{ for Regions I, II, III, IV, and VI} \\ \dot{Q}_h(8.33), \text{ for Region V} \end{array} \right\} \quad (15.338)$$

$$DHR_{max} = \left\{ \begin{array}{l} 2 \cdot \dot{Q}_h(8.33) \cdot (1.8) \cdot \left(\frac{18.33 - T_{OD}}{60.0} \right), \text{ for Regions I, II, III, IV, and VI} \\ 2.2 \cdot \dot{Q}_h(8.33), \text{ for Region V} \end{array} \right\} \quad (15.339)$$

Both DHR_{min} and DHR_{max} above should be rounded to the nearest standardized DHR given in Table 15.11.

The intermediate term used in the calculations of HSPF can be calculated using the equations described below.

$$\frac{e_h(T_j)}{N} = \frac{X(T_j) \cdot \dot{E}_h(T_j) \cdot \delta(T_j)}{PLF_j} \cdot \frac{n_j}{N} \quad (15.340)$$

$$\frac{RH(T_j)}{N} = \left[BL(T_j) - \left(X(T_j) \cdot \dot{Q}_h(T_j) \cdot \delta(T_j) \right) \right] \cdot \frac{n_j}{N} \quad (15.341)$$

Where,

$$X(T_j) = \left\{ \begin{array}{l} BL(T_j) / \dot{Q}_h(T_j) \\ \text{or} \\ 1 \end{array} \right\} \quad (15.342)$$

whichever is less; the heating mode load factor for temperature bin j , dimensionless.

$\dot{Q}_h(T_j)$ is the space heating capacity of the heat pump when operating at outdoor temperature T_j (W)

$\dot{E}_h(T_j)$ is the electrical power consumption of the heat pump when operating at outdoor temperature T_j (W)

$\delta(T_j)$ is the heat pump low temperature cut-out factor (dimensionless)

PLF_j is the part load factor (dimensionless)

The part load factor is determined as follows:

$$PLF_j = 1 - C_{Dh}[1 - X(T_j)] \quad (15.343)$$

where C_{Dh} is the degradation coefficient which is defaulted to the value of 0.25.

The low temperature cut-out factor $\delta(T_j)$ is determined as follows:

$$\delta(T_j) = \left\{ \begin{array}{l} 0, \text{ if } T_j \leq T_{off} \text{ or } \frac{\dot{Q}_h(T_j)}{\dot{E}_h(T_j)} < 1 \\ 1/2, \text{ if } T_{off} < T_j \leq T_{on} \text{ and } \frac{\dot{Q}_h(T_j)}{\dot{E}_h(T_j)} \geq 1 \\ 1, \text{ if } T_j > T_{on} \text{ and } \frac{\dot{Q}_h(T_j)}{\dot{E}_h(T_j)} \geq 1 \end{array} \right. \quad (15.344)$$

where:

T_{off} is the outdoor temperature when the compressor is automatically shut off ($^{\circ}\text{C}$). Note that if no such temperature exists, T_j is always greater than T_{off} and T_{on} .

T_{on} is the outdoor temperature when the compressor is automatically turned back on, if applicable, following an automatic shut-off ($^{\circ}\text{C}$).

Calculate $\dot{Q}_h \cdot (T_j)$ and $\dot{E}_h \cdot (T_j)$ using:

$$\dot{Q}_h(T_j) = \begin{cases} \dot{Q}_h(-8.33) + \frac{[\dot{Q}_h(8.33) - \dot{Q}_h(-8.33)] \cdot (T_j + 8.33)}{16.67}, & \text{if } T_j \geq 7.22^{\circ}\text{C} \text{ or } T_j \leq -8.33^{\circ}\text{C} \\ \dot{Q}_h(-8.33) + \frac{[\dot{Q}_h(1.67) - \dot{Q}_h(-8.33)] \cdot (T_j + 8.33)}{10}, & \text{if } -8.33^{\circ}\text{C} < T_j < 7.22^{\circ}\text{C} \end{cases} \quad (15.345)$$

$$\dot{E}_h(T_j) = \begin{cases} \dot{E}_h(-8.33) + \frac{[\dot{E}_h(8.33) - \dot{E}_h(-8.33)] \cdot (T_j + 8.33)}{16.67}, & \text{if } T_j \geq 7.22^{\circ}\text{C} \text{ or } T_j \leq -8.33^{\circ}\text{C} \\ \dot{E}_h(-8.33) + \frac{[\dot{E}_h(1.67) - \dot{E}_h(-8.33)] \cdot (T_j + 8.33)}{10}, & \text{if } -8.33^{\circ}\text{C} < T_j < 7.22^{\circ}\text{C} \end{cases} \quad (15.346)$$

$\dot{Q}_h(-8.33)$, $\dot{Q}_h(1.67)$, $\dot{Q}_h(8.33)$, $\dot{E}_h(-8.33)$, $\dot{E}_h(1.67)$ and $\dot{E}_h(8.33)$ are the **(net)** values calculated using performance curves entered by the user and supply fan power per rated air flow rate.

Table 15.9: Heating Mode Test Conditions for Units Having a Single-Speed Compressor and a Fixed-Speed Indoor Fan, a Constant Air Volume Rate Indoor Fan, or No Indoor Fan

Test description	Air Entering Indoor Unit Temperature ($^{\circ}\text{C}$)		Air Entering Outdoor Unit Temperature ($^{\circ}\text{C}$)		Heating Air Volume Rate
	Dry Bulb	Wet Bulb	Dry Bulb	Wet Bulb	
H1 Test (Required, Steady)	21.11	15.56	8.33	6.11	Heating Full-load
H1C Test (Required, Steady)	21.11	15.56	8.33	6.11	(2)

15.2.13 Multi-Speed Electric Heat Pump DX Air Heating Coil

15.2.13.1 Overview

This model (object name `Coil:Heating:DX:MultiSpeed:`) simulates the performance of an air-to-air direct expansion (DX) heating system. The main difference compared to the other heating coil model (`Coil:Heating:DX:SingleSpeed`) is that this heating coil allows modeling of two to four discrete compressor speeds. Each speed has a set of corresponding performance information at rated conditions along with curve fits for variations in total capacity, energy input ratio and part-load fraction to determine the performance of the unit at part-load conditions (DOE 1982). The full load supply airflow rate is dependent on the speed number and is set by its parent object (Ref: `AirLoopHVAC:UnitaryHeatPump:AirToAir:MultiSpeed`). The part-load impact on coil energy use is automatically applied to the lowest speed. A choice is provided to determine whether part-load impacts on coil energy use are applied when the coil is operating at speeds greater than Speed 1. Adjustment factors applied to total capacity and input power to account for frost formation on the outdoor coil are calculated at each speed.

This model simulates the thermal performance of the indoor DX heating coil, and the power consumption of the outdoor unit (multispeed compressor, fans, crankcase heaters and defrost heaters). The performance of the indoor supply air fan varies widely from system to system depending on control strategy (e.g., constant fan vs. AUTO fan), fan type, fan motor efficiency and pressure losses through the air distribution system. Therefore, this DX system model does not account for the thermal effects or electric power consumption of the indoor supply air fan. EnergyPlus contains separate models for simulating the performance of various indoor fan configurations, and these models can be easily linked with the DX system model described here to simulate the entire DX system being considered. For the time being, this coil model can only be called by the parent object `AirLoopHVAC:UnitaryHeatPump:AirToAir:MultiSpeed`.

When the model determines performance at Speed 1 (the lowest speed) or cycling between OFF and Speed 1, its performance is almost the same as the performance for the `Coil:Heating:DX:SingleSpeed` model. However, the outlet conditions are calculated slightly differently. Therefore, the `Coil:Heating:DX:SingleSpeed` model may be considered as a subset of the model described here. When the multispeed coil model determines performance at higher speeds (above 1), the model linearly interpolates the performance at two consecutive speeds ($n-1$ and n) as needed to meet the heating load, with the fraction of time at each speed established by the speed ratio.

When single mode operation is specified at higher speeds (above 1), defined in the `UnitarySystemPerformance:Multispeed` object, a child object of `AirLoopHVAC:UnitarySystem`, its performance is almost the same as the performance for the `Coil:Heating:DX:SingleSpeed` model at different flow rate and capacity with given speed number. No linear interpolation is performed between two adjacent speeds. The highest speed which does not exceed the sensible load is used for each HVAC timestep. This operation does not apply to speed 1 operation and the case when the sensible load

is above the highest sensible capacity.

15.2.13.2 Model Inputs

The model inputs are also very similar to the inputs of the Coil:Heating:DX:SingleSpeed object. The main difference is that this multispeed model requires a set of fields at each speed, such as rated capacity, rated COP, two capacity modifiers, two energy input ratio modifiers, and part-load correction. The inputs also include waste heat fraction and modifier as a function of temperature to calculate recoverable waste heat for heat recovery, which are not available in the similar Coil:Heating:DX:SingleSpeed object.

15.2.13.3 Speed 1 Operation

The calculation procedures in this model, including defrost and crankcase heater, are identical to the Coil:Heating:DX:SingleSpeed object (Ref: Coil:Heating:DX:SingleSpeed) with one exception: outlet node condition calculation when the supply air fan operation mode is ContinuousFanWithCyclingCompressor. The following procedure provides the detailed description of the exception.

- Total delivered heating capacity

The total delivered heating capacity for speed 1 operating at the cycling ratio needed to meet the requested heating load is:

$$Q_{coil,cycling} = \dot{m}_{Speed\ 1} (CycRatio) (h_{inlet} - h_{outlet,full}) \quad (15.347)$$

where:

$Q_{coil,cycling}$ is the delivered sensible heating capacity for Speed 1 operating at a specific cycling ratio (W)

$\dot{m}_{Speed\ 1}$ is the air mass flow rate through heating coil at Speed 1 as set by the parent object (kg/s)

$h_{outlet,full}$ is the specific enthalpy of the coil outlet air during full-load operation at Speed 1 (no cycling) (J/kg)

h_{inlet} is the specific enthalpy of the coil inlet air (J/kg)

$CycRatio$ is the cycling ratio at Speed 1, ratio of requested heating load to the full-load capacity of the coil at Speed 1 (dimensionless).

It is assumed that the coil provides no heating capacity when the coil is OFF, even if the supply air fan continues to operate.

- Outlet air specific enthalpy

The average specific enthalpy of the coil outlet air is then calculated based on the delivered sensible heating capacity and the average air mass flow rate entering the coil:

$$h_{outlet,average} = h_{inlet} - \frac{Q_{coil,cycling}}{\dot{m}_{inlet}} \quad (15.348)$$

where:

$h_{outlet,average}$ is the average specific enthalpy at the coil outlet (J/kg)

\dot{m}_{inlet} is the mass flow rate at the inlet to the coil as established by the parent object (Ref. AirLoopHVAC:UnitaryHeatPump:AirToAir:MultiSpeed, Mass Flow Rate Calculation). This flow rate is the average value determined by the parent object, accounting for the specified flow rate when the heating coil is ON and the specified flow rate when the heating coil is OFF for the time step being simulated.

- Outlet air temperature

The heating coil's outlet air humidity ratio equals the inlet air humidity ratio since the coil does not change the moisture content of the air. So the average outlet air temperature is calculated based on the inlet air humidity ratio and the average outlet air enthalpy using the psychrometric function PsyTdbFnHW .

The main reason for using the above approach is that outlet air conditions are calculated in the same way for all operating speeds.

The crankcase heater defined for this DX heating coil is enabled during the time that the compressor is not running for either heating or cooling. The crankcase heater power use from either heating or cooling is reported in the heating coil.

15.2.13.4 Higher Speed Operation

This section describes how higher speed operation is simulated. When the required sensible load is less than the full load sensible capacity at Speed n (Speed Number > 1), the following calculations are performed:

Total delivered heating capacity at Speed n-1 and Speed n

$$TotCap_{n-1} = RatedCap_{n-1} (TotCapTempModFac_{n-1}) (TotCapFlowModFac_{n-1}) \quad (15.349)$$

$$TotCap_n = RatedCap_n (TotCapTempModFac_n) (TotCapFlowModFac_n) \quad (15.350)$$

where:

$TotCap_i$ is the total delivered heating capacity at given temperatures and flow rates at Speed i (W)

$RatedCap_i$ is the heating capacity at the rated conditions at Speed i (W)

$TotCapTempModFac_i$ is the total heating capacity modifier as a function of indoor and outdoor air dry-bulb temperature at Speed i

$TotCapFlowModFac_i$ is the total heating capacity modifier as a function of the ratio of the actual flow rate across the heating coil to the rated airflow rate at Speed i
i is Speed n or Speed n-1.

- EIR at Speed n-1 and Speed n

$$EIR_{n-1} = RatedEIR_{n-1} (EIRTempModFac_{n-1}) (EIRFlowModFac_{n-1}) \quad (15.351)$$

$$EIR_n = RateEIR_n (EIRTempModFac_n) (EIRFlowModFac_n) \quad (15.352)$$

where:

EIR_i is the energy input ratio at given temperatures and flow rates at Speed i (W)

$RatedEIR_i$ is the energy input ratio at the rated conditions at Speed i (W)

$EIRTempModFac_i$ is the energy input ratio modifier as a function of indoor and outdoor air dry-bulb temperature at Speed i

$EIRFlowModFac_i$ is the energy input ratio modifier as a function of the ratio of the actual flow rate across the heating coil to the rated airflow rate at Speed i

i is Speed n or Speed n-1.

- Full load outlet air specific enthalpy at Speed n-1 and Speed n

$$h_{outlet,full\ Speed,n} = h_{inlet} - \frac{TotCap_n \cdot HeatingCapacityMultiplier}{\dot{m}_{inlet}} \quad (15.353)$$

$$h_{outlet,full\ Speed,n-1} = h_{inlet} - \frac{TotCap_{n-1} \cdot HeatingCapacityMultiplier}{\dot{m}_{inlet}} \quad (15.354)$$

where,

$HeatingCapacityMultiplier$ is the frost adjustment factor for heating capacity (See Ref. Coil:Heating:DX:SingleSpeed)

$h_{outlet,full\ Speed,n}$ is the specific enthalpy of the coil outlet air during full-load operation at Speed n (no cycling) (J/kg)

$h_{outlet,full\ Speed,n-1}$ is the specific enthalpy of the coil outlet air during full-load operation at Speed n-1 (no cycling) (J/kg).

- Effective total heating capacity

$$Q_{coil,SpeedRatio} = (SpeedRatio) \dot{m}_{Speed\ n} (h_{inlet} - h_{outlet,full\ Speed,n}) + (1 - SpeedRatio) \dot{m}_{Speed\ n-1} (h_{inlet} - h_{outlet,full\ Speed,n-1}) \quad (15.355)$$

where,

$Q_{coil,SpeedRatio}$ is the delivered sensible heating capacity at a given speed ratio between two consecutive speeds (W)

$\dot{m}_{Speed\ n}$ is the air mass flow rate through heating coil at Speed n as set by the parent object (kg/s)

$\dot{m}_{Speed\ n-1}$ is the air mass flow rate through heating coil at Speed 1 as set by the parent object (kg/s).

- Average outlet air enthalpy

$$h_{outlet,average} = h_{inlet} - \frac{Q_{coil,SpeedRatio}}{\dot{m}_{inlet}} \quad (15.356)$$

where:

$h_{outlet,average}$ is the average specific enthalpy at the coil outlet (J/kg)

h_{inlet} is the specific enthalpy of the coil inlet air (J/kg)

\dot{m}_{inlet} is the mass flow rate at the inlet to the coil as established by the parent object (Ref. AirLoopHVAC:UnitaryHeatPump:AirToAir:MultiSpeed, Mass Flow Rate Calculation). This flow rate is the average value determined by the parent object, accounting for the specified flow rate when the heating coil is at Speed n and the specified flow rate when the heating coil is at Speed n-1 for the time step being simulated.

- Average outlet air temperature

The heating coil's outlet air humidity ratio equals the inlet air humidity ratio since the coil does not change the moisture content of the air. So the average outlet air temperature is calculated based on the inlet air humidity ratio and the average outlet air enthalpy using the psychrometric function `PsyTdbFnHW`.

- Full load energy inputs at Speed n-1 and Speed n

$$HeatingPower_n = TotCap_n (EIR_n) (HeatingCapacityMultiplier) (InputPowerMultiplier) \quad (15.357)$$

$$HeatingPower_{n-1} = TotCap_{n-1} (EIR_{n-1}) (HeatingCapacityMultiplier) (InputPowerMultiplier) \quad (15.358)$$

where *InputPowerMultiplier* is the frost adjustment factor for heating power calculation (Ref. Coil:Heating:DX:SingleSpeed).

- Calculate combined energy input

When the input for the field 'Apply Part Load Fraction to Speeds Greater than 1' is No (equivalent to a single compressor), the combined energy output is calculated as follows:

$$HeatingPower = HeatingPower_n (SpeedRatio) + HeatingPower_{n-1} (1.0 - SpeedRatio) \quad (15.359)$$

When the input for the field 'Apply Part Load Fraction to Speeds Greater than 1' is Yes (equivalent to multiple compressors), the combined energy output is calculated as follows:

$$HeatingPower = HeatingPower_n (RTF) + HeatingPower_{n-1} (1.0 - RTF) \quad (15.360)$$

where:

HeatingPower is the power used (W)

RTF is the run time fraction (SpeedRatio/Part-load Fraction) at Speed n.

- Calculate defrost power

When the defrost strategy is resistive, the power calculation is the same as Speed 1 operation (Ref. Coil:Heating:DX:SingleSpeed). When the defrost strategy is reverse-cycle, the following calculations are performed:

$$Q_{defrost,n} = 0.01(t_{frac,defrost})(7.222 - T_{db,o}) \left(\frac{Q_{total,rated,n}}{1.01667} \right) \quad (15.361)$$

$$P_{defrost,n-1} = DefrostEIRTempModFac \left(\frac{Q_{total,rated,n-1}}{1.01667} \right) (t_{frac,defrost}) \quad (15.362)$$

$$P_{defrost,n} = DefrostEIRTempModFac \left(\frac{Q_{total,rated,n}}{1.01667} \right) (t_{frac,defrost}) \quad (15.363)$$

where:

$Q_{defrost,n}$ is the additional indoor heating load due to reverse-cycle defrost at Speed n (W)

$Q_{total,rated,n}$ is the total full-load heating capacity of the coil at rated conditions at Speed n (W)

$P_{defrost,n-1}$ is the full load defrost power for the simulation time step at Speed n-1 (W)

$P_{defrost,n}$ is the full load defrost power for the simulation time step at Speed n (W)

$Q_{total,rated,n-1}$ is the capacity of the resistive defrost heating element at Speed n-1 (W)

$Q_{total,rated,n}$ is the capacity of the resistive defrost heating element at Speed n (W)

DefrostEIRTempModFac is the defrost energy input ratio (EIR) modifier curve (Ref. Coil:Heating:DX:SingleSpeed).

$T_{frac,defrost}$ is the fractional defrost time (Ref. Coil:Heating:DX:SingleSpeed).

When the input for the field 'Apply Part Load Fraction to Speeds Greater than 1' is No (equivalent to a single compressor), the average defrost power is calculated as follows:

$$P_{defrost} = P_{defrost,n}(SpeedRatio) + P_{defrost,n-1}(1.0 - SpeedRatio) \quad (15.364)$$

When the input for the field 'Apply Part Load Fraction to Speeds Greater than 1' is Yes (equivalent to multiple compressors), the combined defrost energy is calculated as follows:

$$P_{defrost} = P_{defrost,n}(RTF) + P_{defrost,n-1}(1.0 - RTF) \quad (15.365)$$

where:

$P_{defrost}$ is the average defrost power used (W)

RTF is the run time fraction (SpeedRatio/Part-load Fraction) at Speed n.

- Crankcase heater

There is no power need at higher speed operation.

15.2.13.5 Higher Speed Operation with Single Mode Operation

This section describes how higher speed operation is simulated with single mode operation. When the required sensible load is less than the full load sensible capacity at Speed n (Speed Number > 1), its performance is almost the same as the performance for the Coil:Heating:DX:SingleSpeed model at different flow rate and capacity with given Speed n. No linear interpolation is performed between two adjacent speeds. The highest speed which does not exceed the sensible load is used for each HVAC timestep. This operation does not apply to the case when the sensible load is above the highest sensible capacity.

15.2.13.6 Waste heat calculation

The waste heat generated by this coil object is calculated as:

$$Q_{WasteHeat} = (Fraction)(TempModifier)(HeatingPower) \quad (15.366)$$

where:

Fraction is the rated waste heat fraction of the energy input

TempModifier is the waste heat modifier as a function of indoor and outdoor air dry-bulb temperature.

15.2.13.7 Standard Rating of Multi-Speed DX Heating Coils

For multi-speed direct expansion heating coils, the industry standard ratings of Standard Rating Heating Seasonal Performance Factor (HSPF) are calculated according to ANSI/AHRI Standard 210/240 (AHRI 2008). These standard ratings can be calculated using the user-entered information for the Coil:Heating:DX:MultiSpeed object. According to Standard 210/240, the Standard Rating HSPF applies to air-to-air unitary heat pumps with rated heating capacities under 19,000 watts (65,000 Btu/h). The Heating Mode Test Conditions for Units Having two-capacity Compressor standard tests H0₁, H1₁, H2₁, H3₁, H1₂, H2₂, and H3₂ are also provided in Table 15.12. The rated Energy Efficiency Ratio (EER) is not calculated for any DX Heating Coils as this time. The equations required to calculate the net heating capacity and HSPF values are described next.

15.2.13.8 Standard Ratings Heating Capacity

The Standard Rating (Net) Heating Capacity calculation is calculated using the same procedure as the single speed DX heating coils except the capacities are evaluated at the maximum speed only. Refer to the standard ratings calculation for Coil:DX:Heating:SingleSpeed for description of the procedure.

The Rated Supply Fan Power Per Volume Flow Rate is a user-entered value, with a default of 773.3 W/(m³/s) if the user leaves this input field blank. The default value is taken from ANSI/ASHRAE Standard 210/240-2008 where it is defined for systems which do not have an Indoor Coil (Evaporator) fan furnished as part of the system. The test conditions in ANSI/AHRI Standard 210/240 vary the external static pressure (i.e., pressure drop associated with ductwork and other devices external to the indoor fan/coil section) seen by the supply air fan based on the standard rating cooling capacity. New input field Rated Supply Fan Power Per Volume Flow Rate for each speed will be added to the IDD.

15.2.13.9 Heating seasonal performance factors (HSPF) for Multi-Speed DX Coil

The following section describes the test condition for heating mode tests for Air-Source Heat Pumps, including heating-only heat pumps, and the equations required to calculate the HSPF. The HSPF for multi-speed compressor heat pumps in Btu/W-h is given by:

$$HSPF = \frac{\sum_j^M \frac{n_j}{N} \cdot BL(T_j)}{\sum_j^M \frac{e_h(T_j)}{N} + \sum_j^M \frac{RH(T_j)}{N}} \cdot F_{def} \quad (15.367)$$

where:

$BL(T_j)$ is the building space conditioning load corresponding to an outdoor temperature of T_j ; the heating season building load also depends on the generalized climatic region's outdoor design temperature and the design heating requirement (Btu/h).

$e_h(T_j)/N$ is the ratio of the electrical energy consumed by the heat pump during periods of the space heating season when the outdoor temperature fell within the range represented by bin temperature T_j to the total number of hours (N) in the heating season (W). For heat pumps having a heat comfort controller, this ratio may also include electrical energy used by resistive elements to maintain a minimum air delivery temperature.

$RH(T_j)/N$ is the ratio of the electrical energy used for resistive space heating during periods when the outdoor temperature fell within the range represented by bin temperature T_j to the total number of hours (N) in the heating season (W). Resistive space heating is modeled as being used to meet that portion of the building load that the heat pump does not meet because of insufficient capacity or because the heat pump automatically turns off at the lowest outdoor temperatures.

T_j is the outdoor bin temperature ($^{\circ}\text{C}$). Outdoor temperatures are "binned" such that calculations are only performed based one temperature within the bin. Bins of 2.78°C are used.

n_j/N is the fractional bin hours for the heating season; the ratio of the number of hours during the heating season when the outdoor temperature fell within the range represented by bin temperature T_j to the total number of hours in the heating season, dimensionless, given in Table 15.10.

j is the bin number (dimensionless)

M is for each generalized climatic region, the total number of temperature bins, dimensionless. Referring to Table 15.10, M is the highest bin number (j) having a nonzero entry for the fractional bin hours for the generalized climatic region of interest.

F_{def} is the demand defrost credit described in section 3.9.2 of AHRI Std. 210/240-2008, dimensionless. For simplification, assigned a value of 1 for timed defrost control and a value of 1.03 for demand defrost control.

The building heating load is calculated as follows:

$$BL(T_j) = \frac{18.33 - T_j}{18.33 - T_{OD}} \cdot C \cdot DHR \quad (15.368)$$

The minimum and maximum design heating requirements for each generalized climate regions are given by:

$$DHR_{min} = \begin{cases} 8.33\dot{Q}_h^{k=2} \frac{18.33 - T_{OD}}{33.33} & \text{for Regions I, II, III, IV, and VI} \\ 8.33\dot{Q}_h^{k=2} & \text{for Region V} \end{cases} \quad (15.369)$$

and

$$DHR_{min} = \begin{cases} 2 \cdot 8.33\dot{Q}_h^{k=2} \frac{18.33 - T_{OD}}{33.33} & \text{for Regions I, II, III, IV, and VI} \\ 2 \cdot 8.33\dot{Q}_h^{k=2} & \text{for Region V} \end{cases} \quad (15.370)$$

where:

$C = 0.77$, a correction factor which tends to improve the agreement between calculated and measured building loads (dimensionless)

DHR is the design heating requirement for each generalized climate region (Btu/h)

$\dot{Q}_h^{k=2}(8.33)$ is the heating capacity determined from H1₂ test (W).

The heating capacity delivered and electric power input of the heat pump when operating at minimum (low) compressor capacity and outdoor air temperature of T_j is given by:

$$Q_h^{k=1}(T_j) = \left\{ \begin{array}{ll} Q_h^{k=1}(8.33) + \frac{[Q_h^{k=1}(16.67) - Q_h^{k=1}(8.33)] \cdot (T_j - 8.33)}{(16.67 - 8.33)}, & \text{if } T_j \geq 4.44^\circ\text{C} \\ Q_h^{k=1}(-8.33) + \frac{[Q_h^{k=1}(1.67) - Q_h^{k=1}(-8.33)] \cdot (T_j + 8.33)}{(1.67 + 8.33)}, & \text{if } -8.33^\circ\text{C} \leq T_j < 4.44^\circ\text{C} \\ Q_h^{k=1}(-8.33) + \frac{[Q_h^{k=1}(8.33) - Q_h^{k=1}(-8.33)] \cdot (T_j + 8.33)}{(8.33 + 8.33)}, & \text{if } T_j < -8.33^\circ\text{C} \end{array} \right\} \quad (15.371)$$

$$E_h^{k=1}(T_j) = \left\{ \begin{array}{ll} E_h^{k=1}(8.33) + \frac{[E_h^{k=1}(16.67) - E_h^{k=1}(8.33)] \cdot (T_j - 8.33)}{(16.67 - 8.33)}, & \text{if } T_j \geq 4.44^\circ\text{C} \\ E_h^{k=1}(-8.33) + \frac{[E_h^{k=1}(1.67) - E_h^{k=1}(-8.33)] \cdot (T_j + 8.33)}{(1.67 + 8.33)}, & \text{if } -8.33^\circ\text{C} \leq T_j < 4.44^\circ\text{C} \\ E_h^{k=1}(-8.33) + \frac{[E_h^{k=1}(8.33) - E_h^{k=1}(-8.33)] \cdot (T_j + 8.33)}{(8.33 + 8.33)}, & \text{if } T_j < -8.33^\circ\text{C} \end{array} \right\} \quad (15.372)$$

where:

$Q_h^{k=1}(16.67)$ and $E_h^{k=1}(16.67)$ are determined from the H0₁ test

$Q_h^{k=1}(8.33)$ and $E_h^{k=1}(8.33)$ are determined from the H1₁ test

$Q_h^{k=1}(1.67)$ and $E_h^{k=1}(1.67)$ are determined from the H2₁ test

$Q_h^{k=1}(-8.33)$ and $E_h^{k=1}(-8.33)$ are determined from the H3₁ test.

An alternative to conducting or evaluating the performance at the H2₁ test is to approximate the capacity and electric power inputs as follows:

$$Q_h^{k=1}(1.67) = 0.9 \cdot \{Q_h^{k=1}(-8.33) + 0.6 [Q_h^{k=1}(8.33) - Q_h^{k=1}(-8.33)]\} \quad (15.373)$$

$$E_h^{k=1}(1.67) = 0.985 \cdot \{E_h^{k=1}(-8.33) + 0.6 [E_h^{k=1}(8.33) - E_h^{k=1}(-8.33)]\} \quad (15.374)$$

The heating capacity delivered and electric power input of the heat pump when operating at maximum (high) compressor speed and outdoor air temperature of T_j is given by:

$$\dot{Q}_h^{k=2}(T_j) = \left\{ \begin{array}{ll} \dot{Q}_h^{k=2}(-8.33) + \frac{[\dot{Q}_h^{k=2}(8.33) - \dot{Q}_h^{k=2}(-8.33)] \cdot (T_j + 8.33)}{8.33 + 8.33}, & \text{if } T_j \geq 7.2^\circ\text{C or } T_j \leq -8.33^\circ\text{C} \\ \dot{Q}_h^{k=2}(-8.33) + \frac{[\dot{Q}_h^{k=2}(1.67) - \dot{Q}_h^{k=2}(-8.33)] \cdot (T_j + 8.33)}{1.67 + 8.33}, & \text{if } -8.33^\circ\text{C} < T_j < 7.2^\circ\text{C} \end{array} \right\} \quad (15.375)$$

$$\dot{E}_h^{k=2}(T_j) = \left\{ \begin{array}{ll} \dot{E}_h^{k=2}(-8.33) + \frac{[\dot{E}_h^{k=2}(8.33) - \dot{E}_h^{k=2}(-8.33)] \cdot (T_j + 8.33)}{8.33 + 8.33}, & \text{if } T_j \geq 7.2^\circ\text{C or } T_j \leq -8.33^\circ\text{C} \\ \dot{E}_h^{k=2}(-8.33) + \frac{[\dot{E}_h^{k=2}(1.67) - \dot{E}_h^{k=2}(-8.33)] \cdot (T_j + 8.33)}{1.67 + 8.33}, & \text{if } -8.33^\circ\text{C} < T_j < 7.2^\circ\text{C} \end{array} \right\} \quad (15.376)$$

where:

$\dot{Q}_h^{k=2}(8.33)$ and $\dot{E}_h^{k=2}(8.33)$ are determined from the H1₂ test

$\dot{Q}_h^{k=2}(1.67)$ and $\dot{E}_h^{k=2}(1.67)$ are determined from the H2₂ test

$\dot{Q}_h^{k=2}(-8.33)$ and $\dot{E}_h^{k=2}(-8.33)$ are determined from the H3₂ test.

The electric energy used by the heat pumps differs depending up on whether the heat pump would operate at low (minimum) capacity, cycle between successive lower and higher speed capacities, or operate at high speed capacity in responding to the building load. The procedure for each operation cases is described next.

Case 1: The steady state heating capacity when the unit is operating at minimum or low capacity, i.e., when the building heating load is less or equal to the low capacity:

$$\dot{Q}_c^{k=1}(T_j) \geq BL(T_j) \quad (15.377)$$

$$\frac{e_h(T_j)}{N} = \frac{X^{k=1}(T_j) \cdot E_h^{k=1}(T_j) \cdot \delta(T_j)}{PLF_j} \cdot \frac{n_j}{N} \quad (15.378)$$

$$\frac{RH(T_j)}{N} = BL(T_j) \cdot [1 - \delta'(T_j)] \cdot \frac{n_j}{N} \quad (15.379)$$

$$X^{k=1}(T_j) = \text{MIN} \left\{ \frac{BL(T_j) / Q_h^{k=1}(T_j)}{1.0} \right\} \quad (15.380)$$

$$\delta'(T_j) = \begin{cases} 0, & \text{if } T_j \leq T_{\text{off}} \\ 1/2, & \text{if } T_{\text{off}} < T_j \leq T_{\text{on}} \\ 1, & \text{if } T_j > T_{\text{on}} \end{cases} \quad (15.381)$$

$$PLF_j = 1 - C_D^h \cdot [1 - X^{k=1}(T_j)] \quad (15.382)$$

where C_D^h is the degradation coefficient which has a minimum value of 0.25.

Case 2: The unit cycles between the low (minimum) and high (maximum) compressor capacity to meet the building heating load at outdoor air temperature T_j . That is, the heating building load is between the unit low and high compressor capacities:

$$\dot{Q}_h^{k=1}(T_j) < BL(T_j) < \dot{Q}_h^{k=2}(T_j) \quad (15.383)$$

$$\frac{e_c(T_j)}{N} = [X^{k=1}(T_j) \cdot \dot{E}_h^{k=1}(T_j) + X^{k=2}(T_j) \cdot \dot{E}_h^{k=2}(T_j)] \cdot \delta'(T_j) \cdot \frac{n_j}{N} \quad (15.384)$$

$$\frac{RH(T_j)}{N} = BL(T_j) \cdot [1 - \delta'(T_j)] \cdot \frac{n_j}{N} \quad (15.385)$$

$$\delta'(T_j) = \begin{cases} 0, & \text{if } T_j \leq T_{\text{off}} \\ \frac{1}{2}, & \text{if } T_{\text{off}} < T_j \leq T_{\text{on}} \\ 1, & \text{if } T_j > T_{\text{on}} \end{cases} \quad (15.386)$$

$$X^{k=1}(T_j) = \frac{\dot{Q}_h^{k=2}(T_j) - BL(T_j)}{\dot{Q}_h^{k=2}(T_j) - \dot{Q}_h^{k=1}(T_j)} \quad (15.387)$$

$$X^{k=2}(T_j) = 1 - X^{k=1}(T_j) \quad (15.388)$$

Case 3: The steady-state heating capacity when the unit is operating continuously at high or maximum compressor capacity at outdoor air temperature T_j . The building heating load is greater than the available capacity at maximum or high compressor capacity:

$$BL(T_j) \geq \dot{Q}_c^{k=2}(T_j) \quad (15.389)$$

For units when operating continuously at maximum compressor speed ($k = 2$) speed at temperature T_j , the delivered heating capacity and electric power inputs are calculated as follows:

$$\frac{e_c(T_j)}{N} = \left[\dot{E}_h^{k=2}(T_j) \cdot \delta''(T_j) \right] \cdot \frac{n_j}{N} \quad (15.390)$$

$$\frac{RH(T_j)}{N} = \left\{ BL(T_j) - \left[\dot{Q}_h^{k=2}(T_j) \cdot \delta''(T_j) \right] \right\} \cdot \frac{n_j}{N} \quad (15.391)$$

$$\delta''(T_j) = \left\{ \begin{array}{ll} 0, & \text{if } T_j \leq T_{\text{off}} \text{ or } \frac{\dot{Q}_h^{k=2}(T_j)}{\dot{E}_h^{k=2}(T_j)} < 1 \\ \frac{1}{2}, & \text{if } T_{\text{off}} < T_j \leq T_{\text{on}} \text{ and } \frac{\dot{Q}_h^{k=2}(T_j)}{\dot{E}_h^{k=2}(T_j)} \geq 1 \\ 1, & \text{if } T_j > T_{\text{on}} \text{ and } \frac{\dot{Q}_h^{k=2}(T_j)}{\dot{E}_h^{k=2}(T_j)} \geq 1 \end{array} \right\} \quad (15.392)$$

where:

$X(T_j)$ is the heating mode load factor for temperature bin j (-)

$Q_h(T_j)$ is the space heating capacity of the heat pump when operating at outdoor temperature T_j (W)

$E_h(T_j)$ is the electrical power consumption of the heat pump when operating at outdoor temperature T_j (W)

$\delta(T_j)$ is the heat pump low temperature cut-off factor (-)

T_{off} is the outdoor temperature when the compressor is automatically shut off ($^{\circ}\text{C}$). (If no such temperature exists, T_j is always greater than T_{off} and T_{on}).

T_{on} is the outdoor temperature when the compressor is automatically turned back on, if applicable, following an automatic shut-off ($^{\circ}\text{C}$).

Table 15.12: Heating Mode Test Conditions for Units Having Two-Capacity Compressor

Test Description	Air Entering Indoor Unit Temperature		Air Entering Outdoor Unit Temperature		Compressor Speed	Heating Air Volume Flow Rate
	Dry Bulb °C (°F)	Wet Bulb °C (°F)	Dry Bulb °C (°F)	Wet Bulb °C (°F)		
H01 Test (required,steady)	21.1 (70)	15.6 (60) (max)	16.7 (62)	18.3 (56.5)	Low	Heating Minimum (1)
H12 Test (required,steady)	21.1 (70)	15.6 (60) (max)	8.33 (47)	6.11 (43)	High	Heating Full-Load (2)
H1C2 Test (required, cyclic)	21.1 (70)	15.6 (60) (max)	8.33 (47)	6.11 (43)	High	

H11	Test (required,steady)	(re-	21.1 (70)	15.6 (60) (max)	8.33 (47)	6.11 (43)	Low	Heating Minimum (1)
H1C1	Test (required, cyclic)	(re-	21.1 (70)	15.6 (60) (max)	8.33 (47)	6.11 (43)	Low

15.2.14 Variable Speed DX Heating Coil

15.2.14.1 Overview

The latest technology for commercial air conditioners and air-to-air heat pumps can utilize a variable speed compressor with a variable speed indoor blower and outdoor fan. The indoor and outdoor air flow rates are usually a function of the compressor speed. Refrigerant mass flow rate is a function of compressor speed as well as outdoor heat exchanger entering air temperature and indoor dry bulb or wet bulb. The control system adjusts the equipment capacity based on zone temperature measurements relative to the thermostat set point. The control logic determines what compressor speed is required to control to the zone temperature requirement in response to increased or decreased capacity (heating or cooling load). The compressor, fan and blower speeds are not discrete values and can be considered to vary infinitesimally between the minimum and maximum compressor speed. At the minimum compressor speed (which is different for heating and cooling), for a continuous fan, the supply airflow is fixed and the unit will have to cycle for reduced part loads below this point. For a cycling fan, the fan will cycle with the compressor.

Similar to variable-speed water source heat pump, we expand the number of speed levels and the corresponding curve sets up to ten. The number of speed levels is selectable by the user. The user can provide speed levels at any number from 1 to 10. In the case that the given speed levels are above 1, the model would do linear interpolation between neighboring speeds. The more curves, the more accurate. Furthermore, using linear interpolation and inputting air flow rates at individual speed levels facilitates arbitrary relationships of flow rate as a function of the compressor speed level.

The Coil:Heating:DX:VariableSpeed object will simulate the performance of a DX heating coil used in combination with a variable-speed air-to-air heat pump. It will fit into the parent objects of AirLoopHVAC:UnitaryHeatPump:AirToAir and

ZoneHVAC:PackagedTerminalHeatPump, etc.

The rated conditions for obtaining the capacities and COPs are at indoor dry-bulb temperature of 21.1°C (70°F) and the source side entering air temperature of 8.3°C (47°F). Some equations are provided below to help explain the function of the various performance curves and data fields.

15.2.14.2 Model Description

The Coil:Heating:DX:VariableSpeed object is modeled similar to Coil:Heating:WaterToAirHeatPump:VariableSpeedEquationFit. Of course, rather than referencing a water source evaporator, the new coil object references an air source and has defrosting operation. The evaporator entering air temperature is used in lieu of the entering water temperature.

It shall be noted for the capacity and flow rate inputs, two fields are autosizable, which are Rated Heating Capacity at the Selected Nominal Speed Level and the Rated Volumetric Air Flow Rate at the Selected Nominal Speed Level. They are used to scale the performances of a specific unit and correlate with the actual loop flow. Except these two fields, all other capacity and flow rate inputs at individual speed levels should be directly obtained from Reference Unit catalog data, specific to an actual unit.

The Rated Heating Capacity at Selected Nominal Speed Level contains the rated capacity to match the building heating load at the design day. The rated heating capacity is used to determine a capacity scaling factor, as compared to the Reference Unit capacity at the nominal speed level.

$$\text{CapacityScaleFactor} = \frac{\text{RatedTotalHeatingCapacity}}{\text{ReferenceUnitTotalHeatingCapacity@NominalSpeedLevel}} \quad (15.393)$$

And then, this scaling factor is used to determine capacities at rated conditions for other speed levels, $\text{RatedTotalHeatingCapacity@SpeedLevel}(x) = \text{CapacityScaleFactor} \times \text{ReferenceUnitTotalHeatingCapacity@SpeedLevel}(x)$

The Rated Volumetric Air Flow Rate is used to determine an internal scaling factor, and calculate the air flow rates in the parent objects, as follows:

$$\text{AirFlowScaleFactor} = \frac{\text{RatedVolumetricAirFlowRate}}{\text{ReferenceUnitVolAirFlowRate@NominalSpeedLevel} \times \text{CapacityScaleFactor}} \quad (15.394)$$

where the loop volumetric air flow rates at various speed levels in the parent objects are calculated as $\text{LoopVolumetricAirFlowRate @ SpeedLevel}(x) = \text{AirFlowScaleFactor} \times \text{ReferenceUnitVolAirFlowRate @ SpeedLevel}(x) \times \text{CapacityScaleFactor}$.

If the volumetric air flow rate at one speed level is higher than the flow rate allowed by the fan in the parent object, the flow rate will be set back to the fan flow rate.

If AirFlowScaleFactor equals unity, the loop air flow rate becomes the design flow rate of the Reference Unit (after scaled by the rated heating capacity). The Rated Volumetric Air Flow Rate is introduced here to correlate with the actual flow rate in the air loop, in case that it differs from the design specification. Certainly, it is recommended that the Rated Volumetric Air Flow Rate is selected in the way that AirFlowScaleFactor is unity, so as to get more accurate results from the performance curves.

15.2.14.3 Performance curves:

This object includes 4 curve objects at each individual speed level.

1. Total heating capacity modifier curve (function of temperature).
2. Total heating capacity modifier curve (function of air flow fraction).
3. Energy input ratio (EIR) modifier curve (function of temperature).
4. Energy input ratio (EIR) modifier curve (function of air flow fraction).

The flow fraction modifier curves are used as a placeholder, to account for off-design flow rates if needed. If the manufacturer doesn't provide off-design performances, we can simply use a default modification multiplier of 1.0.

At the lowest speed, there will be one additional performance curve to account for the part-load condition, i.e.

- 5) Part load fraction correlation (function of part load ratio).

Additional details on each of the above five curves are provided in the following paragraphs.

- 1) Total heating capacity modifier curve (function of temperature)

The total heating capacity modifier as a function of temperature curve (CAP-FT) is a bi-quadratic curve with two independent variables: dry-bulb temperature of the air entering the heating coil and the air DB temperature entering the evaporator coil. The output of this curve is multiplied by the rated total heating capacity at the speed, to give the total heating capacity at the specific entering air temperatures at which the ASHP unit is operating (i.e., at temperatures different from the rating point temperatures).

$$\text{TotCapTempModFac} = a + b * DB_i + c * DB_i^2 + d * DB_o + e * DB_o^2 + f * DB_i * DB_o \quad (15.395)$$

where:

DB_i is the dry-bulb temperature of the air entering the heating coil (°C)

DB_o is the dry-bulb temperature of the air entering the outdoor coil (°C)

a-f are regression curve-fit coefficients.

- 2) Total heating capacity modifier curve (function of air flow fraction)

$$\text{TotCapAirFlowModFac} = a + b * ff_a + c * ff_a^2 + d * ff_a^3 \quad (15.396)$$

where:

ff_a is the actual air mass flow rate/design air mass flow rate, at one speed level

$\text{DesignAirMassFlowRate@SpeedLevel}(x)$ is equal to the $\text{ReferenceUnitAirMassFlowRate@SpeedLevel}(x)$ times $\text{CapacityScaleFactor}$

a-d are regression curve-fit coefficients. If no data are available for the correction, the user can simply set $a = 1.0$ and the other coefficients to 0.0.

3) Energy input ratio (EIR) modifier curve (function of temperature)

The energy input ratio modifier curve as a function of temperature (EIR-FT) is a biquadratic curve with two independent variables DB_i and DB_o . The output of this curve is multiplied by the rated EIR at the speed (inverse of the rated COP), to give the EIR at the specific entering air temperatures at which the ASHP coil unit is operating (i.e., at temperatures different from the rating point temperatures).

$$\text{EIRTempModFac} = a + b * DB_i + c * DB_i^2 + d * DB_o + e * DB_o^2 + f * DB_i * DB_o \quad (15.397)$$

where a-f are regression curve fit coefficients.

4) Energy input ratio (EIR) modifier curve (function of air flow fraction)

$$\text{EIRAirFlowModFac} = a + b * ff_a + c * ff_a^2 + d * ff_a^3 \quad (15.398)$$

where a-d are regression curve-fit coefficients. If no data are available for the correction, the user can simply set $a = 1.0$ and the other coefficients to 0.0.

5) Part load fraction correlation (function of part load ratio)

This field defines the name of a quadratic or cubic performance curve (Ref: Performance Curves) that parameterizes the variation of electrical power input to the unit as a function of the part load ratio (PLR, heating load/steady-state heating capacity for Speed 1):

$$\text{PartLoadFrac} = a + b * \text{PLR} + c * \text{PLR}^2 + d * \text{PLR}^3 \quad (15.399)$$

and

$$\text{RTF} = (\text{PLR} / \text{PartLoadFrac}) = \text{runtime fraction of the heating coil} \quad (15.400)$$

The part load fraction (PLF) correlation accounts for efficiency losses due to compressor cycling. The part load fraction correlation should be normalized to a value of 1.0 when the part load ratio equals 1.0 (i.e., no efficiency losses when the compressor runs continuously for the simulation timestep). For PLR values between 0 and 1 ($0 < \text{PLR} < 1$), the following rules apply: $\text{PLF} > 0.7$ and $\text{PLF} > \text{PLR}$

If $\text{PLF} < 0.7$, the program resets the PLF value to 0.7, and the simulation proceeds. The runtime fraction of the coil is defined as PLR / PLF . If $\text{PLF} < \text{PLR}$, the runtime fraction of the coil is limited to 1.0. A typical part load fraction correlation would be:

$$\text{PLF} = 0.85 + 0.15 \times \text{PLR} \quad (15.401)$$

If the user wishes to model no efficiency degradation due to compressor cycling, the part load fraction correlation should be defined as follows:

$$\text{PLF} = 0.85 + 0.0 \times \text{PLR} \quad (15.402)$$

15.2.14.4 Lowest Speed Operation

The lowest speed operation of the variable-speed DX heating coil is similar to the single speed DX heating coil. The total (gross) heating capacity of the variable-speed DX coil is calculated as follows:

$$Q_{total,1} = \text{RatedTotalHeatingCapacity@SpeedLevel1} \times \text{TotCapTemModFac}_1 \times \text{TotCapAirFlowModFac}_1 \quad (15.403)$$

And the EIR is calculated as:

$$\text{EIR}_1 = \frac{1.0}{\text{ReferenceUnitCOP@Speed}(1)} \times \text{EIRTempModFac}_1 \times \text{EIRAirFlowModFac}_1 \quad (15.404)$$

And the power consumption including the compressor, outdoor fan and accessories (not including indoor fan power) is,

$$\text{Power}_1 = Q_{total,1} \times \text{EIR}_1 \times \text{RTF} \quad (15.405)$$

The fraction of the actual air mass flow to the design air mass flow rate is calculated:

$$ff_{a,1} = \frac{\text{actual air mass flow rate}}{(\text{ReferenceUnitAirMassFlowRate@SpeedLevel}(1) \times \text{CapacityScaleFactor})} \quad (15.406)$$

15.2.14.5 Higher Speed Operation

At the speed level between the lowest and the highest, there is no part-load loss. A parameter of speed ratio (SpeedRatio) is used to define the capacity partition between Speed x-1 and Speed x.

The design air flow rate at the speed ratio are given as following:

$$\begin{aligned} \text{DesignAirFlowRateSpeedRatio} &= \text{ReferenceUnitAirMassFlowRate@SpeedLevel}(x-1) \\ &\quad \times \text{CapacityScaleFactor} \times (1 - \text{SpeedRatio}) \\ &\quad + \text{ReferenceUnitAirMassFlowRate@SpeedLevel}(x) \\ &\quad \times \text{CapacityScaleFactor} \times \text{SpeedRatio} \end{aligned} \quad (15.407)$$

and the fractions of air flow is given as:

$$ff_{a,x-1} = ff_{a,x} = \text{actual air mass flow rate} / \text{DesignAirFlowRateSpeedRatio} \quad (15.408)$$

The total heating capacities and EIRs at Speed x-1 and Speed x are given:

$$Q_{total,x-1} = \text{RatedTotalHeatingCapacity@SpeedLevel}(x-1) \times \text{TotCapTemModFac}_{x-1} \times \text{TotCapAirFlowModFac}_{x-1} \quad (15.409)$$

$$Q_{\text{total},x} = \text{RatedTotalHeatingCapacity@SpeedLevel}(x) \quad (15.410)$$

$$* \text{TotCapTempModFac}_x * \text{TotCapAirFlowModFac}_x$$

$$\text{EIR}_{x-1} = \frac{1.0}{\text{ReferenceUnitCOP@Speed}(x-1)} \text{EIRTempModFac}_{x-1} * \text{EIRAirFlowModFac}_{x-1} \quad (15.411)$$

$$\text{EIR}_x = \frac{1.0}{\text{ReferenceUnitCOP@Speed}(x)} \text{EIRTempModFac}_x * \text{EIRAirFlowModFac}_x \quad (15.412)$$

The total heating capacity at the corresponding speed ratio is:

$$Q_{\text{total,SpeedRatio}} = (1.0 - \text{SpeedRatio}) * Q_{\text{total},x-1} + \text{SpeedRatio} * Q_{\text{total},x} \quad (15.413)$$

and the power consumption is:

$$\text{Power}_{\text{SpeedRatio}} = (1.0 - \text{SpeedRatio}) * Q_{\text{total},x-1} * \text{EIR}_{x-1} + \text{SpeedRatio} * Q_{\text{total},x} * \text{EIR}_x \quad (15.414)$$

The total amount of heat absorbed by the outdoor evaporator is calculated as:

$$Q_{\text{evap,SpeedRatio}} = Q_{\text{total,SpeedRatio}} - \text{Power}_{\text{SpeedRatio}} \quad (15.415)$$

Finally:

$$Q_{\text{total,SpeedRatio}} = \text{HeatingLoad} \quad (15.416)$$

If the speed reaches the highest level, the speed ratio becomes 1.0, and Speed x represents the highest speed.

15.2.14.6 Defrost Operation

The defrost operation of a variable-speed DX heating coil is treated the same as the single-speed DX heating coil, except using the total heating capacity at the max speed level to replace the rated heating capacity of the single-speed DX coil, when a reverse-cycle defrost strategy is specified.

We keep the defrost energy input ratio (EIR) modifier curve (function of temperature) as the single speed DX heating coil. It is a biquadratic curve with two independent variables: outdoor air dry-bulb temperature and the heating coil entering air wet-bulb temperature. The output of this curve is multiplied by the heating coil capacity, the fractional defrost time period and the runtime fraction of the heating coil to give the defrost power at the specific temperatures at which the coil is operating. This curve is only required when a reverse-cycle defrost strategy is specified.

$$\text{DefrostEIRTempModFac} = a + b * \text{WB}_i + c * \text{WB}_i^2 + d * \text{DB}_o + e * \text{DB}_o^2 + f * \text{WB}_i * \text{DB}_o \quad (15.417)$$

where:

WB_i is the wet-bulb temperature of the air entering the indoor coil (°C)

DB_o is the dry-bulb temperature of the air entering the outdoor coil (°C)

a-f are regression curve-fit coefficients.

15.2.14.7 Crankcase Heater Operation

This is the same as the single-speed DX heating coil.

15.2.15 Desuperheater-Recovery-Based Air Heating Coil

15.2.15.1 Overview

The input object `Coil:Heating:Desuperheater` provides a model that simulates the thermal performance of a refrigerant-to-air heating coil and the parasitic electric consumption of its control valves or other auxiliary devices. The model assumes that the heating energy provided by this coil is reclaimed from the superheated refrigerant gas leaving a compressor and does not impact the performance of the compressor. The objects from which this coil can obtain its heating energy are:

- `Coil:Cooling:DX:SingleSpeed`
- `Coil:Cooling:DX:TwoSpeed`
- `Coil:Cooling:DX:TwoStageWithHumidityControlMode`
- `Refrigeration:CompressorRack`
- `Refrigeration:Condenser*` (multiple objects)

The heat reclaim recovery efficiency (specified by the user) defines the amount of heat available for use by this coil. Approximately 25-30% of the energy rejected by typical refrigeration system condensers is to reduce the superheated refrigerant vapor temperature to the condensing temperature. Recovery efficiencies higher than 30% may cause the refrigerant gas to condense which in turn impacts the performance of the refrigeration compressor rack. For this reason, the maximum heat reclaim recovery efficiency for this coil for all sources except the `Refrigeration:Condenser:(Air, Water, or Evap)Cooled` is 30%. For these refrigeration condensers, the amount of waste energy available in the superheat region is explicitly calculated, so for these condensers the maximum heat recovery efficiency is 90% of this superheat energy. Also, for these refrigeration condensers, an estimate of the temperature of the reclaimed heat source is made and compared to the inlet air temperature for the coil. If the reclaimed heat source is too cool, the amount of available reclaim energy is set to zero.

NOTE: When the heating source is a refrigeration compressor rack, the heat rejection location in the `Refrigeration:CompressorRack` object must be “Outdoors”. If the compressor rack heat rejection location is “Zone”, the total amount of heat rejection available for reclaim (e.g., by this desuperheater heating coil) is set to zero by the compressor rack object and the simulation proceeds.

The sources for the waste heat can also be used to supply other coils. To avoid double-counting this waste heat, the amount available is corrected to reflect these other uses. For the three DX Cooling Coil sources, this correction is made within the same time step loop. For the two refrigeration system sources, the correction is made using the value from the previous time step.

The desuperheater heating coil can be used in air loop simulations for various air heating applications. For example, it can be used as an air reheat coil for high humidity control in the compound objects `AirLoopHVAC:Unitary:Furnace:HeatCool` and `AirLoopHVAC:Unitary:HeatCool` (see High Humidity Control With HeatCool Configuration). For this application, the desuperheater coil is controlled based on the calculated heating load to maintain the zone temperature and humidity setpoints (load-based control). The source of reclaimed heat could be the direct expansion (DX) cooling coil itself (`Coil:Cooling:DX:SingleSpeed`) or a refrigerated case compressor rack (`Refrigeration:CompressorRack`).

The desuperheater heating coil can also be used with cooling/heating systems that maintain specific air loop (deck) temperatures. For example, Figure 15.10 shows a schematic diagram of the desuperheater heating coil used in conjunction with the CoilSystem:Cooling:DX object. The desuperheater heating coil must be placed downstream of the DX cooling coil when reclaiming heat from that cooling coil's compressor(s). Desuperheating heating coil placement is unrestricted when reclaiming heat from a refrigeration compressor rack or refrigeration condenser. The configuration in Figure 15.10 shows the heating coil being controlled via a temperature-based strategy. In this example, the DX cooling coil could be used to maintain its discharge air temperature at 11°C for zone dehumidification. The desuperheater heating coil could then raise the air dry-bulb temperature to 16°C providing a dry supply air stream at a temperature which does not require much additional heating by terminal units to meet the zone temperature setpoint.

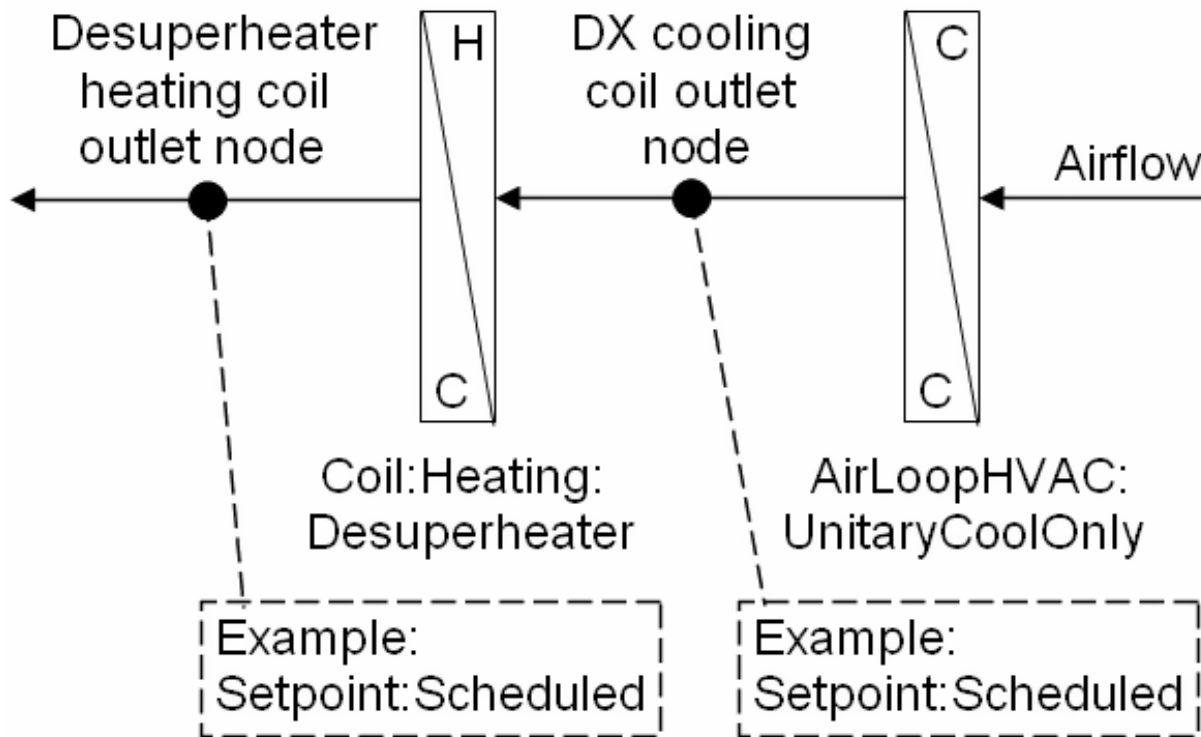

Figure 15.10: Desuperheater Heating Coil Used as a Reheat Coil with CoilSystem:Cooling:DX

Since the heating provided by the desuperheater coil is based on available waste heat from another system, the selection of fan control for the air loop equipment is essential for proper modeling. When the coil's heating source is a direct expansion cooling coil (`Coil:Cooling:DX:SingleSpeed`, `Coil:Cooling:DX:TwoSpeed`, or `Coil:Cooling:DX:TwoStageWithHumidityControlMode`), the air loop's fan control mode may be auto fan (cycling fan cycling coil), constant fan, or variable volume since the desuperheater heating coil cycles on/off with the DX cooling coil. When the heating source is a compressor rack or condenser for refrigerated cases, the supply air fan control should be either variable volume or constant fan since the desuperheater heating coil will typically be available the entire simulation time step.

NOTE: Use of the desuperheater heating coil in variable air volume systems should be done with caution since the model assumption of a fixed heat reclaim recovery efficiency may not be valid if the air flow rate over the coil varies significantly.

The following sections describe the calculations used for both the load-based and temperature-based strategies that can control the desuperheater heating coil.

15.2.15.2 Model Inputs

A minimum of seven inputs must be defined for the desuperheater heating coil. The user must input the coil's name, an availability schedule name, and the heat reclaim recovery efficiency (default of 25%, with a range of 0% to 30% except for detailed refrigeration condensers which have a default of 80%, with a range of 0% to 90%). The next two inputs are the heating coil's inlet and outlet air node names. The user must also enter the desuperheater heat source type and name which are validated when the model inputs are read into the program.

The final two fields are optional. The first of these is the coil temperature setpoint node name. This field is used when the desuperheater heating coil is controlled based on an air loop temperature and a setpoint manager (Ref. SetpointManager:*) is used to place a temperature setpoint on this air node. The latter of these optional fields is the parasitic electric load. This field allows the user to define the electric energy use of parasitic equipment associated with the desuperheater heating coil (e.g. control valves).

15.2.15.3 Model Description

The model calculates the thermal performance of the heating coil based on the control strategy used. When a temperature setpoint node name is not entered, the control type is assumed to be load-based operation. This method should be used when this coil is specified as the air reheat coil for high humidity control with the compound object AirLoopHVAC:Unitary:Furnace:HeatCool or AirLoopHVAC:UnitaryHeatCool. If the temperature setpoint node name is entered, the control type is temperature-based operation. This method is used when the heating coil is controlled to maintain a dry-bulb temperature setpoint in an air loop.

15.2.15.4 Load-Based Operation

When load-based operation is selected, a load to be met by the heating coil is requested by the parent object (e.g., AirLoopHVAC:Unitary:Furnace:HeatCool). The model first calculates the heating coil capacity based on the total condenser waste heat rejected by the heating source.

$$\dot{Q}_{coil} = \dot{Q}_{cond} \times \varepsilon_{reclaim} \quad (15.418)$$

where:

\dot{Q}_{coil} is the heating capacity of the desuperheater coil (W)

\dot{Q}_{cond} is the total amount of condenser waste heat rejected by the heating source (W)

$\varepsilon_{reclaim}$ is the heat reclaim recovery efficiency.

The model then compares the coil's heating capacity to the heating load being requested. If the heating capacity is greater than the heating load, then the amount of reclaimed heat (average heating rate over the simulation time step) is set equal to the requested load and the desuperheater heating coil will cycle off when the requested load is satisfied.

$$\dot{Q}_{reclaim} = \dot{Q}_{load} \quad (15.419)$$

Otherwise the amount of reclaimed heat is set equal to the coil's heating capacity and the desuperheater heating coil will operate the entire time that the waste heat source operates.

$$\dot{Q}_{reclaim} = \dot{Q}_{coil} \quad (15.420)$$

In either case, the coil's leaving air temperature is then calculated based on the amount of heat recovered and the air mass flow rate through the coil.

$$T_{out} = T_{in} + \frac{\dot{Q}_{reclaim}}{\dot{m}C_p} \quad (15.421)$$

where:

T_{out} is the coil outlet air temperature (°C)

T_{in} is the coil inlet air temperature (°C)

\dot{m} is the air mass flow rate through the heating coil (kg/s)

C_p is the specific heat of air entering the heating coil (J/kg-°C).

A final calculation is made to determine the runtime fraction of the desuperheater heating coil. Since the maximum amount of reclaim heat available is dependent on the runtime fraction of the waste heat source, the runtime fraction of the desuperheater heating coil is the product of the waste heat source's runtime fraction and the ratio of the amount of heat reclaimed to the desuperheater coil's heating capacity.

$$RTF_{coil} = RTF_{source} \left(\frac{\dot{Q}_{reclaim}}{\dot{Q}_{coil}} \right) \quad (15.422)$$

where:

RTF_{coil} is the runtime fraction of the desuperheater heating coil

RTF_{source} is the runtime fraction of the desuperheater heating source.

The heating coil's outlet air humidity ratio and air mass flow rate are simply set equal to the coil inlet air values. The outlet air enthalpy is calculated based on the outlet air dry-bulb temperature and the outlet air humidity ratio.

$$h_{out} = PsyHFnTdbW(T_{out}, \omega_{out}) \quad (15.423)$$

where:

h_{out} is the enthalpy of the air leaving the heating coil (J/kg)

ω_{out} is the humidity ratio of the air leaving the heating coil (kg/kg)

$PsyHFnTdbW$ is an EnergyPlus psychrometric function, returns enthalpy given dry-bulb temperature and humidity ratio.

15.2.15.5 Temperature-Based Operation

When temperature-based operation is selected, the model first calculates the heating coil capacity based on the total condenser waste heat rejected by the heating source (same as for load-based operation).

$$\dot{Q}_{coil} = \dot{Q}_{cond} \times \varepsilon_{reclaim} \quad (15.424)$$

The model then calculates the heating load required to reach the desired setpoint temperature.

$$\dot{Q}_{load} = \dot{m}C_p (T_{setpoint} - T_{in}) \quad (15.425)$$

where:

\dot{Q}_{load} is the heating load to meet the desired dry-bulb temperature setpoint (W)

$T_{setpoint}$ is the desired dry-bulb temperature setpoint (°C).

A comparison is then made to determine if the desuperheater heating coil should be energized. If the calculated load is less than or equal to 0, the coil's inlet air dry-bulb temperature is at or above the setpoint. In this case the desuperheater heating coil is not active and the outlet air dry-bulb temperature is set equal to the inlet air dry-bulb temperature.

$$\dot{Q}_{reclaim} = 0 \quad (15.426)$$

$$T_{out} = T_{in} \quad (15.427)$$

If the amount of heat required to meet the setpoint is larger than the desuperheater coil's heating capacity, then the amount of reclaimed heat is set equal to the coil heating capacity and the outlet air dry-bulb temperature is calculated.

$$\dot{Q}_{reclaim} = \dot{Q}_{coil} \quad (15.428)$$

$$T_{out} = T_{in} + \frac{\dot{Q}_{reclaim}}{\dot{m}C_p} \quad (15.429)$$

If the amount of heat required to meet the setpoint is less than the desuperheater coil's heating capacity, the amount of reclaimed heat is set equal to the calculated heating load and the outlet air dry-bulb temperature is set equal to the setpoint temperature. In this case the desuperheater heating coil will cycle off when the requested load is satisfied.

$$\dot{Q}_{reclaim} = \dot{Q}_{load} \quad (15.430)$$

$$T_{out} = T_{setpoint} \quad (15.431)$$

A final calculation is made to determine the runtime fraction of the desuperheater heating coil. Since the maximum amount of reclaim heat available is dependent on the runtime fraction of the waste heat source, the runtime fraction of the desuperheater heating coil is the product of the waste heat source's runtime fraction and the ratio of the amount of heat reclaimed to the desuperheater coil's heating capacity.

$$RTF_{coil} = RTF_{source} \left(\frac{\dot{Q}_{reclaim}}{\dot{Q}_{coil}} \right) \quad (15.432)$$

The heating coil's outlet air humidity ratio and air mass flow rate are simply set equal to the coil inlet air values. The outlet air enthalpy is calculated based on the outlet air dry-bulb temperature and the outlet air humidity ratio.

$$h_{out} = PsyHFnTdbW(T_{out}, \omega_{out}) \quad (15.433)$$

15.2.15.6 Parasitic Electric Load

The parasitic electric load attributed to the desuperheater heating coil is calculated using the user-supplied input value ($P_{parasitic}$) and the desuperheater heating coil runtime fraction calculated above.

$$P_{elec} = P_{parasitic} \times RTF_{coil} \quad (15.434)$$

The model assumes that this electric load is small and does not contribute to heating the air stream.

15.2.16 Desuperheater-Recovery-Based Water Heating Coil

15.2.16.1 Overview

The input object Coil:WaterHeating:Desuperheater provides a model that simulates the thermal performance of a refrigerant-to-water heating coil and the electric consumption of its water circulation pump, control valves, and other auxiliary devices. The model assumes that the heating energy provided by this coil is reclaimed from the superheated refrigerant gas leaving a compressor and does not impact the performance of the compressor. For water cooled systems, the impact of the desuperheater is reflected by reducing the heat transfer to the condensing plant loop. The objects from which this coil can obtain its heating energy are:

- Coil:Cooling:DX:SingleSpeed
- Coil:Cooling:DX:TwoSpeed
- Coil:Cooling:DX:TwoStageWithHumidityControlMode
- Coil:Cooling:WaterToAirHeatPump:EquationFit
- Refrigeration:CompressorRack
- Refrigeration:Condenser* (multiple objects)

The heat reclaim recovery efficiency (specified by the user) defines the amount of heat available for use by this coil. Approximately 25-30% of the energy rejected by typical refrigeration system condensers is to reduce the superheated refrigerant vapor temperature to the condensing temperature. Recovery efficiencies higher than 30% may cause the refrigerant gas to condense, which in turn impacts the performance of the refrigeration compressor rack. For this reason, the maximum heat reclaim recovery efficiency for this coil for all sources except the Refrigeration:Condenser:(Air, Water, or Evap)Cooled is 30%. For these refrigeration condensers, the amount of waste energy available in the superheat region is explicitly calculated, so for these condensers the maximum heat recovery efficiency is 90% of this superheat energy. Also, for these refrigeration condensers, an estimate of the temperature of the reclaimed heat source is made and compared to the inlet air temperature

for the coil. If the reclaimed heat source is too cool, the amount of available reclaim energy is set to zero. For all heat sources, the model includes the ability to modify the heat reclaim recovery efficiency based on variations in inlet water temperature and outdoor air dry-bulb temperature.

NOTE: When the heating source is a refrigerated case compressor rack, the heat rejection location in the Refrigeration:CompressorRack object must be “Outdoors”. If the compressor rack heat rejection location is “Zone”, the total amount of heat rejection available for reclaim (e.g., by this desuperheater heating coil) is set to zero by the compressor rack object and the simulation proceeds.

To model a desuperheater water heating coil, the input data file must include the following objects:

- Coil:WaterHeating:Desuperheater
- WaterHeater:Mixed or WaterHeater:Stratified
- Coil:Cooling:DX:* or Refrigeration:CompressorRack or Refrigeration:Condenser:* or Coil:Cooling:WaterToAirHeatPump:EquationFit

A schematic diagram showing the desuperheater water heating coil with its water heater and DX system condenser is shown below.

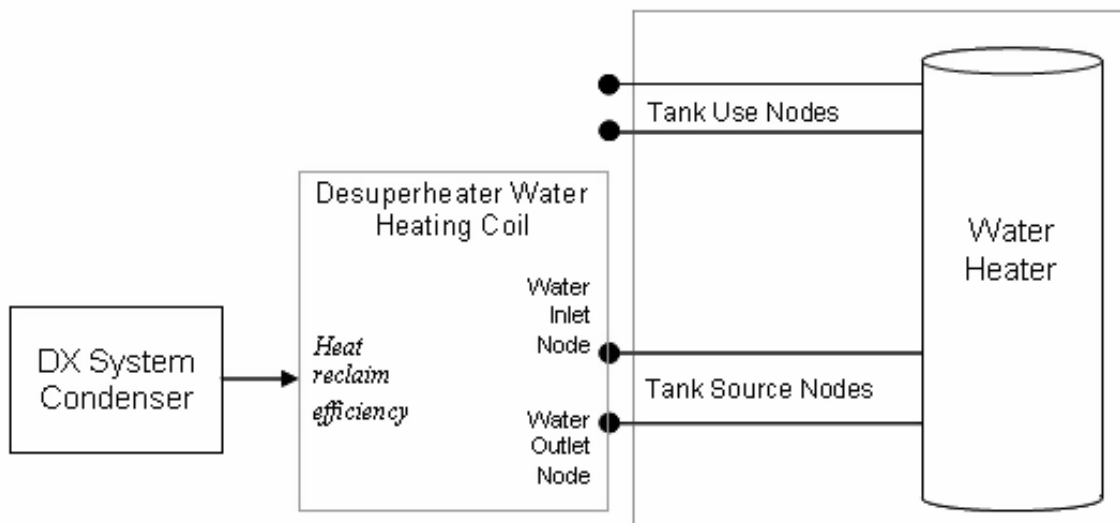

Figure 15.11: Schematic of Desuperheater Water Heating Coil

15.2.16.2 Model Description

The desuperheater heating coil input requires a setpoint temperature schedule and dead band temperature difference, which are independent from the setpoint temperature schedule and dead band temperature difference for the heater (element or burner) associated with the water heater tank. The cut-in temperature for the desuperheater coil is defined as the desuperheater coil's setpoint temperature minus its dead band temperature difference.

$$T_{cut-in} = T_{set\ point} - T_{dead\ band} \quad (15.435)$$

where:

T_{cut-in} is the cut-in temperature (°C)

$T_{set\ point}$ is the setpoint temperature (°C)

$T_{dead\ band}$ is the dead band temperature difference (°C).

Desuperheater water heating coils are typically used to offset energy consumption by the water tank's heater (element or burner). Therefore, the cut-in temperature of the desuperheater coil should always be higher than the water heater tank's setpoint temperature. At times when the water heater tank's setpoint temperature is greater than or equal to the cut-in temperature of the desuperheater coil, the desuperheater is disabled and the water heater tank heating element is used to heat the water. An additional input parameter sets the maximum inlet water temperature allowed for desuperheater heat reclaim. Any time the inlet water temperature to the desuperheater coil is above this maximum allowed temperature, heat reclaim is restricted so that the tank water does not exceed this temperature.

When the desuperheater coil is scheduled off by its availability schedule, the water heater tank's setpoint temperature is greater than or equal to the desuperheater coil cut-in temperature, or if the DX system's compressor (source of heat reclaim) is off, the water heating capacity and water mass flow rate for the desuperheater coil are set to zero and the water heater tank is simulated with the desuperheater heating coil disabled. Otherwise, the simulation proceeds by first determining the maximum amount of heat available for heat reclaim. If a heat reclaim efficiency modifier curve object is specified by the user, this bi-quadratic curve is evaluated using the desuperheater coil inlet water temperature and the outdoor air dry-bulb temperature; otherwise, the output is assumed to be equal to 1.

If $HEffFTemp$ is specified:

$$HEffFTemp = \max(0.0, f(T_{water,inlet}, T_{DB,outdoor})) \quad (15.436)$$

Else:

$$HEffFTemp = 1.0 \quad (15.437)$$

where:

$HEffFTemp$ is the heat reclaim efficiency modifier

$T_{water,inlet}$ is the desuperheater coil inlet water temperature (°C)

$T_{DB,outdoor}$ is the outdoor air dry-bulb temperature (°C).

Except for the detailed condenser source, heat reclaim recovery efficiencies higher than 30% may cause the refrigerant gas to condense which in turn impacts the performance of the refrigeration system. The model is unable to account for this refrigeration system impact, so the product of the rated heat reclaim recovery efficiency and heat reclaim efficiency modifier is not allowed to exceed 0.3. For the detailed refrigeration condenser, the limit for the heat reclaim efficiency has been set at 0.9 as follows:

$$\text{IF } (\varepsilon_{reclaim,rated})(HEffFTemp) > Limit, \text{ THEN } HEffFTemp = \frac{Limit}{\varepsilon_{reclaim,rated}} \quad (15.438)$$

where:

Limit is 0.3 for most sources or 0.9 for detailed condensers

$\varepsilon_{reclaim,rated}$ is the rated heat reclaim recovery efficiency.

The heating capacity of the desuperheater coil is then calculated based on the product of total amount of condenser waste heat rejected by the heating source, the desuperheater coil's rated heat reclaim recovery efficiency, and the heat reclaim efficiency modifier.

$$\dot{Q}_{coil} = \left(\dot{Q}_{cond} \right) (\varepsilon_{reclaim,rated}) HEffFTemp / DXSystemPLR \quad (15.439)$$

where:

\dot{Q}_{coil} is the water heating capacity of the desuperheater coil (W)

\dot{Q}_{cond} is the average rate of condenser waste heat rejected by the heating source (W)

$DXSystemPLR$ is the part load ratio for the desuperheater coil heating source (1.0 for refrigerated case compressor rack and detailed refrigeration condenser).

The desuperheater is assumed to have a water circulation pump located downstream of the refrigerant-to-water coil. Pump heat is added to the desuperheater water heating capacity based on a user-defined fraction as follows:

$$\dot{Q}_{coil} = \dot{Q}_{coil} + P_{pump} (Frac_{pumptowater}) \quad (15.440)$$

where:

P_{pump} is the water pump power (W)

$Frac_{pumptowater}$ is the fraction of pump heat to water

The temperature of the water leaving the desuperheater is then calculated as

$$T_{water,outlet} = T_{water,inlet} + \frac{Q_{coil}}{\dot{m}_{water} \cdot C_{p,water}} \text{ for } \dot{m}_{water} > 0 \quad (15.441)$$

$$T_{water,outlet} = T_{water,inlet} \text{ for } \dot{m}_{water} = 0 \quad (15.442)$$

Simulation of the desuperheater heating coil is based on its current mode of operation. This mode of operation is either floating (heating coil off and tank water temperature has not fallen below the heater cut-in temperature) or heating (tank water temperature dropped below the heater cut-in temperature on a previous time step but was unable to reach the heater setpoint temperature). Each mode is handled differently and they will be discussed separately.

15.2.16.3 Float Mode

When the water heater tank temperature is floating between the desuperheater coil's cut-in and cut-out temperatures at the end of the previous simulation time step, both the desuperheater coil and the water heater tank's heating element are disabled and a resulting tank temperature is calculated. If the resulting tank temperature is below the desuperheater coil cut-in temperature the desuperheater coil part-load ratio is estimated using a ratio of temperature differences as shown below. The part-load ratio can not be less than zero or greater than the part-load ratio of the DX system from which the desuperheater coil is reclaiming heat.

$$PLR = MIN \left(DXSystemPLR, MAX \left(0.0, \left(\frac{T_{cut-in} - T_{tank,float}}{T_{tank,initial} - T_{tank,float}} \right) \right) \right) \quad (15.443)$$

where:

PLR is the part load ratio of desuperheater heating coil

$T_{tank,float}$ is the tank temperature in float mode when heating capacity is set to zero ($^{\circ}\text{C}$)

$T_{tank,initial}$ is the tank water temperature at the beginning of a simulation time step ($^{\circ}\text{C}$)

Since the water pump is assumed to cycle on and off with the desuperheater coil, the average water mass flow rate through the desuperheater coil is then set proportional to the PLR calculated above:

$$\dot{m}_{water,avg} = \dot{m}_{water} (PLR) \quad (15.444)$$

where $\dot{m}_{water,avg}$ is the average desuperheater water mass flow rate for the time step (kg/s).

The water tank temperature is then calculated based on desuperheater heating coil operation (outlet water temperature and average water mass flow rate as calculated above) and with the water tank's heater element enabled. If the resulting water tank temperature is above the desuperheater coil's setpoint temperature, then the part-load ratio is reduced in the same manner described in the heating mode section below.

15.2.16.4 Heating Mode

When the desuperheater heating coil is in heating mode at the end of the previous simulation time step (i.e., desuperheater coil operated during the previous simulation time step but was unable to achieve the setpoint temperature), both the desuperheater and the water heater tank's heating element are enabled. The desuperheater coil outlet water temperature is calculated (as described above) and the water mass flow rate through the desuperheater coil is set to the maximum operating flow rate:

$$\dot{m}_{water,avg} = \dot{m}_{water} (DXSystemPLR) \quad (15.445)$$

If the resulting tank water temperature is above the desuperheater coil's setpoint (cut-out) temperature, the part load ratio of the desuperheater coil is reduced and the water heater tank is simulated again. The process is performed iteratively until the part load ratio of the desuperheater coil achieves the desired setpoint temperature.

15.2.16.5 Model Outputs

After completing the float mode or heating mode calculations and the final desuperheater part load ratio has been determined, the output (report) variables are calculated as follows:

$$Desuperheater\ Part\ Load\ ,\ Ratio = MIN \left(\frac{\dot{m}_{water,avg}}{\dot{m}_{water}}, DXSystemPLR \right) \quad (15.446)$$

$$Desuperheater\ Water\ Heating\ Rate\ (W) = \dot{Q}_{coil} (PLR) \quad (15.447)$$

$$Desuperheater\ Water\ Heating\ Energy\ (J) = \dot{Q}_{coil} (PLR) (3600) (t_{sys}) \quad (15.448)$$

$$Desuperheater\ Pump\ Electric\ Power\ (W) = P_{pump} (PLR) \quad (15.449)$$

$$\text{Desuperheater Pump Electric Consumption (J)} = P_{\text{pump}}(PLR)(3600)(t_{\text{sys}}) \quad (15.450)$$

$$\text{Desuperheater Heat Reclaim Efficiency Modifier Curve Output} = HEffFTemp \quad (15.451)$$

$$\text{Desuperheater On-Cycle Parasitic Electric Power (W)} = P_{\text{parasiticload,on}}(PLR) \quad (15.452)$$

$$\begin{aligned} \text{Desuperheater On-Cycle Parasitic Electric , Consumption (J)} = \\ P_{\text{parasiticload,on}}(PLR)(3600)t_{\text{sys}} \end{aligned} \quad (15.453)$$

$$\text{Desuperheater Off-Cycle Parasitic Electric Power (W)} = P_{\text{parasiticload,off}}(1 - PLR) \quad (15.454)$$

$$\begin{aligned} \text{Desuperheater Off-Cycle Parasitic Electric Consumption (J)} = \\ P_{\text{parasiticload,off}}(1 - PLR)(3600)(t_{\text{sys}}) \end{aligned} \quad (15.455)$$

where:

$P_{\text{parasiticload,on}}$ is the on-cycle parasitic electric load (W)

$P_{\text{parasiticload,off}}$ is the off-cycle parasitic electric load (W)

t_{sys} is the HVAC system simulation time step (hours).

Note: All output variables, including off cycle parasitic electrical power and energy, equal 0 when the desuperheater heating coil availability schedule equals 0.

15.2.17 Heat Exchanger Assisted Air Cooling Coil Systems

An air-to-air heat exchanger can be used to enhance the dehumidification performance of a conventional cooling coil. EnergyPlus has two compound objects to model this scenario: CoilSystem:Cooling:DX:HeatExchangerAssisted and CoilSystem:Cooling:Water:HeatExchangerAssisted. The input syntax for these compound objects can be found in the EnergyPlus Input/Output Reference.

As shown in Figure 15.12, the air-to-air heat exchanger pre-conditions the air entering the cooling coil, and reuses this energy to post-condition the supply air leaving the cooling coil. This heat exchange process improves the latent removal performance of the cooling coil by allowing it to dedicate more of its cooling capacity toward dehumidification (lower sensible heat ratio).

NOTE: Node naming shown in Figure 15.12 is representative for HeatExchanger:AirToAir:SensibleAndLatent. For HeatExchanger:AirToAir:FlatPlate, the exhaust air nodes are referred to as ‘secondary air’ nodes. For HeatExchanger:Desiccant:BalancedFlow (heat exchanger assisted DX coil only), the supply air nodes are referred to as ‘regeneration air’ nodes and the exhaust air nodes as ‘process air’ nodes.

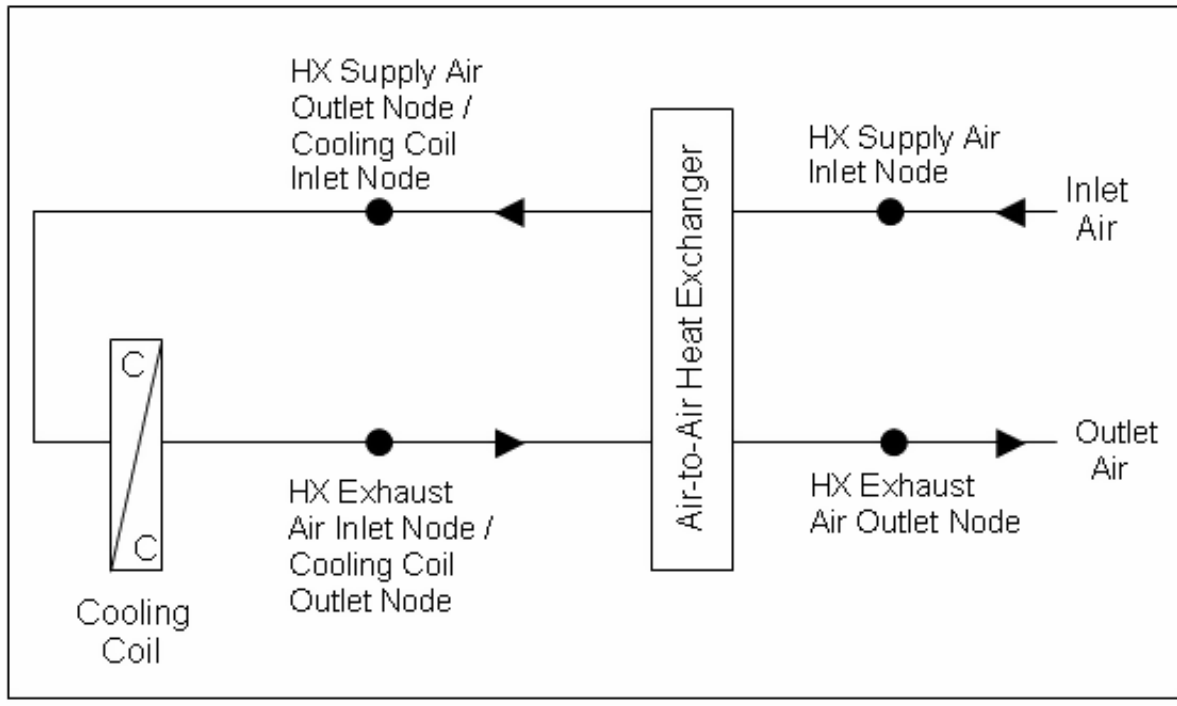

Figure 15.12: Schematic of a Heat Exchanger Assisted Cooling Coil

The dehumidification performance of cooling coils can be enhanced using a sensible-only heat exchanger (e.g., heat pipes, runaround coils, cross-flow heat exchangers). For example, a `CoilSystem:Cooling:DX:HeatExchangerAssisted` object could be used with a `HeatExchanger:AirToAir:FlatPlate` object or `HeatExchanger:AirToAir:SensibleAndLatent` object with only sensible effectiveness specified (see resulting psychrometric process in Figure 15.13). The dehumidification performance of cooling coils can also be enhanced using heat exchangers that transfer both sensible and latent energy (e.g., rotary desiccant heat exchanger). For example, a `CoilSystem:Cooling:DX:HeatExchangerAssisted` object could be used with a `HeatExchanger:Desiccant:BalancedFlow` object (see resulting psychrometric process in Figure 15.14).

Note that while the `HeatExchanger:AirToAir:SensibleAndLatent` and `HeatExchanger:Desiccant:BalancedFlow` objects can transfer both sensible and latent heat between two air streams, the `HeatExchanger:Desiccant:BalancedFlow` object with appropriate Performance Data Type object is the proper heat exchanger model to use for the heat exchanger assisted cooling coil described here. The `HeatExchanger:AirToAir:SensibleAndLatent` object should only be used to model the sensible-only heat exchange case (Figure 15.13).

Modeling of the heat exchanger assisted cooling coil is performed by consecutively modeling the air-to-air heat exchanger and the cooling coil until convergence on a solution is achieved. The detailed modeling calculations for the individual components (air-to-air heat exchangers and cooling coils) are described elsewhere in this document.

Modeling of the heat exchanger assisted cooling coil begins by initializing the air mass flow rate (based on the air mass flow rate placed on the compound object's inlet air node) and passing this value to the exhaust air inlet node of the air-to-air heat exchanger. The heat exchanger and cooling coil are then successively modeled using the calculation routines specific to the type of heat exchanger and cooling coil selected. The air temperature exiting the cooling coil is compared with

Figure 15.13: Psychrometric Process for Heat Exchanger Assisted Cooling Coil (Sensible HX Only)

the air temperature exiting the cooling coil on the previous modeling iteration for this simulation time step. Convergence is reached when the change in this air temperature for successive iterations is within a specified tolerance (0.0005°C). Consecutive modeling of the heat exchanger and cooling coil is terminated and a warning message is issued if the number of modeling iterations exceeds 50.

For the `CoilSystem:Cooling:DX:HeatExchangerAssisted` object, heat exchanger operation can be controlled based on high humidity levels in a zone. By default, the heat exchanger is assumed to always provide its heat transfer when the associated DX cooling coil is operating and no humidity control mechanism is specified. However, the heat exchanger's energy transfer may be controlled (i.e., turned on and off) based on a zone air humidity level using either a humidistat alone (Figure 15.15) or a humidistat and a maximum humidity setpoint manager (Figure 15.16) depending on the HVAC system that is utilizing the heat exchanger assisted cooling coil.

The heat exchanger assisted DX cooling coil may be used with furnaces or unitary systems located in an air loop (ref. `AirLoopHVAC:Unitary:Furnace:HeatCool` or `AirLoopHVAC:UnitaryHeatCool`). These system objects have three options for dehumidification control (None, Multimode, and CoolReheat). When no dehumidification control is specified in the furnace or unitary system object (None), the heat exchanger is always active when the cooling coil is operating. When multimode or coolreheat dehumidification control is specified, a humidistat is required as shown in Figure 15.15. For the case of multimode dehumidification control, the heat exchanger is only active when the zone air humidity level is above the humidistat setpoint (i.e., the system's cooling coil can't meet the latent cooling load when operating without heat exchanger energy transfer) while the AC system operates to meet the sensible (dry-bulb cooling thermostat) load. For the case of coolreheat dehumidification control, the heat exchanger is always active when

Figure 15.14: Psychrometric Process for Heat Exchanger Assisted Cooling Coil (Sensible+Latent HX)

the cooling coil operates and this system tries to meet both the sensible (thermostat) and latent (humidistat) loads.

The heat exchanger assisted DX cooling coil may also be used with a DX system located in an air loop (ref. `CoilSystem:Cooling:DX`). This system object also has three options for dehumidification control (None, Multimode, and CoolReheat). When no dehumidification control is specified (None), the heat exchanger is always active when the cooling coil is operating. When multimode or coolreheat dehumidification control is specified, a humidistat and a maximum humidity setpoint manager are required as shown in Figure 15.16 (setpoint needs to be placed on the DX system's control node). For multimode dehumidification control, the heat exchanger is only active when the zone humidity levels are above the humidistat setpoint (i.e., the system's cooling coil can't meet the maximum humidity ratio setpoint when operating without heat exchanger energy transfer) while the AC system operates to meet the sensible (dry-bulb cooling thermostat) load. For coolreheat dehumidification control, the heat exchanger is always active when the cooling coil operates and this system tries to meet both the sensible (thermostat) and latent (humidistat) loads.

When the heat exchanger assisted cooling coil is used with a furnace or unitary system (ref. `AirLoopHVAC:Unitary:Furnace:HeatCool` or `AirLoopHVAC:UnitaryHeatCool`) or DX system (ref. `CoilSystem:Cooling:DX`) located in an air loop (or DX system used in an outside air system), an economizer function may be customized as necessary. For economizer control, an outdoor air controller (ref. `Controller:OutdoorAir`) is used to define the economizer control inputs and determine when economizer mode is active. The heat exchanger (ref. `HeatExchanger:*`) object provides an economizer lockout feature which disables heat recovery any time the economizer is active. This feature can be turned on and off using the heat exchanger lockout input. Heat exchanger assisted

Figure 15.15: Schematic of a heat exchanger assisted DX cooling coil with optional humidistat

cooling coils used with the zone equipment described below disregard this economizer control feature.

The heat exchanger assisted DX cooling coil may also be used with the unitary changeover bypass system and the unitary air-to-air heat pump system (ref. `AirLoopHVAC:UnitaryHeatCool:VAV-ChangeoverBypass` and `AirLoopHVAC:UnitaryHeatPump:AirToAir`); however, the heat exchanger is assumed to always provide its heat transfer when the cooling coil operates and can not be turned on and off based on a zone air humidity setpoint (ref. Figure 15.12). Two zone air conditioners may also use this heat exchanger/coil assembly model for improved dehumidification. The first type is the packaged terminal heat pump (ref. `ZoneHVAC:PackagedTerminalHeatPump`) where the heat exchanger's heat transfer is always active whenever the cooling coil operates (ref. Figure 15.12). The second type is the window air conditioner (ref. `ZoneHVAC:WindowAirConditioner`) where the heat exchanger's heat transfer is always active when the cooling coil operates and no humidity control mechanism is specified (ref. Figure 15.12), or the heat exchanger's heat transfer may be controlled based on zone air humidity level when a humidistat and high humidity setpoint manager are specified (maximum humidity ratio setpoint must be placed on the heat exchanger's exhaust air outlet node). For this case, the heat exchanger is only active when the zone air humidity level is above the humidistat setpoint (i.e., the system's cooling coil can't meet the maximum humidity ratio setpoint when operating without heat exchanger energy transfer) while only the sensible (dry-bulb cooling thermostat) load is met by the AC system (ref. Figure 15.16).

For the `CoilSystem:Cooling:Water:HeatExchangerAssisted` object, there is currently no method to enable or disable heat exchange based on zone air humidity level. Heat exchange will occur whenever the heat exchanger is available to operate (via its availability schedule) and a temperature difference exists between the two air streams.

15.2.18 Air Source Integrated Heat Pump

15.2.18.1 Overview

Air Source Integrated Heat Pump (ASIHP) is an air source, multi-functional spacing conditioning unit with water heating function (WH), which usually uses a variable-speed compressor, variable-speed indoor blower, and outdoor fan. By recovering the condenser waste heat for water heating, ASIHPs are able to achieve significant energy savings.

15.2.18.2 Model Description

The latest technology for commercial air conditioners and air-to-air heat pumps can utilize a variable-speed compressor with a variable-speed indoor blower and outdoor fan. Integrated heat pumps are multi-functional units capable of space conditioning and water heating. They use con-

denser waste heat for water heating, and thus achieve significant energy saving. The control and operation of ASIHPs are complicated because they have six working modes in total: (1) space cooling (SC), (2) space heating (SH), (3) dedicated water heating (DWH), (4) combined space cooling and water heating with full condensing (SCWH), (5) combined space cooling and water heating with desuperheating (SCDWH), and (6) combined space heating and water heating with desuperheating (SHDWH).

The SC mode has the same operation as `Coil:Cooling:DX:VariableSpeed`. The SH mode has the same operation as `Coil:Heating:DX:VariableSpeed`. The DWH mode uses outdoor air as the heating source, which can be represented by an object of `Coil:WaterHeating:AirToWaterHeatPump:VariableSpeed`. The SCWH mode uses indoor air as the heating source and full condenser heat for water heating. `Coil:WaterHeating:AirToWaterHeatPump:VariableSpeed` is used for the mode.

The SCDWH mode uses the superheated section of an outdoor condenser to heat the water. In this combined SCDWH mode, the cooling function is simulated using an object of `Coil:Cooling:DX:VariableSpeed`, containing temperature correction curves as a function of the indoor air and ambient temperatures at each speed level. The water heating function is simulated using an object of `Coil:WaterHeating:AirToWaterHeatPump:VariableSpeed`, having temperature correction curves as a function of the ambient air temperature and entering water temperature at each speed level. It should be noted that the rated power and power correction curves are contained in the `Coil:Cooling:DX:VariableSpeed` object. Thus, the power values and curves in the `Coil:WaterHeating:AirToWaterHeatPump:VariableSpeed` are not used. That means the power consumption at each speed level of the SCDWH mode is accounted by the cooling coil part.

The SHDWH uses the superheated section of an indoor condenser to heat the water. In this combined mode, the heating function is simulated using an object of `Coil:Heating:DX:VariableSpeed`, having temperature correction curves as a function of the indoor air and ambient temperatures at each speed level. The water heating function is simulated using an object of `Coil:WaterHeating:AirToWaterHeatPump:VariableSpeed`, having temperature correction curves as a function of the ambient air temperature and entering water temperature at each speed level. It should be noted that the rated power and power correction curves are contained in the `Coil:Heating:DX:VariableSpeed` object. Thus, the power values and curves in the `Coil:WaterHeating:AirToWaterHeatPump:VariableSpeed` are not used. That means the power consumption at each speed level of the SHDWH mode is accounted by the heating coil. `Coil:Heating:DX:VariableSpeed` object calculates the total heating capacity added to the indoor air flow. The WH capacity is calculated using `Coil:WaterHeating:AirToWaterHeatPump:VariableSpeed`.

The parent object of the ASIHP is named as `CoilSystem:IntegratedHeatPump-AirSource`, which is a collection of all the sub-models as above. Also, `CoilSystem:IntegratedHeatPump:AirSource` facilitates mode switch and control algorithms.

15.2.18.3 Working Modes

The ASIHP is a collection of working modes, i.e., objects, as described below:

Space Cooling Mode (SC):

–Coil object: `Coil:Cooling:DX:VariableSpeed`.

–Loop object: `AirLoopHVAC:UnitarySystem`, which refers to the `CoilSystem:IntegratedHeatPump:AirSource` object.

–Load matching: the same as a regular variable-speed air source heat pump in cooling mode.

Space Heating Mode (SH):

- Coil object: Coil:Heating:DX:VariableSpeed.

- Loop object: AirLoopHVAC:UnitarySystem, which refers to the CoilSystem:IntegratedHeatPump:AirSource object.

- Load matching: the same as a regular variable-speed air source heat pump in heating mode

Dedicated Water Heating Mode (DWH):

- Coil object: Coil:WaterHeating:AirToWaterHeatPump:VariableSpeed. The water heating coil uses outdoor air as the heating source.

- Loop object: WaterHeater:HeatPump:PumpedCondenser, which refers to the CoilSystem:IntegratedHeatPump:AirSource object.

- Load matching: the same as a regular variable-speed heat pump water heating coil with outdoor air source.

Combined Space Cooling and Water Heating with Full Condensing Mode (SCWH):

- Coil object: Coil:WaterHeating:AirToWaterHeatPump:VariableSpeed. The water heating coil uses indoor air as the heating source.

- Loop object:

- Air side: the same loop object as the SC mode, i.e., AirLoopHVAC:UnitarySystem, which refers to the CoilSystem:IntegratedHeatPump:AirSource object.

- Water side: the same loop object as the DWH mode, i.e., WaterHeater:HeatPump: Pumped-Condenser, which refers to the CoilSystem:IntegratedHeatPump:AirSource object.

- Load matching:

- If one chooses to match the space cooling load, iterate the AirLoopHVAC object, and the water heating capacity in the water tank object is resultant.

- If one chooses to match the water heating load, iterate the water tank object, and the space cooling capacity is resultant.

Combined Space Cooling and Water Heating with Desuperheating Mode (SCDWH):

- Coil object: use two coil objects, Coil:Cooling:DX:VariableSpeed and – Coil:WaterHeating:AirToWaterHeatPump:VariableSpeed. The desuperheater heat is used for water heating, which changes with the compressor speed and operation conditions. This is a dual-function coil, which provides both space cooling and water heating, and so performance curves for the dual functions will be included in the coil objects, respectively. These should be different objects from the SCWH mode and SC mode. The water heating coil contains temperature correction curves as a function of the ambient air temperature and entering water temperature.

It should be noted that the rated power and power correction curves are contained in the Coil:Cooling:DX:VariableSpeed object. Thus, the power values and curves in the Coil:WaterHeating:AirToWaterHeatPump:VariableSpeed are not used. That means the power consumption at each speed level of the SCDWH mode is accounted by the cooling coil part.

- Loop object:

- Air side: the same loop object as the SC mode, i.e., AirLoopHVAC:UnitarySystem.

- Water side: the same loop object as the DWH mode, i.e., WaterHeater:HeatPump:PumpedCondenser.

- Load matching:

Always match the space cooling load by iterating the AirLoopHVAC object, and the water heating amount in the water tank object is resultant.

Combined Space Heating and Water Heating with Desuperheating Mode (SHDWH):

- Coil object: use two coil objects, Coil:Heating:DX:VariableSpeed and Coil:WaterHeating: AirToWaterHeatPump:VariableSpeed, contained in CoilSystem:IntegratedHeatPump:AirSource. The

desuperheater heat is used for water heating, which changes with the compressor speed and operation conditions. This is a dual-function coil, which provides both space heating and water heating, and so performance curves for the dual functions will be included in the coil objects, respectively.

It should be noted that the rated power and power correction curves are contained in the Coil:Heating:DX:VariableSpeed object. Thus, the power values and curves in the Coil:WaterHeating:AirToWaterHeatPump:VariableSpeed are not used. That means the power consumption at each speed level of the SHDWH mode is accounted for by the heating coil part.

The Coil:WaterHeating:AirToWaterHeatPump:VariableSpeed object contains rated water heating capacity and capacity correction curves to simulate water heating capacity as a function of the outdoor air temperature and the water entering temperature at each speed level. The Coil:Heating:DX:VariableSpeed object calculates the total heating capacity, added to indoor air flow.

–Loop object:

–Air side: share the same air side connections as the SH mode, i.e., AirLoopHVAC:UnitarySystem.

–Water side: the same loop object as the DWH mode, i.e., WaterHeater:HeatPump:PumpedCondenser.

–Load matching:

Always match the space heating load by iterating the AirLoopHVAC object, and the water heating amount in the water tank object is resultant.

15.2.18.4 Control and Mode Switch

At the beginning of each time step, an CoilSystem:IntegratedHeatPump:AirSource object surveys calls from all of its connected parent objects and nodes, e.g., AirLoopHVAC:UnitarySystem, WaterHeater:HeatPump:PumpedCondenser. Upon analyzing the space conditioning and water heating calls, the ASIHP will operate in a selected mode for the following timestep, as shown below:

Case I: If there is only a space cooling call, – run SC mode.

Case II: If there is only a space heating call, – run SH mode.

Case III: If there is only a water heating call, and if ambient temperature and indoor temperature are larger than the temperature settings above which indoor overcooling is allowed, – run SCWH mode to match the water heating load above a minimum speed allowed. Else – run DWH mode.

Case IV: If there are simultaneous space cooling and water heating calls, and if the sum of heated water going through the ASIHP is less than the threshold, – run SCDWH mode by iterating the speed to match the space cooling load above a minimum speed specified. Else – run SCWH mode to match either the space cooling load or the water heating load, as specified, above a minimum speed allowed.

Case V: If there are simultaneous space heating and water heating calls, and if the ambient temperature and indoor temperature are larger than temperature settings above which water heating has a higher priority and space heating call can be ignored – run DWH mode. Otherwise, if running time of the water heating is less than a setting, – run SHDWH mode to match the space heating load by iterating the compressor speed above a minimum speed specified, with the WH electric element in the water tank disabled. Otherwise, if running time of the water heating is bigger than the setting, – run SHDWH mode to match the space heating load by iterating the compressor speed above a minimum speed allowed, with the WH electric element enabled.

15.2.19 Single-Speed Electric Heat Pump DX Water Heating Coil

15.2.19.1 Overview

The input object `Coil:WaterHeating:AirToWaterHeatPump:*` provides a model used in a heat pump water heater (HPWH) consisting of a water heater tank (e.g., `WaterHeater:Mixed` or `WaterHeater:Stratified`), a direct expansion (DX) “coil” (i.e., an air-to-water DX compression system which includes a water heating coil, air coil, compressor, and water pump), and a fan to provide air flow across the air coil associated with the DX compression system. These objects work together to model a system which heats water using zone air, outdoor air, or a combination of zone and outdoor air as the primary heat source. The heat pump water heater (Ref. `WaterHeater:HeatPump:*`), water heater tank (Ref. `WaterHeater:Mixed` and `WaterHeater:Stratified`), and fan (Ref. `Fan:*`) objects are described elsewhere in this document.

Figure 15.17: Schematic of a Heat Pump Water Heater using Optional Mixer/Splitter Nodes

The heat pump water heater DX coil model described here determines the thermal performance and energy consumption of the DX compression system, which includes a water heating coil (condenser), a coil used to extract heat from air (evaporator), and the compressor. This model also simulates the performance of a condenser water pump that is assumed to cycle on and off with the compressor.

Virtually all of the inputs to this DX coil model relate to its water heating performance and energy consumption. Model inputs differ between the `Coil:WaterHeating:AirToWaterHeatPump:Pumped` and `Coil:WaterHeating:AirToWaterHeatPump:Wrapped` to include only the relevant inputs for `WaterHeater:HeatPump:PumpedCondenser` and `WaterHeater:HeatPump:WrappedCondenser`, respectively. The air-side cooling capacity of this DX system is derived from user inputs and some model assumptions. The sensible/latent cooling capacity split is defined by the user at rated conditions, and the model adjusts this split at off-rated conditions.

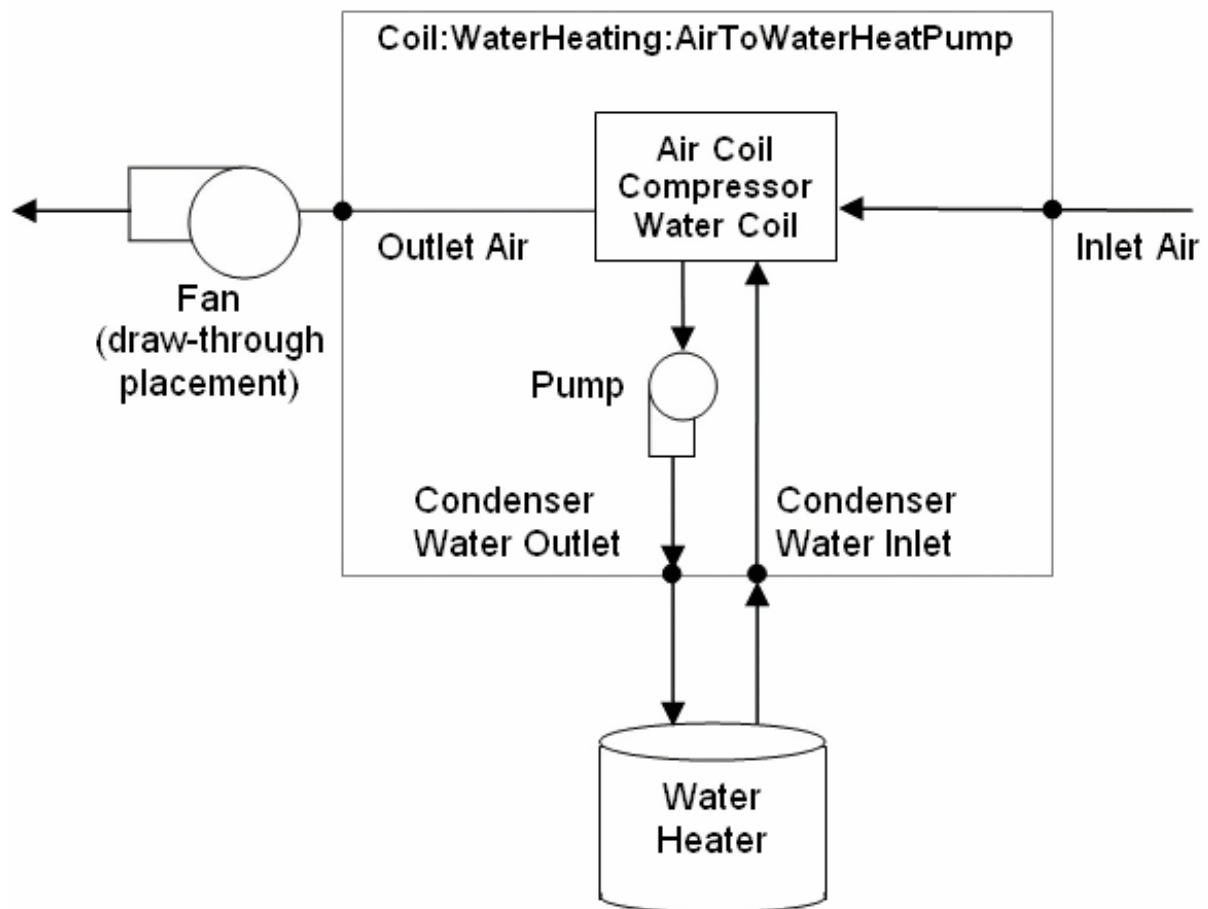

Figure 15.18: Schematic of the Heat Pump Water Heater DX Coil

15.2.19.2 Model Description

The user must input the heating capacity, coefficient of performance (COP), and the sensible heat ratio (SHR) of the evaporator coil at rated inlet fluid temperatures and flow rates that are also specified by the user. The evaporator SHR should be a “gross” value, excluding any thermal impacts due to the indoor supply air fan. The user may also input up to seven performance curves that describe the change in total water heating capacity and efficiency at off-rated and part-load conditions.

1. Heating capacity modifier curve (function of temperature)
2. Heating capacity modifier curve (function of air flow fraction)
3. Heating capacity modifier curve (function of water flow fraction, pumped condenser only)
4. Heating COP modifier curve (function of temperature)
5. Heating COP modifier curve (function of air flow fraction)
6. Heating COP modifier curve (function of water flow fraction, pumped condenser only)
7. Part load fraction correlation (function of part load ratio)

Note: The air dry-bulb or wet-bulb temperature used in the following curve objects is the inlet air temperature to the HPWH evaporator coil/fan assembly. If the fan placement specified in the WaterHeater:HeatPump:* compound object is draw-through, then the inlet air temperature represents the temperature of the air entering the evaporator coil itself. If blow-through fan placement is specified, then the inlet air temperature represents air conditions entering the fan located immediately in front (upstream) of the evaporator coil.

The heating capacity as a function of temperature modifier curve defines the variation in DX coil heating capacity as a function of inlet fluid (air and water) temperatures. The curve object may use either a bi-quadratic or cubic form. The bi-quadratic curve uses inlet air temperature (dry-bulb or wet-bulb temperature based on the input field Evaporator Air Temperature Type for Curve Objects) and condenser inlet water temperature as the independent variables. The cubic curve uses inlet air (dry-bulb or wet-bulb) temperature as the independent variable. The curve should be normalized to have the value of 1.0 at the rating point temperatures specified by the user.

$$HCapFTemp = a + b(T_{evap,in}) + c(T_{evap,in})^2 + d(T_{cond,in}) + e(T_{cond,in})^2 + f(T_{evap,in})(T_{cond,in}) \quad (15.456)$$

or

$$HCapFTemp = a + b(T_{evap,in}) + c(T_{evap,in})^2 + d(T_{evap,in})^3 \quad (15.457)$$

where:

$T_{evap,in}$ is the dry-bulb or wet-bulb temperature of the air entering the evaporator coil/fan assembly based on the Evaporator Air Temperature Type for Curve Objects specified by the user (°C)

$T_{cond,in}$ is the temperature of the water entering the DX coil condenser (°C).

The heating capacity as a function of air flow fraction modifier curve is a quadratic or cubic curve that defines the variation in DX coil heating capacity as a function of the ratio of actual air flow rate across the evaporator coil to the rated evaporator air flow rate (i.e., fraction of full load air flow rate). When used, the output of this curve should be normalized to have the value of 1.0 at an air flow fraction of 1.

$$HCapFAirFlow = a + b(ff_{air}) + c(ff_{air})^2 \quad (15.458)$$

or

$$HCapFAirFlow = a + b(ff_{air}) + c(ff_{air})^2 + d(ff_{air})^3 \quad (15.459)$$

where:

$$ff_{air} = \text{air flow fraction} = \left(\frac{\text{Actual air mass flow rate}}{\text{Rated air mass flow rate}} \right) \quad (15.460)$$

Note: The actual volumetric air flow rate through the evaporator coil/fan assembly for any simulation time step where the compressor is operating must be between 0.00002684 m³/s and .00008056 m³/s per watt of rated total heating capacity. The simulation will issue a warning message if this air flow range is exceeded, but the simulation will continue.

The heating capacity as a function of water flow fraction modifier curve is a quadratic or cubic curve that defines the variation in DX coil heating capacity as a function of the ratio of actual water flow rate through the condenser to the rated condenser water flow rate (i.e., fraction of full load water flow rate). *It is only used for the pumped condenser configuration.* When used, the output of this curve should be normalized to have the value of 1.0 at a water flow fraction of 1.

$$HCapFWaterFlow = a + b(ff_{water}) + c(ff_{water})^2 \quad (15.461)$$

or

$$HCapFWaterFlow = a + b(ff_{water}) + c(ff_{water})^2 + d(ff_{water})^3 \quad (15.462)$$

where:

$$ff_{water} = \text{water flow fraction} = \left(\frac{\text{Actual water mass flow rate}}{\text{Rated water mass flow rate}} \right) \quad (15.463)$$

The heating COP as a function of temperature modifier curve defines the variation in DX coil heating COP as a function of inlet fluid (air and water) temperatures. The curve object may use either a bi-quadratic or cubic form. The bi-quadratic curve uses inlet air temperature (dry-bulb or wet-bulb temperature based on the input field Evaporator Air Temperature Type for Curve Objects) and condenser inlet water temperature as the independent variables. The cubic curve uses inlet air (dry-bulb or wet-bulb) temperature as the independent variable. The curve should be normalized to have the value of 1.0 at the rating point temperatures specified by the user.

$$HCOPFTemp = a + b(T_{evap,in}) + c(T_{evap,in})^2 + d(T_{cond,in}) + e(T_{cond,in})^2 + f(T_{evap,in})(T_{cond,in}) \quad (15.464)$$

or

$$HCOPFTemp = a + b(T_{evap,in}) + c(T_{evap,in})^2 + d(T_{evap,in})^3 \quad (15.465)$$

The heating COP as a function of air flow fraction modifier curve is a quadratic or cubic curve that defines the variation in DX coil heating COP as a function of the ratio of actual air flow rate across the evaporator coil to the rated evaporator air flow rate (i.e., fraction of full load air flow rate). When used, the output of this curve should be normalized to have the value of 1.0 at an air flow fraction of 1.

$$HCOPFAirFlow = a + b(ff_{air}) + c(ff_{air})^2 \quad (15.466)$$

or

$$HCOPFAirFlow = a + b(ff_{air}) + c(ff_{air})^2 + d(ff_{air})^3 \quad (15.467)$$

The heating COP as a function of water flow fraction modifier curve is a quadratic or cubic curve that defines the variation in DX coil heating COP as a function of the ratio of actual water flow rate through the condenser to the rated condenser water flow rate (i.e., fraction of full load water flow rate). *It is only used for the pumped condenser configuration.* When used, the output of this curve should be normalized to have the value of 1.0 at a water flow fraction of 1.

$$HCOPFWaterFlow = a + b(ff_{water}) + c(ff_{water})^2 \quad (15.468)$$

or

$$HCOPFWaterFlow = a + b(ff_{water}) + c(ff_{water})^2 + d(ff_{water})^3 \quad (15.469)$$

The part load fraction as a function of part load ratio correlation curve parameterizes the variation of electrical power input to the heat pump DX coil as a function of the part load ratio (PLR, heating delivered/steady-state heating capacity). The part load ratio divided by the part load fraction yields the runtime fraction of the DX heating coil for a given simulation time step. The part load fraction correlation accounts for efficiency losses due to compressor cycling.

$$PartLoadFrac = PLF = a + b(PLR) + c(PLR)^2 \quad (15.470)$$

or

$$PartLoadFrac = a + b(PLR) + c(PLR)^2 + d(PLR)^3 \quad (15.471)$$

where:

$$PLR = \text{part load ratio} = \left(\frac{\text{water heating delivered}}{\text{steady-state water heating capacity}} \right) \quad (15.472)$$

The part load fraction correlation should be normalized to a value of 1.0 when the part load ratio equals 1.0 (i.e., no efficiency losses when the compressor runs continuously for the simulation time step). For PLR values between 0 and 1 ($0 < = PLR < 1$), the following rules apply: $PLF > = 0.7$ and $PLF > = PLR$.

If $PLF < 0.7$ a warning message is issued, the program resets the PLF value to 0.7, and the simulation proceeds. The runtime fraction of the coil is defined as PLR/PLF . If $PLF < PLR$, then a warning message is issued and the runtime fraction of the coil is limited to 1.0.

When the part load fraction correlation for a heat pump water heater DX coil is unknown, the typical part load fraction correlation for a conventional, single-speed DX cooling coil (e.g., residential or small commercial unit) may be used:

$$PLF = 0.85 + 0.15(PLR) \quad (15.473)$$

All seven curves are accessed through EnergyPlus' built-in performance curve equation manager (curve:quadratic, curve:cubic and curve:biquadratic). It is not imperative that the user utilize all coefficients shown in the equations above if their performance equation has fewer terms (e.g., if the user's part load fraction correlation curve is linear instead of quadratic, simply enter the values for a and b, and set coefficient c equal to zero).

Note: If any of the above performance curves are not specified by the user, the output of that curve is assumed to be 1 for the entire simulation.

For any simulation time step, the heating capacity of the heat pump water heater DX coil is calculated as follows:

$$\dot{Q}_{heating} = \dot{Q}_{heating,rated} (HCapFTemp) (HCapFAirFlow) (HCapFWaterFlow) \quad (15.474)$$

In a similar fashion, the coefficient of performance for the DX coil for any simulation time step is calculated using the following equation:

$$COP_{heating} = COP_{heating,rated} (HCOPFTemp) (HCOPFAirFlow) (HCOPFWaterFlow) \quad (15.475)$$

The electric power for the heat pump water heater DX coil is then calculated using the water heating capacity and coefficient of performance calculated above.

$$P_{heating} = \left(\frac{\dot{Q}_{heating}}{COP_{heating}} \right) \quad (15.476)$$

where:

$\dot{Q}_{heating}$ is the water heating capacity at the current operating conditions (W)

$\dot{Q}_{heating,rated}$ is the water heating capacity at rated conditions, user input (W)

$COP_{heating}$ is the coefficient of performance at the current operating conditions (W/W)

$COP_{heating,rated}$ is the coefficient of performance at rated conditions, user input (W/W)

$P_{heating}$ is the DX heating coil power (electricity consumption rate) at the current operating conditions (W).

The heating capacity calculated above may or may not include the impact of pump heat. For this reason, the user input Condenser Pump Heat Included in Rated Heating Capacity and Rated COP is used to determine the total water heating capacity including pump heat.

If (Condenser Pump Heat Included In Rated Heating Capacity and Rated COP), then:

$$\dot{Q}_{heating,total} = \dot{Q}_{heating} \quad (15.477)$$

Else:

$$\dot{Q}_{heating,total} = \dot{Q}_{heating} + P_{pump} FracPumpToWater \quad (15.478)$$

where:

$\dot{Q}_{heating,total}$ is the total water heating capacity including condenser pump heat (W)

P_{pump} is the condenser water pump power, user input (W)

$Frac_{pumptowater}$ is the fraction of condenser pump heat to water, user input.

Compressor power (electricity consumption rate) is then calculated based on two additional inputs provided by the user. The first input specifies if the condenser pump heat is included in the rated heating capacity and rated COP. If the condenser pump heat is included in the rated heating capacity and COP, then condenser pump power must be subtracted from the DX heating coil power calculated above to determine the compressor power.

The second of these inputs specifies if the evaporator fan power is included in the rated heating COP. If evaporator fan power is included in the rated COP, then fan power must also be subtracted from the DX heating coil power to determine the compressor power as follows:

If (Cond Pump Power in COP), then:

$$P_{comp} = P_{heating} - P_{pump} - P_{fan} \quad (15.479)$$

Else:

$$P_{comp} = P_{heating} - P_{fan} \quad (15.480)$$

where:

P_{comp} is the compressor power (electric consumption rate) at the current operating conditions (W)

P_{fan} is the fan power, specified in Fan:OnOff object (W).

If fan power is NOT included in the rated heating COP, then the calculation of compressor power only includes condenser pump power and does not involve the fan:

If (Cond Pump Power in COP), then:

$$P_{comp} = P_{heating} - P_{pump} \quad (15.481)$$

Else:

$$P_{comp} = P_{heating} \quad (15.482)$$

The model assumes that all compressor power is rejected as heat via the DX heating coil. Therefore, the evaporator total cooling capacity at the current operating conditions is determined depending on the user input for pump heat:

If (Condenser Pump Heat Included In Rated Heating Capacity and Rated COP), then:

$$\dot{Q}_{Evap} = \dot{Q}_{heating} - P_{comp} - P_{pump} Frac_{pumptowater} \quad (15.483)$$

Else:

$$\dot{Q}_{Evap} = \dot{Q}_{heating} - P_{comp} \quad (15.484)$$

where \dot{Q}_{Evap} is the total evaporator cooling capacity at the current operating conditions (W).

This evaporator cooling capacity is used to calculate the air-side performance of the heat pump water heater DX coil. The sensible heat ratio of the cooling capacity at rated conditions is specified by the user in the input for this DX coil object. The calculation of sensible heat ratio at off-rated

conditions uses the ADP/BF approach described for the DX cooling coil model (Ref. Coil Model – DX Cooling Coil Model). The exiting air conditions for the HPWH DX coil are calculated the same way as they are for the DX cooling coil model (cycling fan, cycling coil). The crankcase heater power and consumption are also calculated using the same equations used for the DX cooling coil model.

The runtime fraction of the DX coil compressor is calculated as the ratio of the compressor part load ratio to the part load fraction correlation entered by the user. The part load ratio of the DX coil is determined by the heat pump water heater compound object (Ref. WaterHeater:HeatPump:*) and is used by the DX coil to determine the run time fraction of the compressor.

$$RTF = \left(\frac{PartLoadFrac}{PartLoadFrac} \right) = \text{runtime fraction of the compressor} \quad (15.485)$$

Finally, the condenser water outlet temperature is calculated based on the total water heating capacity of the DX coil and the actual condenser water mass flow rate.

$$T_{cond,out} = T_{cond,in} + \left(\frac{\dot{Q}_{heating,total}}{\dot{m}_{cond}C_p} \right) \quad (15.486)$$

where:

$T_{cond,out}$ is the condenser outlet water temperature when the DX coil is operating (°C)

$T_{cond,in}$ is the condenser inlet water temperature (°C)

C_p is the specific heat of water entering the condenser coil (J/kg-°C)

\dot{m}_{cond} is the actual condenser water mass flow rate when the coil is operating, defined in the WaterHeater:HeatPump:PumpedCondenser parent object (kg/s).

15.2.19.3 Model Outputs

After completing the calculations for heating capacity and power and the final compressor part load ratio has been determined, the output (report) variables are calculated as follows:

$$DX \text{ Coil Total Water Heating Rate } (W) = \dot{Q}_{heating,total} (PLR) \quad (15.487)$$

$$DX \text{ Coil Total Water Heating Energy } (J) = \dot{Q}_{heating,total} (PLR) (3600) (t_{sys}) \quad (15.488)$$

$$DX \text{ Coil Water Heating Electric Power } (W) = (P_{comp} + P_{pump}) (RTF) \quad (15.489)$$

$$DX \text{ Coil Water Heating Electric Consumption } (J) = (P_{comp} + P_{pump}) (RTF) (3600) (t_{sys}) \quad (15.490)$$

$$DX \text{ Coil Total Cooling Rate } (W) = \dot{Q}_{evap} (PLR) \quad (15.491)$$

$$DX \text{ Coil Total Cooling Energy } (J) = \dot{Q}_{evap} (PLR) (3600) (t_{sys}) \quad (15.492)$$

$$DX \text{ Coil Sensible Cooling Rate } (W) = \dot{Q}_{evap} (PLR) (SHR) \quad (15.493)$$

$$DX \text{ Coil Sensible Cooling Energy } (J) = \dot{Q}_{evap} (PLR) (SHR) (3600) (t_{sys}) \quad (15.494)$$

$$DX \text{ Coil Latent Cooling Rate } (W) = \dot{Q}_{evap} (PLR) (1.0 - SHR) \quad (15.495)$$

$$DX \text{ Coil Latent Cooling Energy } (J) = \dot{Q}_{evap} (PLR) (1.0 - SHR) (3600) (t_{sys}) \quad (15.496)$$

$$DX \text{ Coil Runtime Fraction} = \left(\frac{PLR}{PartLoadFrac} \right) \quad (15.497)$$

$$DX \text{ Coil Crankcase Heater Power } (W) = (P_{crankcase}) (1.0 - RTF) \quad (15.498)$$

$$DX \text{ Coil Crankcase Heater Consumption } (J) = (P_{crankcase}) (1.0 - RTF) (3600) (t_{sys}) \quad (15.499)$$

where:

t_{sys} is the HVAC system simulation time step (hr)

SHR is the sensible heat ratio at the current inlet air conditions and air flow rate (Ref. Coil Model – DX Cooling Coil Model, ADP/BF approach)

$P_{crankcase}$ is the crankcase heater capacity, user input (W).

15.2.20 Water Source Electric DX Air Cooling Coil

There are two objects for water-to-air heat pumps in cooling mode:

Coil:Cooling:WaterToAirHeatPump:EquationFit and

Coil:Cooling:WaterToAirHeatPump:ParameterEstimation. These are described elsewhere.

15.2.21 Water Source Electric Heat Pump DX Air Heating Coil

There are two objects for water-to-air heat pumps in heating mode:

Coil:Heating:WaterToAirHeatPump:EquationFit and

Coil:Heating:WaterToAirHeatPump:ParameterEstimation. These are described elsewhere.

15.2.22 Steam-Based Air Heating Coil

The steam coils are included in the discussion on steam loops, see: Steam To Air Heat Exchanger.

15.2.23 Variable Refrigerant Flow Cooling Coil

15.2.23.1 Overview

The variable refrigerant flow (VRF) DX cooling coil model is identical to the single-speed DX cooling coil model (Ref. Coil:Cooling:DX:SingleSpeed) when the compressor operates at its maximum speed. The calculations used when the VRF heat pump operates at part-load are slightly different than the single-speed DX cooling coil model. For this reason, an adaptation of the single-speed DX cooling coil model is used to model the variable-speed compression system used in the VRF model. The difference in model calculations occur when the VRF DX cooling coil's electronic expansion device reduces refrigerant flow through the cooling coil. When the refrigerant flow is reduced, the coil's apparatus dew point (ADP) temperature changes, as well as the coil's sensible heat ratio (SHR). Since the single-speed DX cooling coil model is able to determine the ADP and SHR of a cooling coil at various operating conditions, this same model concept will be used to determine the ADP and SHR of the variable refrigerant flow DX cooling coil.

15.2.23.2 Model Description

The user must input the total cooling capacity and the volumetric air flow rate across the cooling coil at rated conditions. The capacity input should be “gross” values, excluding any thermal or energy impacts due to the indoor supply air fan. The rated volumetric air flow should be between 0.00004027 m³/s and 0.00006041 m³/s per watt of rated total cooling capacity (300 – 450 cfm/ton).

The user is required to input a performance curve in the heat pump object (ref: AirConditioner:VariableRefrigerantFlow) that describes the change in total cooling capacity at various operating conditions (i.e. at cooling coil inlet air wet-bulb and condenser entering air dry-bulb temperatures different than those used to define total capacity). Each DX cooling coil uses two Cooling Capacity Ratio Modifier curves to define the DX cooling coil performance. The first curve defines the full load performance solely as a function of indoor wet-bulb temperature or uses both indoor wet-bulb temperature and outdoor dry-bulb temperature as the independent variables. The specific performance curves are:

- Total cooling capacity modifier curve (function of temperature)
- Total cooling capacity modifier curve (function of flow fraction)

The *total cooling capacity modifier curve (function of temperature)* defines the performance of the DX cooling coil as a function of operating conditions. These operating conditions may be specified as either a linear, quadratic or cubic equation using coil entering air wet-bulb temperature as the independent variable or as a biquadratic equation using both coil entering air wet-bulb temperature and outdoor dry-bulb temperature as the independent variables. Since the variable refrigerant flow system modulates the compressor speed to serve the individual cooling coils, the single independent variable equation is likely to be sufficient to define the DX cooling coil performance. However, if other more accurate information is available, a biquadratic curve using two independent variables may be used. The output of this curve is multiplied by the rated total cooling capacity to give the total cooling capacity at the specific entering air temperatures at which the DX coil unit is operating (i.e., at temperatures different from the rating point temperatures).

$$TotCapTempModFac = a + b(T_{wb,i}) + c(T_{wb,i})^2 + d(T_{wb,i})^3 \quad (15.500)$$

or

$$TotCapTempModFac = a + b(T_{wb,i}) + c(T_{wb,i})^2 + d(T_{c,i}) + e(T_{c,i})^2 + f(T_{wb,i})(T_{c,i}) \quad (15.501)$$

where:

$T_{wb,i}$ is the wet-bulb temperature of the air entering the cooling coil (°C)

$T_{c,i}$ is the dry-bulb temperature of the air entering an air-cooled condenser or wet-bulb temperature of the air entering an evaporative-cooled condenser (°C).

The total cooling capacity modifier curve (function of flow fraction) is a linear, quadratic, or cubic curve with the independent variable being the ratio of the actual air flow rate across the cooling coil to the rated air flow rate (i.e., fraction of full load flow). The output of this curve is multiplied by the operating (modulated) total cooling capacity and the total cooling capacity modifier curve (function of temperature) to give the total cooling capacity at the specific temperature and air flow conditions at which the DX unit is operating. The cubic form of the equation is:

$$TotCapFlowModFac = a + b(ff) + c(ff)^2 + d(ff)^3 \quad (15.502)$$

where:

$$ff = flow\ fraction = \left(\frac{Actual\ air\ mass\ flow\ rate}{Rated\ air\ mass\ flow\ rate} \right) \quad (15.503)$$

Note: The actual volumetric air flow rate through the cooling coil for any simulation time step where the DX unit is operating must be between 0.00002684 m³/s and .00006713 m³/s per watt of rated total cooling capacity (200 - 500 cfm/ton). The simulation will issue a warning message if this air flow range is exceeded.

For any simulation time step, the total (gross) cooling capacity of the DX unit is calculated as follows:

$$\dot{Q}_{total} = \dot{Q}_{reference} (TotCapTempModFac) (TotCapFlowModFac) \quad (15.504)$$

where:

\dot{Q}_{total} = Total available cooling capacity (W)

$\dot{Q}_{reference}$ = Total reference (rated) cooling capacity (W).

In addition to calculating the total cooling capacity provided by the DX cooling coil, it is important to properly determine the break down of total cooling capacity into its sensible (temperature) and latent (dehumidification) components. The model computes the sensible/ latent split using the SHR and ADP/BF approach (Carrier et al. 1959). When the DX coil model is initially called during an EnergyPlus simulation, the rated total capacity and rated SHR are used to calculate the coil bypass factor (BF) at rated conditions. The rated total capacity and rated SHR are first used to determine the ratio of change in air humidity ratio to air dry-bulb temperature:

$$SlopeRated = \left(\frac{\omega_{in} - \omega_{out}}{T_{db,in} - T_{db,out}} \right)_{rated} \quad (15.505)$$

where:

ω_{in} is the humidity ratio of the air entering the cooling coil at rated conditions (kg/kg)

ω_{out} is the humidity ratio of the air leaving the cooling coil at rated conditions (kg/kg)

$T_{db,in}$ is the dry-bulb temperature of the air entering the cooling coil at rated conditions ($^{\circ}\text{C}$)

$T_{db,out}$ is the dry-bulb temperature of the air leaving the cooling coil at rated conditions ($^{\circ}\text{C}$).

Along with the rated entering air conditions, the algorithm then searches along the saturation curve of the psychrometric chart until the slope of the line between the point on the saturation curve and the inlet air conditions matches *SlopeRated*. Once this point, the apparatus dew point, is found on the saturation curve the coil bypass factor at rated conditions is calculated as follows:

$$BF_{rated} = \frac{h_{out,rated} - h_{ADP}}{h_{in,rated} - h_{ADP}} \quad (15.506)$$

where:

$h_{out,rated}$ is the enthalpy of the air leaving the cooling coil at rated conditions (J/kg)

$h_{in,rated}$ is the enthalpy of the air entering the cooling coil at rated conditions (J/kg)

h_{ADP} is the enthalpy of saturated air at the coil apparatus dew point (J/kg).

The coil bypass factor is analogous to the “ineffectiveness” ($1-\epsilon$) of a heat exchanger, and can be described in terms of the number of transfer of unit (NTU).

$$BF = e^{-NTU} = e^{-\left(\frac{UA}{\dot{m}c_p}\right)} = e^{-A_o/\dot{m}} \quad (15.507)$$

For a given coil geometry, the bypass factor is only a function of air mass flow rate. The model calculates the parameter A_o in the equation above based on BF_{rated} and the rated air mass flow rate. With A_o known, the coil BF can be determined for non-rated air flow rates.

For each simulation time step when the DX cooling coil operates, the total cooling capacity and coil bypass factor at the actual operating conditions are calculated. The coil bypass factor is used to calculate the operating sensible heat ratio (SHR) of the cooling coil using the following equations. Here is where the difference in models occur for the VRF DX cooling coil and single-speed DX cooling coil. The original coil model (ref: Coil:Cooling:DX:SingleSpeed) calculates the full load outlet air enthalpy and, considering the bypass factor, finds the coil surface temperature (h_{ADP}) at full load (i.e., $PLR = 1$). Conversely, the VRF coil model modulates refrigerant flow to the VRF DX cooling coil which is why this model uses the full load coil capacity multiplied by the part-load ratio (the modulated refrigerant flow). The effectively finds the coil surface temperature for a variable refrigerant flow DX cooling coil and the operating sensible heat ratio (SHR) can be calculated.

$$h_{ADP} = h_{in} - \frac{(\dot{Q}_{total}/\dot{m})}{1 - BF} \quad \text{for a single - speed DX coil model (} h_{ADP1} \text{ in figure below)} \quad (15.508)$$

$$h_{ADP} = h_{in} - \frac{(\dot{Q}_{total} \times PLR)/\dot{m}}{1 - BF} \quad \text{for a variable refrigerant flow DX coil model} \quad (15.509)$$

$$SHR = Minimum \left(\left(\frac{h_{T_{in,w,ADP}} - h_{ADP}}{h_{in} - h_{ADP}} \right), 1 \right) \quad (15.510)$$

where:

h_{in} is the enthalpy of the air entering the cooling coil (J/kg)

h_{ADP} is the enthalpy of air at the apparatus dew point condition (J/kg)

$h_{T_{in},w,ADP}$ is the enthalpy of air at the entering coil dry-bulb temperature and humidity ratio at ADP (J/kg)

\dot{m} is the air mass flow rate (kg/s).

With the SHR for the coil at the current operating conditions, the properties of the air leaving the cooling coil are calculated using the following equations:

$$h_{out} = h_{in} - \left(\left(\dot{Q}_{total} \times PLR \right) / \dot{m} \right) \quad (15.511)$$

$$h_{T_{in},\omega_{out}} = h_{in} - (1 - SHR) (h_{in} - h_{out}) \quad (15.512)$$

$$\omega_{out} = PsyWFnTdbH (T_{in}, h_{T_{in},\omega_{out}}) \quad (15.513)$$

$$T_{db,out} = PsyTdbFnHW (h_{out}, \omega_{out}) \quad (15.514)$$

where:

h_{out} is the enthalpy of the air leaving the cooling coil (J/kg)

$h_{T_{in},\omega_{out}}$ is the enthalpy of air at the entering coil dry-bulb temperature and leaving air humidity ratio (J/kg)

ω_{out} is the leaving air humidity ratio (kg/kg)

$T_{db,out}$ is the leaving air dry-bulb temperature (°C)

$PsyWFnTdbH$ is an EnergyPlus psychrometric function that returns humidity ratio given dry-bulb temperature and enthalpy

$PsyTdbFnHW$ is an EnergyPlus psychrometric function that returns dry-bulb temperature given enthalpy and humidity ratio.

The following figure shows this process on a psychrometric chart. This variable refrigerant flow DX cooling coil model follows the dotted process line from h_{in} towards the outlet air enthalpy (the clear circles, o) based on the modulated refrigerant flow (PLR). The coil surface temperature (ADP, apparatus dew point) is found by drawing a straight line through these points. The process line from h_{in} to h_{ADP1} represents the full load (PLR = 1). This would be what the original DX cooling coil model calculates. At this point the sensible heat ratio is at the design point (assuming h_{in} is the rating point and the coil operates at the rated air mass flow rate). As the coil load is reduced, the refrigerant flow rate is restricted and the outlet air condition rides up the dotted line. The outlet air condition and associated h_{ADP2} is shown for a PLR of 0.7 (for example purposes only). Here the sensible heat ratio is higher than that found at full load operation. As the load continues to reduce, the refrigerant flow rate continues to throttle back and there comes a point where the coil's ADP is equal to the inlet air dew point temperature (h_{ADP3}). At this point, and for all other PLR's less than this value, the coil surface becomes dry (at PLR = 0.4 in this example) and the coil's sensible heat ratio = 1. Between this PLR and PLR = 0, the coil outlet air condition follows the dotted line back towards h_{in} .

Figure 180. Process on psychrometric chart

15.2.23.3 Dry Coil Conditions

If the model determines that the cooling coil is dry ($\omega_{in} < \omega_{ADP}$), then the equation for total cooling capacity is invalid since it is a function of entering wet-bulb temperature. Under dry-coil conditions, coil performance is a function of dry-bulb temperature rather than wet-bulb temperature. In this case, the model recalculates the performance of the DX cooling unit using the calculation procedure described above but with $\omega_{in} = \omega_{dry}$, where ω_{dry} is the inlet air humidity ratio at the coil dry-out point (SHR = 1.0).

15.2.23.4 Condenser Options: Air Cooled vs. Evaporative Cooled

As described previously, this model can simulate the performance of air-cooled or evaporative-cooled DX air conditioners. The choice of condenser type impacts the air dry-bulb temperature entering the heat pump's condenser. Although the actual input for the selection is contained in the variable refrigerant flow air conditioner object, the calculations are repeated here to aid the user in understanding the condenser option choices. The following paragraphs describe three modeling options.

If the user wants to model an air-cooled condenser, they should simply specify AirCooled in the field Condenser Type. In this case, the Total Cooling Capacity Modifier Curve (function of temperature) and the Energy Input Ratio Modifier Curve (function of temperature) will utilize the outdoor dry-bulb temperature.

If the user wishes to model an evaporative-cooled condenser AND they have performance curves that are a function of the wet-bulb temperature of air entering the condenser coil, then the user should specify Condenser Type = EvapCooled and the evaporative condenser effectiveness value should be entered as 1.0. In this case, the Total Cooling Capacity Modifier Curve (function of temperature) will utilize the outdoor wet-bulb temperature.

If the user wishes to model an air-cooled condenser that has evaporative media placed in front of it to cool the air entering the condenser coil, then the user should specify Condenser Type = EvapCooled. The user must also enter the appropriate evaporative effectiveness for the media. In this case, the Total Cooling Capacity Modifier Curve (function of temperature) and the Energy Input Ratio Modifier Curve (function of temperature) will utilize the condenser inlet air temperature as calculated below:

$$T_{c,i} = (T_{wb,o}) + (1 - EvapCondEffectiveness) (T_{db,o} - T_{wb,o}) \quad (15.515)$$

where:

$T_{c,i}$ is the temperature of the air entering the condenser coil (°C)

$T_{wb,o}$ is the wet-bulb temperature of the outdoor air (°C)

$T_{db,o}$ is the dry-bulb temperature of the outdoor air (°C).

The Total Cooling Capacity Modifier Curve (function of temperature) and the Energy Input Ratio Modifier Curve (function of temperature) input fields for the variable refrigerant flow air conditioner object should reference performance curves that are a function of outdoor dry-bulb temperature. Be aware that the evaporative media will significantly reduce the dry-bulb temperature of the air entering the condenser coil, so the Total Cooling Capacity and EIR Modifier Curves must be valid for the expected range of dry-bulb temperatures that will be entering the condenser coil.

15.2.23.5 Condenser Inlet Air Temperature

The air temperature entering the outdoor condenser is based on the weather data used during a simulation. This temperature is either taken directly from the weather data, or can be adjusted based on the height of the outdoor condenser. The input for Condenser Air Inlet Node Name can be used to control this optional feature. If this input is left blank, the air temperature entering the condenser is based solely on the weather data. If this input is not blank, then the node name specified must also be listed in an Outside Air Node or Outside Air Inlet Node List object. When the node name is listed in an Outside Air Inlet Node List object, the air temperature entering the condenser is based solely on the weather data. When the node name is listed in an Outside Air Node object, the height of the node determines the air temperature entering the outdoor condenser (see description of Local Outdoor Air Temperature Calculation in the Atmospheric Variation section of this document for further details).

15.2.23.6 Supply Air Fan Control: Cycling vs. Continuous

One of the inputs to the variable refrigerant flow terminal unit model is the supply air fan operation mode: cycling fan, cycling compressor or continuous fan, cycling compressor. The mode specified in the terminal unit object is passed to the DX cooling coil for use in the model calculations. The first operation mode is frequently referred to as “AUTO fan”, where the compressor(s) and supply air fan operate in unison to meet the zone cooling load, and cycle off together when the cooling load has been met. The second operation mode is often referred to as “fan ON”, where the compressor(s) cycle on and off to meet the zone cooling load but the supply air fan operates continuously regardless of compressor operation.

The fan operation mode schedule value determines the fan operation mode for each time step throughout the simulation. A fan operation mode schedule value of 0 specifies AUTO fan mode

operation while values other than 0 specify fan ON operation. The use of a schedule allows the fan operation mode to change based on time-of-day or with changes in season.

The EnergyPlus methodology for determining the impact that HVAC equipment has on an air stream is to calculate the mass flow rate and air properties (e.g., enthalpy, dry-bulb temperature, humidity ratio) exiting the equipment. These exiting conditions are passed along as inlet conditions to the next component model in the air stream. Eventually the flow rate and properties of the air being supplied to the conditioned zone are used in the zone energy balance to determine the resulting zone air temperature and humidity ratio.

With this methodology, the determination of the air mass flow rate and air properties for the two different supply air fan operation modes is slightly different. For the case of cycling fan/cycling compressor, the conditions of the air leaving the cooling coil are the steady-state values calculated using the equations described above. However the air mass flow rate passed along to the next component (and eventually to the conditioned zone) is the average air mass flow rate for the system simulation time step.

For the case of continuous fan/cycling compressor, the air mass flow rate is constant. However, the air properties leaving the cooling coil are calculated as the average conditions during the system simulation time step. The model assumes that the exiting air conditions are the steady-state values calculated using the equations described above when the heat pump operates. For the remainder of the system simulation time step, it is assumed that the air exiting the DX coil has the same properties as the air entering the coil. For this supply air fan operating strategy, the leaving air properties are calculated as follows:

$$h_{out,ContFanCycComp} = h_{out}(CyclingRatio) + h_{in}(1 - CyclingRatio) \quad (15.516)$$

$$\omega_{out,ContFanCycComp} = \omega_{out}(CyclingRatio) + \omega_{in}(1 - CyclingRatio) \quad (15.517)$$

$$T_{db,out,ContFanCycComp} = PsyTdbFnHW(h_{out,ContFanCycComp}, \omega_{out,ContFanCycComp}) \quad (15.518)$$

15.2.23.7 Average Air Flow Calculations

The variable refrigerant flow (VRF) terminal unit operates based on user-specified (or autosized) air flow rates. The VRF terminal unit's supply air flow rate during cooling operation may be different than the supply air flow rate during heating operation. In addition, the supply air flow rate when no cooling or heating is required but the supply air fan remains ON can be different than the air flow rates when cooling or heating is required. The outside air flow rates can likewise be different for cooling and heating operating modes. The model takes these different flow rates into account when modeling the heat pump, and the average air flow rate for each simulation time step is reported on the inlet/outlet air nodes of the various terminal unit components in proportion to the calculated cycling ratio of the coil.

The average supply air and outdoor air mass flow rates through the heat pump for the HVAC simulation time step are calculated based on the cycling ratio of the DX cooling coil or heating coil (whichever coil is operating) as follows:

$$\dot{m}_{SA,avg} = \dot{m}_{SA,coil\ on}(CyclingRatio) + \dot{m}_{SA,coil\ off}(1 - CyclingRatio) \quad (15.519)$$

$$\dot{m}_{OA,avg} = \dot{m}_{OA,coil\ on}(CyclingRatio) + \dot{m}_{OA,coil\ off}(1 - CyclingRatio) \quad (15.520)$$

where:

$\dot{m}_{SA,avg}$ is the average supply air mass flow rate during the time step (kg/s)

$\dot{m}_{SA,coil\ on}$ is the supply air mass flow rate when the coil is ON (kg/s)

CyclingRatio is the cycling ratio of the coil (heating or cooling)

$\dot{m}_{SA,coil\ off}$ is the supply air mass flow rate when the coil is OFF (kg/s)

$\dot{m}_{OA,avg}$ is the average outside air mass flow rate during the time step (kg/s)

$\dot{m}_{OA,coil\ on}$ is the average outside air mass flow rate when the coil is ON (kg/s)

$\dot{m}_{OA,coil\ off}$ is the average outside air mass flow rate when the coil is OFF (kg/s).

The supply air and outside air flow rates when the DX cooling or DX heating coil is ON are specified by the user (e.g., supply air volumetric flow rate during cooling operation, supply air volumetric flow rate during heating operation, outside air volumetric air flow rate during cooling operation, and outside air volumetric air flow rate during heating operation) and are converted from volumetric to mass flow rate. If the user has specified cycling fan operation, then the supply air and outside air mass flow rates when the coil is OFF are zero. If the user has specified constant fan operation, then the user-defined air flow rates when no cooling or heating is needed are used when the coil is OFF.

There is one special case. If the user has specified constant fan operation and they specify that the supply air volumetric flow rate when no cooling or heating is needed is zero (or field is left blank), then the model assumes that the supply air and outside air mass flow rates when the coil is OFF are equal to the corresponding air mass flow rates when the coil was last operating (ON).

15.2.24 Variable Refrigerant Flow Heating Coil

The variable refrigerant flow (VRF) DX heating coil model uses performance information at rated conditions along with performance curves for variations in total capacity, energy input ratio and part load fraction to determine performance at part-load conditions. The impacts of defrost operation is modeled based a combination of user inputs and empirical models taken from the air-to-air heat pump algorithms in DOE-2.1E. The VRF DX heating coil model is very similar to the DX heating coil model used in the single-speed heat pump. The only difference being that the energy performance curves were moved to the parent object (Ref. AirConditioner:VariableRefrigerantFlow). See the DX Heating Coil model description for further details.

15.2.25 Variable Speed Water to Air Heat Pump (Heating & Cooling)

15.2.25.1 Overview

A Variable Speed Water Source Heat Pump (let's call it VS WSHP) has a system control which dictates the refrigerant flow rate, the design unit supply airflow and the required water flow rate at each compressor speed. The air and water flow rates are usually a function of the compressor speed. Refrigerant mass flow rate is a function of compressor speed as well as entering water temperature and indoor dry bulb or wet bulb. The control system adjusts the equipment capacity based on zone temperature measurements relative to the thermostat set point. The control logic determines what compressor speed is required to control to the zone temperature requirement in response to increased or decreased capacity (heating or cooling load). The compressor, fan and pump speeds

are not discrete values and can be considered to vary infinitesimally between the minimum and maximum compressor speed. At the minimum compressor speed (which is different for heating and cooling), for a continuous fan, the supply airflow is fixed and the unit will have to cycle for reduced part loads below this point. For a cycling fan, the fan will cycle with the compressor.

Presently, EnergyPlus is capable of modeling multiple-speed DX air-to-air coils. The number of speed levels is up to four. In some cases, four sets of performance curves are not sufficient to include all the information for a variable speed equipment. There is a need to expand the space for containing more performance curves. Here, we expand the number of speed levels and the corresponding curve sets up to ten. The number of speed levels is selectable by the user. The user can provide speed levels at any number from 2 to 10. In any case, our model would just do linear interpolation between neighboring speeds. The more curves, the more accurate. Furthermore, using linear interpolation and inputting air and water flow rates at individual speed levels facilitates arbitrary relationships of flow rates as a function of the compressor speed level.

This model (object name *Coil:Heating:WaterToAirHeatPump:VariableSpeedEquationFit*) simulates the performance of a variable-speed water-to-air heat pump with heating capability. It fits in the parent objects of *AirLoopHVAC:UnitaryHeatPump:WaterToAir* and *ZoneHVAC:WaterToAirHeatPump*. The rated conditions for obtaining the Reference Unit total heating capacities and COPs are indoor dry-bulb temperature at 21.1°C (70°F) and the source side entering water temperature at 21.1°C (70°F).

15.2.25.2 Model Description

The *Coil:Heating:WaterToAirHeatPump:VariableSpeedEquationFit* object is modeled in a manner similar to the multi-speed DX heating coil model (Ref. *Coil:Heating:DX:MultiSpeed*). Of course, rather than referencing an air source evaporator or defrost object, the new coil object references to the water loop, and has the entering water temperature in place of the indoor air entering dry bulb temperature.

It shall be noted for the capacity and flow rate inputs, three fields are autosizable, which are Rated Heating Capacity at the Selected Nominal Speed Level (Numeric Field 3), Rated Volumetric Air Flow Rate (Numeric Field 4) and Rated Volumetric Water Flow Rate (Numeric Field 5). They are used to scale the performances of a specific unit and correlate with the actual loop flows. Except these three fields, all other capacity and flow rate inputs at individual speed levels should be directly obtained from Reference Unit catalog data, specific to an actual unit.

The Rated Heating Capacity at Selected Nominal Speed Level contains the rated capacity to match the building heating load at the design day. The rated heating capacity is used to determine a capacity scaling factor, as compared to the Reference Unit capacity at the nominal speed level.

$$\text{CapacityScaleFactor} = \frac{\text{RatedTotalHeatingCapacity}}{\text{ReferenceUnitTotalHeatingCapacity@NominalSpeedLevel}} \quad (15.521)$$

Then, this scaling factor is used to determine capacities at rated conditions for other speed levels, as $\text{RatedTotalHeatingCapacity@SpeedLevel}(x) = \text{CapacityScaleFactor} * \text{ReferenceUnitTotalHeatingCapacity@SpeedLevel}(x)$

The Rated Volumetric Air Flow Rate is used to determine an internal scaling factor, and calculate the air flow rates in the parent objects, as follows:

$$\text{AirFlowScaleFactor} = \frac{\text{RatedVolumetricAirFlowRate}}{\text{ReferenceUnitVolAirFlowRate@NominalSpeedLevel} \times \text{CapacityScaleFactor}} \quad (15.522)$$

The loop volumetric air flow rates at various speed levels in the parent objects are calculated as $\text{LoopVolumetricAirFlowRate@SpeedLevel}(x) = \text{AirFlowScaleFactor} * \text{ReferenceUnitVolAirFlowRate@SpeedLevel}(x) * \text{CapacityScaleFactor}$

If the volumetric air flow rate at one speed level is higher than the flow rate allowed by the fan in the parent object, the flow rate will be set back to the fan flow rate.

This Rated Volumetric Water Flow Rate is used to determine an internal scaling factor, and calculate the loop water flow rates.

$$\text{WaterFlowScaleFactor} = \frac{\text{RatedVolumetricWaterFlowRate}}{\text{ReferenceUnitVolWaterFlowRate@NominalSpeedLevel} \times \text{CapacityScaleFactor}} \quad (15.523)$$

The required volumetric water flow rates in the parent objects are calculated as $\text{LoopVolumetricWaterFlowRate@SpeedLevel}(x) = \text{WaterFlowScaleFactor} * \text{ReferenceUnitWaterVolFlowRate@SpeedLevel}(x) * \text{CapacityScaleFactor}$

The required volumetric water flow rate as above should be restricted by the pump in the water loop.

If *AirFlowScaleFactor* and *WaterFlowScaleFactor* equal unity, the loop flow rates become the design flow rates of the Reference Unit (after scaled by the rated heating capacity). The Rated Volumetric Air Flow Rate and Rated Volumetric Water Flow Rate are introduced here to correlate with the actual flow rates in the air and water loops, in case that these differ from the design specification. Certainly, it is recommended that the Rated Volumetric Air Flow Rate and Rated Volumetric Water Flow Rate are selected in the way that *AirFlowScaleFactor* and *WaterFlowScaleFactor* are unity, so as to get more accurate results from the performance curves.

Performance curves:

This object includes 7 curve objects at each individual speed level.

- 1) Total heating capacity modifier curve (function of temperature).
- 2) Total heating capacity modifier curve (function of air flow fraction).
- 3) Total heating capacity modifier curve (function of water flow fraction).
- 4) Energy input ratio (EIR) modifier curve (function of temperature).
- 5) Energy input ratio (EIR) modifier curve (function of air flow fraction).
- 6) Energy input ratio (EIR) modifier curve (function of water flow fraction).
- 7) Recoverable heat modifier as a function of indoor air dry-bulb and water entering temperatures.

Curves for (3) and (6) above are new curves as compared to those used for Multi-Speed Electric DX Air Heating Coil, as to correlate the change in water flow rate at the speed. The flow fraction modifier curves are used as a placeholder, to account for off-design flow rates if needed. If the manufacturer doesn't provide off-design performances, we can simply use a default modification multiplier of 1.0.

At the lowest speed, there will be one additional performance curve to account for the part-load condition, i.e.

8) Part load fraction correlation (function of part load ratio)

More details on the various curves listed above are provided in the following paragraphs.

1) Total heating capacity modifier curve (function of temperature)

The total heating capacity modifier as a function of temperature curve (CAP-FT) is a bi-quadratic curve with two independent variables: dry-bulb temperature of the air entering the heating coil and the VS WSHP's entering water temperature. The output of this curve is multiplied by the rated total heating capacity at the speed, to give the total heating capacity at the specific entering air and water temperatures at which the WSHP unit is operating (i.e., at temperatures different from the rating point temperatures).

$$TotCapTempModFac = a + b * DB_i + c * DB_i^2 + d * EWT + e * EWT^2 + f * DB_i * EWT \quad (15.524)$$

where:

DB_i is the dry-bulb temperature of the air entering the heating coil (°C)

EWT is the entering water temperature (°C)

a-f are regression curve-fit coefficients.

2) Total heating capacity modifier curve (function of air flow fraction)

$$TotCapAirFlowModFac = a + b * ff_a + c * ff_a^2 + d * ff_a^3 \quad (15.525)$$

where:

ff_a is the actual air mass flow rate/design air mass flow rate, at one speed level

$DesignAirMassFlowRate@SpeedLevel(x) = ReferenceUnitAirMassFlowRate@SpeedLevel(x) * CapacityScaleFactor$

a-d are regression curve-fit coefficients. If there is no data available for the correction, the user can simply set a = 1.0 and the other coefficients to 0.0.

3) Total heating capacity modifier curve (function of water flow fraction)

$$TotCapWaterFlowModFac = a + b * ff_w + c * ff_w^2 + d * ff_w^3 \quad (15.526)$$

where:

ff_w is the actual water mass flow rate/design water mass flow rate, at one speed level

$DesignWaterMassFlowRate@SpeedLevel(x) = ReferenceUnitWaterMassFlowRate@SpeedLevel(x) * CapacityScaleFactor$

a-d are regression curve-fit coefficients. If there is no data available for the correction, the user can simply set a = 1.0 and the other coefficients to 0.0.

4) Energy input ratio (EIR) modifier curve (function of temperature)

The energy input ratio modifier curve as a function of temperature (EIR-FT) is a biquadratic curve with two independent variables: dry-bulb temperature of the air entering the heating coil and the WSHP's entering water temperature. The output of this curve is multiplied by the rated EIR at the speed (inverse of the rated COP), to give the EIR at the specific entering air and water temperatures at which the WSHP coil unit is operating (i.e., at temperatures different from the rating point temperatures).

$$EIRTempModFac = a + b * DB_i + c * DB_i^2 + d * EWT + e * EWT^2 + f * DB_i * EWT \quad (15.527)$$

where:

DB_i is the dry-bulb temperature of the air entering the heating coil ($^{\circ}\text{C}$)

EWT is the entering water temperature ($^{\circ}\text{C}$)

a-f are regression curve fit coefficients.

5) Energy input ratio (EIR) modifier curve (function of air flow fraction)

$$EIRAirFlowModFac = a + b * ff_a + c * ff_a^2 + d * ff_a^3 \quad (15.528)$$

where a-d are regression curve-fit coefficients. If there is no data available for the correction, the user can simply set a = 1.0 and the other coefficients to 0.0.

6) Energy input ratio (EIR) modifier curve (function of water flow fraction)

$$EIRWaterFlowModFac = a + b * ff_w + c * ff_w^2 + d * ff_w^3 \quad (15.529)$$

where a-d are regression curve-fit coefficients. If there is no data available for the correction, the user can simply set a = 1.0 and the other coefficients to 0.0.

7) Recoverable heat modifier as a function of indoor dry-bulb and water entering temperatures.

Recoverable heat modifier function accounts for the recoverable waste heat at the condensing side, as a fraction to the input power. This part of heat doesn't added to the supply side.

$$WasteHeatTempModFac = a + b * DB_i + c * DB_i^2 + d * EWT + e * EWT^2 + f * DB_i * EWT \quad (15.530)$$

where a-f are regression curve-fit coefficients.

8) Part load fraction correlation (function of part load ratio)

This field defines the name of a quadratic or cubic performance curve (Ref: Performance Curves) that parameterizes the variation of electrical power input to the unit as a function of the part load ratio (PLR, heating load/steady-state heating capacity for Speed 1):

$$PartLoadFrac = a + b * PLR + c * PLR^2 + d * PLR^3 \quad (15.531)$$

and

$$RTF = (PLR/PartLoadFrac) = \text{runtime fraction of the heating coil} \quad (15.532)$$

The part load fraction (PLF) correlation accounts for efficiency losses due to compressor cycling. The part load fraction correlation should be normalized to a value of 1.0 when the part load ratio equals 1.0 (i.e., no efficiency losses when the compressor runs continuously for the simulation timestep). For PLR values between 0 and 1 ($0 <= PLR < 1$), the following rules apply $PLF >= 0.7$ and $PLF >= PLR$.

If $PLF < 0.7$, the program resets the PLF value to 0.7, and the simulation proceeds. The runtime fraction of the coil is defined as PLR/PLF . If $PLF < PLR$, the runtime fraction of the coil is limited to 1.0. A typical part load fraction correlation would be:

$$PLF = 0.85 + 0.15 \times PLR \quad (15.533)$$

If the user wishes to model no efficiency degradation due to compressor cycling, the part load fraction correlation should be defined as follows:

$$PLF = 0.85 + 0.0 \times PLR \quad (15.534)$$

Lowest Speed Operation:

The lowest speed operation of the VS WSHP is similar to the single speed DX heating coil. The total (gross) heating capacity of the WSHP unit is calculated as follows:

$$\begin{aligned} Q_{total,1} = & \text{RatedTotalHeatingCapacity@SpeedLevel}(1) \\ & * TotCapTemModFac_1 \\ & * TotCapAirFlowModFac_1 \\ & * TotCapWaterFlowModFac_1 \end{aligned} \quad (15.535)$$

The EIR is calculated as:

$$\begin{aligned} EIR_1 = & \frac{1.0}{\text{ReferenceUnitCOP@Speed}(1)} * EIRTempModFac_1 \\ & * EIRAirFlowModFac_1 \\ & * EIRWaterFlowModFac_1 \end{aligned} \quad (15.536)$$

The power consumption including the compressor and accessories (not including pump and indoor fan powers) is:

$$Power_1 = Q_{total,1} * EIR_1 * RTF \quad (15.537)$$

The waste heat generated by this coil object is calculated as:

$$\begin{aligned} Q_{RecoverHeat,1} = & \text{ReferenceUnitWasteHeatFractionofEnergyInput@SpeedLevel}(1) \\ & * Power_1 * WasteHeatTempModFac_1 \end{aligned} \quad (15.538)$$

where:

$\text{ReferenceUnitWasteHeatFractionofEnergyInput@SpeedLevel}(1)$ is the waste heat fraction of the energy input at Speed 1, from the Reference Unit data.

The total amount of heat absorbed by the evaporator is calculated as:

$$Q_{evap,1} = Q_{total,1} + Q_{RecoverHeat,1} - Power_1 \quad (15.539)$$

The fraction of the actual air mass flow to the design air mass flow rate is calculated:

$$ff_{a,1} = \text{actual air mass flow rate} / \\ * (ReferenceUnitAirMassFlowRate@SpeedLevel(1) \\ * CapacityScaleFactor) \quad (15.540)$$

The fraction of the actual water mass flow to the design water mass flow rate is calculated:

$$ff_{w,1} = \text{actual water mass flow rate} / \\ (ReferenceUnitWaterMassFlowRate@SpeedLevel(1) \\ * CapacityScaleFactor) \quad (15.541)$$

Higher Speed Operation:

At the speed level between the lowest and the highest, there is no part-load loss. A parameter of speed ratio (SpeedRatio) is used to define the capacity partition between Speed x-1 and Speed x.

The design air and water flow rate at the speed ratio are given as following:

$$DesignAirFlowRateSpeedRatio = ReferenceUnitAirMassFlowRate@SpeedLevel(x-1) \\ * CapacityScaleFactor * (1 - SpeedRatio) \\ + ReferenceUnitAirMassFlowRate@SpeedLevel(x) \\ * CapacityScaleFactor * SpeedRatio \quad (15.542)$$

$$DesignWaterFlowRateSpeedRatio = ReferenceUnitWaterMassFlowRate@SpeedLevel(x-1) \\ * CapacityScaleFactor * (1 - SpeedRatio) \\ + ReferenceUnitWaterMassFlowRate@SpeedLevel(x) \\ * CapacityScaleFactor * SpeedRatio \quad (15.543)$$

The fractions of air flow and water flow are given by:

$$ff_{a,x-1} = ff_{a,x} = \text{actual air mass flow rate} / DesignAirFlowRateSpeedRatio \quad (15.544)$$

$$ff_{w,x-1} = ff_{w,x} = \text{actual water mass flow rate} / DesignWaterFlowRateSpeedRatio \quad (15.545)$$

The total heating capacities and EIRs at Speed x-1 and Speed x are given by:

$$Q_{total,x-1} = RatedTotalHeatingCapacity@SpeedLevel(x-1) \\ * TotCapTempModFac_{x-1} \\ * TotCapAirFlowModFac_{x-1} \\ * TotCapWaterFlowModFac_{x-1} \quad (15.546)$$

$$\begin{aligned}
Q_{total,x} = & \text{RatedTotalHeatingCapacity@SpeedLevel}(x) \\
& * \text{TotCapTempModFac}_x \\
& * \text{TotCapAirFlowModFac}_x \\
& * \text{TotCapWaterFlowModFac}_x
\end{aligned} \tag{15.547}$$

$$\begin{aligned}
EIR_{x-1} = & \frac{1.0}{\text{ReferenceUnitCOP@Speed}(x-1)} \\
& * EIRTempModFac_{x-1} \\
& * EIRAirFlowModFac_{x-1} \\
& * EIRWaterFlowModFac_{x-1}
\end{aligned} \tag{15.548}$$

$$\begin{aligned}
EIR_x = & \frac{1.0}{\text{ReferenceUnitCOP@Speed}(x)} \\
& * EIRTempModFac_x \\
& * EIRAirFlowModFac_x \\
& * EIRWaterFlowModFac_x
\end{aligned} \tag{15.549}$$

The total heating capacity at the corresponding speed ratio is:

$$Q_{total,SpeedRatio} = (1.0 - SpeedRatio) * Q_{total,x-1} + SpeedRatio * Q_{total,x} \tag{15.550}$$

and the power consumption is:

$$Power_{SpeedRatio} = (1.0 - SpeedRatio) * Q_{total,x-1} * EIR_{x-1} + SpeedRatio * Q_{total,x} * EIR_x \tag{15.551}$$

The waste heat generated by this coil object is calculated as:

$$\begin{aligned}
Q_{RecoverHeat,SpeedRatio} = & (1.0 - SpeedRatio) \\
& * \text{ReferenceUnitWasteHeatFractionofEnergyInput@SpeedLevel}(x-1) \\
& * \text{WasteHeatTempModFac}_{x-1} * Q_{total,x-1} * EIR_{x-1} \\
& + SpeedRatio \\
& * \text{ReferenceUnitWasteHeatFractionofEnergyInput@SpeedLevel}(x) \\
& * \text{WasteHeatTempModFac}_x \\
& * Q_{total,x} * EIR_x
\end{aligned} \tag{15.552}$$

The total amount of heat absorbed by the evaporator is calculated as:

$$Q_{evap,SpeedRatio} = Q_{total,SpeedRatio} + Q_{RecoverHeat,SpeedRatio} - Power_{SpeedRatio} \tag{15.553}$$

Finally:

$$Q_{total,SpeedRatio} = HeatingLoad \tag{15.554}$$

If the speed reaches the highest level, the speed ratio becomes 1.0, and Speed x represents the highest speed.

15.2.25.3 Coil:Cooling:WaterToAirHeatPump:VariableSpeedEquationFit

15.2.25.4 Overview

This model (object name *Coil:Cooling:WaterToAirHeatPump:VariableSpeedEquationFit*) simulates the performance of an variable-speed water-to-air heat pump with cooling capability. It fits in the parent objects of *AirLoopHVAC:UnitaryHeatPump:WaterToAir* and *ZoneHVAC:WaterToAirHeatPump*. It has the same logic for varying the compressor, indoor fan and pump speeds as the *Coil:Heating:WaterToAirHeatPump:VariableSpeedEquationFit* object. The rated conditions for obtaining the capacities, COPs and SHR are indoor dry-bulb temperature at 26.67°C (80°F), wet bulb temperature at 19.44°C (67°F), and the source side entering water temperature at 29.4°C (85 °F).

Variable-speed cooling coils lead to varied dehumidification behaviors, that the Bypass Factor (BF) is not only dependent on the indoor air flow rate, but also on the refrigerant mass flow rate, i.e. the compressor speed. It is necessary to assess the BF approach for single-speed DX coil, to be used for the variable-speed systems.

The DOE/ORNL Heat Pump Design Model (HPDM) is a steady-state vapor compression equipment simulation model, which is able to simulate the performance of a VS WSHP system. We ran a calibrated HPDM model to produce performance data of a 2.5-ton, VS WSHP unit in space cooling mode. We ran the model to get the total cooling capacities and SHRs, by specifying the EWT at 65°F, indoor air DB at 80°F and relative humidity at 0.5, and then varying the indoor air flow rate from 400 scfm to 1000 scfm, the compressor speed from 30 Hz to 90 Hz in a 7×7 matrix. Based on the performance results, we used EES (Engineering Equation Solver) to back-calculate the corresponding BF factors and the A_o (effective coil surface area) parameters, using the BF equations for the single speed DX cooling coil in EnergyPlus Engineering Reference.

And then, we plotted the resultant A_o as a function of indoor air flow rate and compressor speed, as below:

As indicated in the two figures above, the compressor speed is a significant factor impacting the A_o parameter and the BF factor. So, the current BF factor approach should be upgraded to accommodate variable-speed cooling coils.

As shown in the A_o figure, we can almost assume that the A_o parameter mainly depends on the compressor speed. And thus, for enhancing the VS WSHP model, in the IDF file, we need to input SHRs at individual compressor speeds (this is similar to the current multi-speed DX cooling coil). And then, within the VS WSHP module, we calculate the A_o parameter specific to each compressor speed at the design air flow rates, and then do linear interpolation of A_o between neighboring compressor speeds. For calculating SHRs in energy simulations, we first calculate the A_o parameter related to the actual compressor speed, and then use the simulated A_o parameter in the original BF correlation to correlate effect of the varied indoor air flow rate.

15.2.25.5 Model Description

The *Coil:Cooling:WaterToAirHeatPump:VariableSpeedEquationFit* object is modeled in a manner similar to the multiple-speed DX cooling coil model (Ref. *Coil:Cooling:DX:MultiSpeed*). Of course, rather than referencing an air-cooled condenser, the new coil object references the water loop, and have the water entering temperature in place of the condenser air entering dry bulb temperature.

It shall be noted for the total cooling capacity and flow rate inputs, three fields are autosizable, which are Rated Total Cooling Capacity (Numeric Field 3) at Selected Nominal Speed Level, Rated

Figure 15.19: Effective Surface Area (A_o) Changing with Compressor Speed and Indoor SCFM

Figure 15.20: Bypass Factor (BF) Changing with Compressor Speed and Indoor SCFM

Volumetric Air Flow Rate (Numeric Field 4) and Rated Volumetric Water Flow Rate (Numeric Field 5). They are used to scale the performances of an actual unit and correlate with the actual loop flows. Except the three fields, all other total cooling capacity and flow rate inputs at individual speed levels should be directly obtained from Reference Unit catalog data, specific to an actual unit.

The Rated Total Cooling Capacity at Selected Nominal Speed Level contains the rated total cooling capacity to match the building sensible or latent cooling load. The rated cooling capacity is used to determine a capacity scaling factor, as compared to the Reference Unit catalog capacity at the nominal speed level.

$$CapacityScaleFactor = \frac{RatedTotalCoolingCapacity}{ReferenceUnitTotalCoolingCapacity@NominalSpeedLevel} \quad (15.555)$$

And then, this scaling factor is used to determine capacities at rated condition for other speed levels, as below,

$$RatedTotalCoolingCapacity@SpeedLevel(x) = CapacityScaleFactor * ReferenceUnitTotalCoolingCapacity@SpeedLevel(x) \quad (15.556)$$

The Rated Volumetric Air Flow Rate is used to determine an internal scaling factor, and calculate the air flow rates in the parent objects, as follows:

$$AirFlowScaleFactor = \frac{RatedVolumetricAirFlowRate}{ReferenceUnitVolAirFlowRate@NominalSpeedLevel * CapacityScaleFactor} \quad (15.557)$$

And the loop volumetric air flow rates in the parent objects are calculated as below,

$$LoopVolumetricAirFlowRate@SpeedLevel(x) = AirFlowScaleFactor * ReferenceUnitVolAirFlowRate@SpeedLevel(x) * CapacityScaleFactor \quad (15.558)$$

If the volumetric air flow rate at one speed level is higher than the flow rate allowed by the fan in the parent object, the flow rate will be set back to the fan flow rate.

This Rated Volumetric Water Flow Rate is used to determine an internal scaling factor, and calculate the loop water flow rates.

$$WaterFlowScaleFactor = \frac{RatedVolumetricWaterFlowRate}{ReferenceUnitVolWaterFlowRate@NominalSpeedLevel \times CapacityScaleFactor} \quad (15.559)$$

And the required volumetric water flow rates in the parent objects are calculated as below,

$$LoopVolumetricWaterFlowRate@SpeedLevel(x) = WaterFlowScaleFactor * ReferenceUnitVolWaterFlowRate@SpeedLevel(x) * CapacityScaleFactor \quad (15.560)$$

The required volumetric water flow rate as above is restricted by the pump in the parent object.

If *AirFlowScaleFactor* and *WaterFlowScaleFactor* are equal to unity, the loop flow rates become the design flow rates of the original unit (after scaled by the rated total cooling capacity). The Rated Volumetric Air Flow Rate and Rated Volumetric Water Flow Rate are introduced here

to correlate with the actual flow rates in the air and water loops, in case that these differ from the design specifications. Certainly, it is recommended that the Rated Volumetric Air Flow Rate and Rated Volumetric Water Flow Rate are selected in the way that *AirFlowScaleFactor* and *WaterFlowScaleFactor* are unity, so as to get more accurate results from the performance curves.

Performance Curves:

This object includes 7 curve objects at each individual speed level.

- 1) Total cooling capacity modifier curve (function of temperature)
- 2) Total cooling capacity modifier curve (function of air flow fraction)
- 3) Total cooling capacity modifier curve (function of water flow fraction)
- 4) Energy input ratio (EIR) modifier curve (function of temperature)
- 5) Energy input ratio (EIR) modifier curve (function of air flow fraction)
- 6) Energy input ratio (EIR) modifier curve (function of water flow fraction)
- 7) Recoverable heat modifier as a function of indoor air wet-bulb and water entering temperatures.

Curves (3) and (6) above are new curves as compared to those used for Multi-Speed Electric DX Air Cooling Coil, to correlate the change in water flow rate at the speed. The flow fraction modifier curves are used as a placeholder, to account for off-design flow rates if needed. If the manufacturer doesn't provide the off-design performances, we can simply use a default modification multiplier of 1.0.

At the lowest speed, there will be one additional performance curve to correlate the part-load condition, i.e.

- 8) Part load fraction correlation (function of part load ratio)

More details on the above curves are provided in the following paragraphs.

- 1) Total cooling capacity modifier curve (function of temperature)

The total cooling capacity modifier as a function of temperature curve (CAP-FT) is a biquadratic curve with two independent variables: wet-bulb temperature of the air entering the cooling coil and the WSHP's entering water temperature. The output of this curve is multiplied by the rated total cooling capacity at the speed, to give the total cooling capacity at the specific entering air WB and water temperatures at which the WSHP unit is operating (i.e., at temperatures different from the rating point temperatures).

Note: The data used to develop the total cooling capacity modifier curve (function of temperature) should represent performance when the cooling coil is 'wet' (i.e., coil providing sensible cooling and at least some dehumidification). Performance data when the cooling coil is 'dry' (i.e., not providing any dehumidification) should not be included when developing this modifier curve. This model automatically detects and adjusts for 'dry coil' conditions.

$$TotCapTempModFac = a + b * WB_i + c * WB_i^2 + d * EWT + e * EWT^2 + f * WB_i * EWT \quad (15.561)$$

where:

WB_i is the wet-bulb temperature of the air entering the heating coil (°C)

EWT is the entering water temperature (°C)

a-f are regression curve-fit coefficients.

2) Total cooling capacity modifier curve (function of air flow fraction)

The total cooling capacity modifier curve (function of air flow fraction) is a cubic curve with the independent variable being the ratio of the actual air flow rate across the cooling coil to the design air flow rate (i.e., fraction of design flow at the speed).

$$TotCapAirFlowModFac = a + b * ff_a + c * ff_a^2 + d * ff_a^3 \quad (15.562)$$

where:

ff_a is the actual air mass flow rate/design air mass flow rate, at one speed level

$$DesignAirMassFlowRate@SpeedLevel(x) = ReferenceUnitAirMassFlowRate@SpeedLevel(x) * CapacityScaleFactor \quad (15.563)$$

a-d are regression curve fit coefficients. If there is no data for correction, the user can simply set a = 1.0, and the other coefficients to 0.0.

3) Total cooling capacity modifier curve (function of water flow fraction)

The total cooling capacity modifier curve (function of water flow fraction) is a cubic curve with the independent variable being the ratio of the actual water flow rate across the water-to-refrigerant heat exchanger to the design water flow rate (i.e., fraction of design flow at the speed).

$$TotCapWaterFlowModFac = a + b * ff_w + c * ff_w^2 + d * ff_w^3 \quad (15.564)$$

where:

ff_w is the actual water mass flow rate/design water mass flow rate, at one speed level

$$DesignWaterMassFlowRate@SpeedLevel(x) = ReferenceUnitWaterMassFlowRate@SpeedLevel(x) * CapacityScaleFactor \quad (15.565)$$

a-d are regression curve-fit coefficients. If there is no data available for the correction, the user can simply set a = 1.0 and the other coefficients to 0.0.

4) Energy input ratio (EIR) modifier curve (function of temperature)

The energy input ratio modifier curve as a function of temperature (EIR-FT) is a biquadratic curve with two independent variables: wet-bulb temperature of the air entering the cooling coil and the WSHP's entering water temperature. The output of this curve is multiplied by the rated EIR (inverse of the rated COP) at the speed level, to give the EIR at the specific entering air and water

temperatures at which the WSHP unit is operating (i.e., at temperatures different from the rating point temperatures).

$$EIRTempModFac = a + b * WB_i + c * WB_i^2 + d * EWT + e * EWT^2 + f * WB_i * EWT \quad (15.566)$$

where:

WB_i is the wet-bulb temperature of the air entering the cooling coil ($^{\circ}\text{C}$)

EWT is the entering water temperature ($^{\circ}\text{C}$)

a-f are regression curve fit coefficients.

5) Energy input ratio (EIR) modifier curve (function of air flow fraction)

$$EIRAirFlowModFac = a + b * ff_a + c * ff_a^2 + d * ff_a^3 \quad (15.567)$$

where a-d are regression curve fit coefficients. If there is no data available for the correction, the user can simply set a = 1.0 and the other coefficients to 0.0.

6) Energy input ratio (EIR) modifier curve (function of water flow fraction)

$$EIRWaterFlowModFac = a + b * ff_w + c * ff_w^2 + d * ff_w^3 \quad (15.568)$$

where a-d are regression curve fit coefficients. If there is no data available for the correction, the user can simply set a = 1.0 and the other coefficients to 0.0.

7) Recoverable heat modifier as a function of indoor wet-bulb and water entering temperatures.

Recoverable heat modifier function is to account for the recoverable heat at the condensing side, as a fraction to the power input, which doesn't discharged to the water side.

$$WasteHeatTempModFac = a + b * WB_i + c * WB_i^2 + d * EWT + e * EWT^2 + f * WB_i * EWT \quad (15.569)$$

where a-f are regression curve fit coefficients.

8) Part load fraction correlation (function of part load ratio)

This field defines the name of a quadratic or cubic performance curve (Ref: Performance Curves) that parameterizes the variation of electrical power input to the unit as a function of the part load ratio (PLR, Sensible or Latent Load/Steady-State Sensible or Latent Capacity for Speed 1). The description of the part load fraction correlation for the VS WSHP cooling coil is similar to the VS WSHP heating coil.

Lowest Speed Operation:

The lowest speed operation of the VS WSHP is similar to the single speed DX cooling coil. The total (gross) cooling capacity of the WSHP unit is calculated as follows:

$$\begin{aligned}
Q_{total,1} = & \text{RatedTotalCoolingCapacity@SpeedLevel} (1) \\
& * \text{TotCapTempModFac}_1 \\
& * \text{TotCapAirFlowModFac}_1 \\
& * \text{TotCapWaterFlowModFac}_1
\end{aligned} \tag{15.570}$$

The EIR is calculated as:

$$\begin{aligned}
EIR_1 = & \frac{1.0}{\text{ReferenceUnitCOP@Speed}(1)} EIRTempModFac_1 \\
& * EIRAirFlowModFac_1 \\
& * EIRWaterFlowModWaterFac_1
\end{aligned} \tag{15.571}$$

The power consumption excluding the indoor fan and the water pump is,

$$Power_1 = Q_{total,1} * EIR_1 * RTF \tag{15.572}$$

where RTF is the run-time fraction.

The recoverable waste heat is:

$$\begin{aligned}
Q_{RecoverHeat,1} = & \text{ReferenceUnitWasteHeatFractionofEnergyInput@SpeedLevel} (1) \\
& * Power_1 \\
& * \text{WasteHeatTempModFac}_1
\end{aligned} \tag{15.573}$$

and the net heat discharged to the water loop is calculated as following:

$$Q_{cond,1} = Power_1 + Q_{total,1} - Q_{RecoverHeat,1} \tag{15.574}$$

At the lowest speed, the dehumidification calculation is exactly the same as the single speed DX coil. That is to use the rated SHR and the design air flow rate at the lowest speed to calculate rated bypass factor of $BF_{rated,1}$, and the corresponding effective surface area of $A_{o,1}$. Wh $A_{o,1}$ known, the coil BF can be adjusted for non-rated air flow rates. It shall be noted if choosing to add hot gas reheating to the supply side, $Q_{RecoverHeat,1}$ should be subtracted from the total cooling capacity and the sensible cooling capacity.

The part load ratio for sensible cooling is:

$$PLR = \text{SensibleCoolingLoad} / (Q_{total,1} * SHR_1) \tag{15.575}$$

For latent cooling:

$$PLR = \text{LatentCoolingLoad} / [Q_{total,1} * (1.0 - SHR_1)] \tag{15.576}$$

Higher Speed Operation:

At the speed level between the lowest and the highest, there is no part-load loss. A parameter of speed ratio (SpeedRatio) is used to define the capacity partition between Speed x-1 and Speed x.

The design air and water flow rate at the speed ratio are given as following:

$$\begin{aligned}
\text{DesignAirFlowRateSpeedRatio} = & \text{ReferenceUnitAirMassFlowRate@SpeedLevel}(x-1) \\
& * \text{CapacityScaleFactor} * (1 - \text{SpeedRatio}) \\
& + \text{ReferenceUnitAirMassFlowRate@SpeedLevel}(x) \\
& * \text{CapacityScaleFactor} * \text{SpeedRatio}
\end{aligned} \tag{15.577}$$

$$\begin{aligned}
\text{DesignWaterFlowRateSpeedRatio} = & \text{ReferenceUnitWaterMassFlowRate@SpeedLevel}(x-1) \\
& * \text{CapacityScaleFactor} * (1 - \text{SpeedRatio}) \\
& + \text{ReferenceUnitWaterMassFlowRate@SpeedLevel}(x) \\
& * \text{CapacityScaleFactor} * \text{SpeedRatio}
\end{aligned} \tag{15.578}$$

And the fractions of air flow and water flow are given:

$$ff_{a,x-1} = ff_{a,x} = \text{actual air mass flow rate} / \text{DesignAirFlowRateSpeedRatio} \tag{15.579}$$

$$ff_{w,x-1} = ff_{w,x} = \text{actual water mass flow rate} / \text{DesignWaterFlowRateSpeedRatio} \tag{15.580}$$

The total cooling capacities and EIRs at Speed x-1 and Speed x are calculated:

$$\begin{aligned}
Q_{total,x-1} = & \text{RatedTotalCoolingCapacity@SpeedLevel}(x-1) \\
& * \text{TotCapTempModFac}_{x-1} \\
& * \text{TotCapAirFlowModFac}_{x-1} \\
& * \text{TotCapWaterFlowModFac}_{x-1}
\end{aligned} \tag{15.581}$$

$$\begin{aligned}
Q_{total,x} = & \text{RatedTotalCoolingCapacity@SpeedLevel}(x) \\
& * \text{TotCapTempModFac}_x \\
& * \text{TotCapAirFlowModFac}_x \\
& * \text{TotCapWaterFlowModFac}_x
\end{aligned} \tag{15.582}$$

$$\begin{aligned}
EIR_{x-1} = & \frac{1.0}{\text{ReferenceUnitCOP@Speed}(x-1)} EIRTempModFac_{x-1} \\
& * EIRAirFlowModFac_{x-1} \\
& * EIRWaterFlowModFac_{x-1}
\end{aligned} \tag{15.583}$$

The total heating capacity at the corresponding speed ratio is:

$$Q_{total,SpeedRatio} = (1.0 - \text{SpeedRatio}) * Q_{total,x-1} + \text{SpeedRatio} * Q_{total,x} \tag{15.584}$$

and the power consumption, excluding the fan and pump power consumptions, is:

$$\text{Power}_{SpeedRatio} = (1.0 - \text{SpeedRatio}) * Q_{total,x-1} * EIR_{x-1} + \text{SpeedRatio} * Q_{total,x} * EIR_x \tag{15.585}$$

The recoverable waste heat is:

$$\begin{aligned}
 Q_{RecoverHeat,SpeedRatio} = & (1.0 - SpeedRatio) \\
 & * ReferenceUnitWasteHeatFractionofEnergyInput@SpeedLevel(x-1) \\
 & * WasteHeatTempModFac_{x-1} * Q_{total,x-1} * EIR_{x-1} \\
 & + SpeedRatio \\
 & * ReferenceUnitWasteHeatFractionofEnergyInput@SpeedLevel(x) \\
 & * WasteHeatTempModFac_x \\
 & * Q_{total,x} * EIR_x
 \end{aligned} \tag{15.586}$$

and the net heat discharged to the water loop is calculated as following:

$$Q_{cond,SpeedRatio} = Power_{SpeedRatio} + Q_{total,SpeedRatio} - Q_{RecoverHeat,SpeedRatio} \tag{15.587}$$

The effective surface area in the correlations of BF factor is calculated as:

$$A_{o,SpeedRatio} = (1 - SpeedRatio) * A_{o,x-1} + SpeedRatio * A_{o,x} \tag{15.588}$$

Using $A_{o,SpeedRatio}$ in the same BF and SHR calculation procedure as the single speed DX cooling coil, we can get $BF_{SpeedRatio}$, and $SHR_{SpeedRatio}$. The sensible cooling capacity is calculated:

$$Q_{sensible,SpeedRatio} = Q_{total,SpeedRatio} * SHR_{SpeedRatio} \tag{15.589}$$

It should be noted if choosing to add hot gas reheating to the supply side, $Q_{RecoverHeat,SpeedRatio}$ should be subtracted from both the total cooling capacity and the sensible cooling capacity.

At last, if the VS WSHP is used to match the sensible cooling load:

$$Q_{sensible,SpeedRatio} = SensibleLoad \tag{15.590}$$

If it intends to match the latent cooling load:

$$Q_{total,SpeedRatio} * (1.0 - SHR_{SpeedRatio}) = LatentLoad \tag{15.591}$$

If the speed reaches the highest level, the speed ratio becomes 1.0, and Speed n represents the highest speed.

15.2.26 Secondary Coils of DX Systems and Heat Pumps

15.2.26.1 Overview

Secondary coils reject to or remove heat from a secondary zone. Secondary coil refers to a condenser of a DX system or a heat pump in cooling operating mode or an evaporator of a heat pump in heating mode. The secondary coil (e.g. condenser) of DX system or heat pumps is commonly installed

outdoor but when installed indoor either heat is dumped to or extracted from the secondary zone. A secondary zone is a conditioned or unconditioned zone where the secondary coil is installed. Secondary coils are not standalone DX coil objects but they are add-on features on existing DX coil objects. A secondary DX coil is modelled by specifying additional inputs in single speed and multi speed DX coil objects: The additional inputs allow us to model the heat rejected or extracted by the secondary coil while the primary coil serves another controlled zone as shown in Figure 15.21. A secondary coil is not controlled directly but responds to the requirements of the primary DX coil. The operating mode of a secondary DX coil is determined by the primary DX coil serving the conditioned zone. If the primary DX coil is in cooling mode, then the secondary coil is rejecting heat (heating mode) to the secondary zone, or else if the primary DX coil is in heating mode, then the secondary coil is extracting heat (cooling mode) from the secondary zone. Heat rejected to a secondary zone by a condenser of a DX system or a heat pump is considered as sensible only. Whereas energy extracted from a secondary zone may contain sensible and latent components. The condenser type of the primary DX coils should be AirCooled. There is no need to specify the condenser air inlet node. The model uses zone air node as the secondary coil air inlet node. Air drawn by the secondary coil fan passes through the secondary coil and dumped back into the secondary zone. The previous time step zone condition is used as an inlet condition to the current time for the secondary DX coil model.

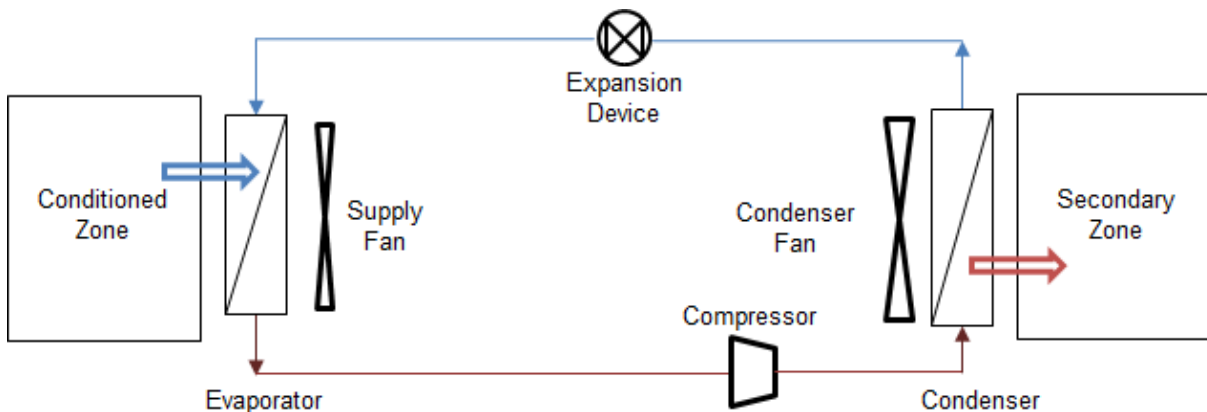

Figure 15.21: Schematic of DX System in cooling operating mode

Applications of this technology include: inter-zone heat pump in NTED (Dixon, 2010), and PTAC or PTHP serving Offices attached to a Warehouse, where the office partially or fully enclosed by the warehouse and the condenser is placed inside the Warehouse. The heat rejected or extracted by the secondary DX coil is estimated from the delivered capacity and electric power input of the primary DX coils. And the rejected or extracted heat is treated as internal gain of the secondary zone. Currently secondary DX coil are allowed in single speed, two speed and multi speed DX coil objects: *Coil:Cooling:DX:SingleSpeed*, *Coil:Heating:DX:SingleSpeed*, *Coil:Cooling:DX:TwoSpeed*, *Coil:Cooling:DX:MultiSpeed*, and *Coil:Heating:DX:MultiSpeed*.

15.2.26.2 Model Description:

The secondary coil performance calculation is invoked using inputs in the DX coil objects. The input required for cooling and heating operation of the primary DX coils are different. In the DX cooling coils the only required input is the zone name where the secondary coil is installed. In

heating DX coils six inputs are required for single speed coils and a minimum of 11 input fields are required for multispeed DX heating coils. And five more inputs are required for every additional compressor speed. The extensible five input fields are used for splitting the total heat extraction rate into sensible and latent components. These five input fields are: rated sensible heat ratio, secondary air flow rates, scaling factor for auto-sizing secondary air flow rates, sensible heat ratio modifier curves as a function of temperature and sensible heat ratio modifier curves as a function of secondary air flow fraction. The secondary coil model assumes that liquid water from defrosting operation is drained to the outdoor and has no impact on the zone air heat balance.

Cooling Operating Mode: the primary DX cooling coil of a DX system serving a primary zone is on and heat is rejected by the secondary coil (condenser) into a secondary zone. The secondary zone name is specified in DX cooling coil objects. This operating mode applies to a DX cooling system and cooling operating mode of air-to-air single and multi-speed heat pumps. The heat rejected by the secondary coil (condenser) of a DX system or heat pump operating in cooling mode is given by:

$$Q_{Cond} = Q_{Evap} + P_{CompCondFan} \quad (15.592)$$

where:

Q_{Evap} is the cooling load delivered by the primary DX cooling coil system (W)

$P_{CompCondFan}$ is the compressor and evaporator fan electric power input of a heat pump in heating mode (W)

Q_{Cond} is the heat rejected by the secondary coil (condenser) of a DX system or heat pump (W).

Heat rejected by a secondary coil (condenser) calculated at each time step becomes internal gain of the secondary zone as shown in Figure 15.22. Whenever a secondary zone name is specified in DX cooling coil objects, the secondary DX coil model calculation is invoked. New input field required as add-on to the DX cooling coil objects is “*Zone Name for Secondary Coil (condenser) Placement*”.

Figure 15.22: Schematic of DX system and secondary coil (condenser)

Heating Operating Mode: When a heat pump operates in heating mode then energy is extracted from the secondary zone. The total energy extracted is estimated by rearranging the equation above as follows:

$$Q_{Evap} = Q_{Cond} - P_{CompCondFan} \quad (15.593)$$

where:

Q_{Cond} is the heat delivered by the primary heating DX coil to the primary zone (W)

$P_{CompCondFan}$ is the compressor and condenser fan electric power input of a DX system or heat pump in cooling mode (W)

Q_{Evap} is the energy extracted by secondary coil (evaporator) from the secondary zone (W).

The total energy extracted from a secondary zone may contain sensible and latent components. The secondary coil model checks for the coil inlet and full load outlet air condition to determine whether dehumidification will occur. The sensible and latent split of the energy extracted is done using a user specified rated sensible heat ratio (SHR) and SHR modifier curves for temperature and the secondary air flow fraction. If the secondary coil operation is dry, then the SHR is set to 1.0. In addition, the model assumes that defrosting operation is on, then the defrosting melts the frost and the liquid water from the collecting pan is drained to outside. Thus defrosting energy is not included in the zone energy balance. The heat extracted from the secondary zone may contain sensible and latent components and the secondary coil model does the sensible/latent heat split calculation.

15.2.26.3 Sensible Heat Ratio Calculation

The SHR calculation method uses user specified SHR modifying curves for temperature and flow fraction. The modifying curves correct the rated SHR value for a given secondary DX coil (evaporator) entering air temperatures and air mass flow fraction for a given speed. If these SHR modifying curves are not specified a constant SHR will be assumed. These two curves are a biquadratic SHR modifier curve for temperature (SHRFT), and a quadratic SHR correction curve for flow fraction (SHRFFF). The SHR is given by:

$$SHR = SHR_{rated} \cdot SHRFT(T_{wb,secondaryZone}, T_{db,primaryCoil}) \cdot SHRFFF(FF) \quad (15.594)$$

where:

$SHRFT$ is the sensible heat ratio modifier normalized biquadratic curve as a function of secondary DX coil entering air wet-bulb and primary DX coil entering air dry-bulb temperature. The secondary DX coil (evaporator) entering air wet-bulb temperature is the secondary zone air wet-bulb temperature.

$SHRFFF$ is the sensible heat ratio modifier normalized quadratic curve as a function of air mass flow fraction.

FF , flow fraction, is the ratio of actual to rated mass flow rate of air through the secondary DX coil.

SHR_{rated} is the sensible heat ratio at rated conditions.

For multispeed secondary DX coils when the system is cycling between two speeds of n and $n-1$ the operating SHR is weighted using *SpeedRatio* as follows:

$$SHR = SHR_n \cdot SpeedRatio + SHR_{n-1}(1 - SpeedRatio) \quad (15.595)$$

where:

SHR_n is the sensible heat ratio at speed n determined from user specified rated SHR, and SHR modifier curves at speed n ,

SHR_{n-1} is the sensible heat ratio at speed $n-1$ determined from user specified rated SHR, and SHR modifier curves at speed $n-1$,

$SpeedRatio$ is a parameter that relates performance between successive compressor speeds,

15.2.26.4 Sensible and Latent Split

The air enthalpy difference across the secondary DX coil (evaporator) at full load is given by:

$$h_{Delta} = \frac{(Q_{Evap}/PLR)}{\dot{m}_{Cond}} \quad (15.596)$$

The coil outlet enthalpy is calculated as follows:

$$h_{Outlet} = h_{Inlet} - h_{Delta} \quad (15.597)$$

Using the SHR calculated above, the secondary DX coil outlet humidity ratio and dry-bulb temperature are given by:

$$h_{T_{in},\omega_{out}} = h_{Inlet} - (1.0 - SHR) \cdot \frac{(Q_{Evap}/PLR) \cdot SHR}{\dot{m}_{Cond} \cdot c_p} \quad (15.598)$$

$$\omega_{Outlet} = \omega(T_{Inlet}, h_{T_{in},\omega_{out}}) \quad (15.599)$$

$$T_{Outlet} = T(h_{Outlet}, \omega_{Outlet}) \quad (15.600)$$

Calculate the saturated outlet temperature at the outlet enthalpy and check the secondary outlet air condition if super-saturation has occurred:

$$T_{Outlet,Sat} = T_{SAT}(h_{Outlet}, P_{Tot}) \quad (15.601)$$

If $T_{Outlet} \leq T_{Outlet,Sat}$, then

$$T_{Outlet} = T_{Outlet,Sat} \quad (15.602)$$

$$\omega_{Outlet} = \omega(T_{Outlet,Sat}, h_{Outlet}) \quad (15.603)$$

where:

h_{Inlet} is the enthalpy of air entering the passive coil (J/kg)

h_{Outlet} is the enthalpy of air leaving the passive coil (J/kg)

$h_{T_{in},\omega_{out}}$ is the enthalpy of air at the leaving humidity ratio and the entering dry bulb temperature

\dot{m}_{sec} is the secondary DX coil mass flow rate (kg/s)

PLR is the primary DX cooling coil compressor part-load ratio

P_{Tot} is the total pressure at the inlet of secondary DX coil (Pa)

T_{Outlet} is the secondary coil outlet air temperature (°C)

$T_{Outlet,Sat}$ is the secondary coil saturated air temperature at the outlet enthalpy (°C)

ω_{Inlet} is the secondary coil inlet node air humidity ratio (kgH₂O/kgDryair)

ω_{Outlet} is the secondary coil outlet node air humidity ratio (kgH₂O/kgDryair).

15.2.27 Packaged Thermal Storage Cooling Coil

The DX cooling coil model for Coil:Cooling:DX:SingleSpeed:ThermalStorage is described in this section. The following diagram shows the main aspects of the model for packaged thermal energy storage cooling coil. This model allows charging and discharging to shift cooling energy use. The dashed line shows the boundary of the empirical “black box” model. The main parts are the Condenser, Evaporator, Compressor, and Thermal Energy Storage (TES) tank. The model interacts with the surroundings via a condenser inlet and outlet nodes, evaporator inlet and outlet nodes, heat transfer between TES tank and surrounding ambient environment, and optional added plant connection to the TES tank.

Figure 15.23: Highlights of Packaged Thermal Storage Cooling Coil

Depending on the operating mode, different parts are active. There are six modes to consider.

Off Mode is when the unit is not running but the TES tank still interacts with ambient and the model needs to track the state of charge in the tank.

Figure 15.24: Thermal Storage Cooling Coil Off Mode

Governing equations for Off Mode include:

$$-M c_p \frac{DT}{Dt} + \dot{Q}_{Amb} + \dot{Q}_{Plant} = 0 \quad (water\ tank) \quad (15.604)$$

$$-M h_{fs} \frac{DF}{Dt} + \dot{Q}_{Amb} + \dot{Q}_{Plant} = 0 \quad (ice\ tank) \quad (15.605)$$

$$\dot{Q}_{Amb} = (UA)_{Tank} (T_{TES} - T_{Amb}) \quad (15.606)$$

$$\dot{Q}_{Plant} = \dot{m} \varepsilon (T_{TES} - T_{w,in}) \quad (15.607)$$

Cooling Only Mode is when the unit is running but since it is neither charging nor discharging the TES tank, the model is essentially the same as a normal single speed DX cooling coil. The latent degradation model is not available. The model uses SHR curves from user input.

The governing equations for Cooling Only Mode include:

$$-M c_p \frac{DT}{Dt} + \dot{Q}_{Amb} + \dot{Q}_{Plant} = 0 \quad (water\ tank) \quad (15.608)$$

$$-M h_{fs} \frac{DF}{Dt} + \dot{Q}_{Amb} + \dot{Q}_{Plant} = 0 \quad (ice\ tank) \quad (15.609)$$

$$\dot{W} + \dot{Q}_{Evap} + \dot{Q}_{Cond} = 0 \quad (15.610)$$

Figure 15.25: Thermal Storage Coil Cooling Only Mode

$$\dot{Q}_{Amb} = (UA)_{Tank} (T_{TES} - T_{Amb}) \quad (15.611)$$

$$\dot{Q}_{Plant} = \dot{m}c_p\varepsilon (T_{TES} - T_{w,in}) \quad (15.612)$$

The input correlations are used in the following manner to determine cooling capacity and energy consumption for a given set of operationg conditions.

One total evaporator cooling capacity modifier curve is a function of evaporator inlet wetbulb temperature and condenser inlet drybulb temperature.

$$EvapCapTempModFac = f(T_{evap,wb}, T_{cond,db}) \quad (15.613)$$

Another total evaporator cooling capacity modifier curve is a function of air flow fraction through the evaporator section where air flow fraction is the ratio of current air mass flow rate to the rated air mass flow rate.

$$EvapCapFlowModFac = f\left(\frac{\dot{m}_{evap,air}}{\dot{m}_{evap,air,rated}}\right) \quad (15.614)$$

One energy input ratio modifier curve is a function of evaporator inlet wetbulb temperature and condenser inlet drybulb temperature.

$$EIRTempModFac = f(T_{evap,wb}, T_{cond,db}) \quad (15.615)$$

Another energy input ratio modifier curve is a function of flow fraction.

$$EIRFlowModFac = f\left(\frac{\dot{m}_{evap,air}}{\dot{m}_{evap,air,rated}}\right) \quad (15.616)$$

Part load degradation curve is a function of part load ratio.

$$EvapPartLoadFac = f(PLR) \quad (15.617)$$

The results of the performance curves are applied as follows to determine cooling capacity and energy performance:

$$\dot{Q}_{Evap} = \dot{Q}_{Evap,RatedCoolOnly} (EvapCapTempModFac) (EvapCapFlowModFac) \quad (15.618)$$

$$\dot{W}_{elec} = \frac{\dot{Q}_{evap} (EIRTempModFac) (EIRFlowModFac) (PLR)}{(COP_{Rated,CoolOnly}) (EvapPartLoadFac)} \quad (15.619)$$

The sensible heat ratio (SHR) is determined by a rated SHR and two performance curves. The SHR temperature modifying factor is a function of evaporator entering wetbulb and evaporator entering drybulb temperature.

$$SHRTempModFac = f(T_{evap,wb}, T_{evap,db}) \quad (15.620)$$

The SHR flow fraction modifying factor is a function of air flow fraction through the evaporator section where air flow fraction is the ratio of current air mass flow rate to the rated air mass flow rate.

$$SHR_{FlowModFac} = f \left(\frac{\dot{m}_{evap,air}}{\dot{m}_{evap,air,rated}} \right) \quad (15.621)$$

The results of the performance curves are applied as follows to determine SHR:

$$SHR = SHR_{rated} * SHRTempModFac * SHR_{FlowModFac} \quad (15.622)$$

Cool and Charge Mode is when the unit is both cooling and charging the TES, then all the parts are active. The electric power into the compressor is split into two terms to accommodate devices that actually have dual compressors.

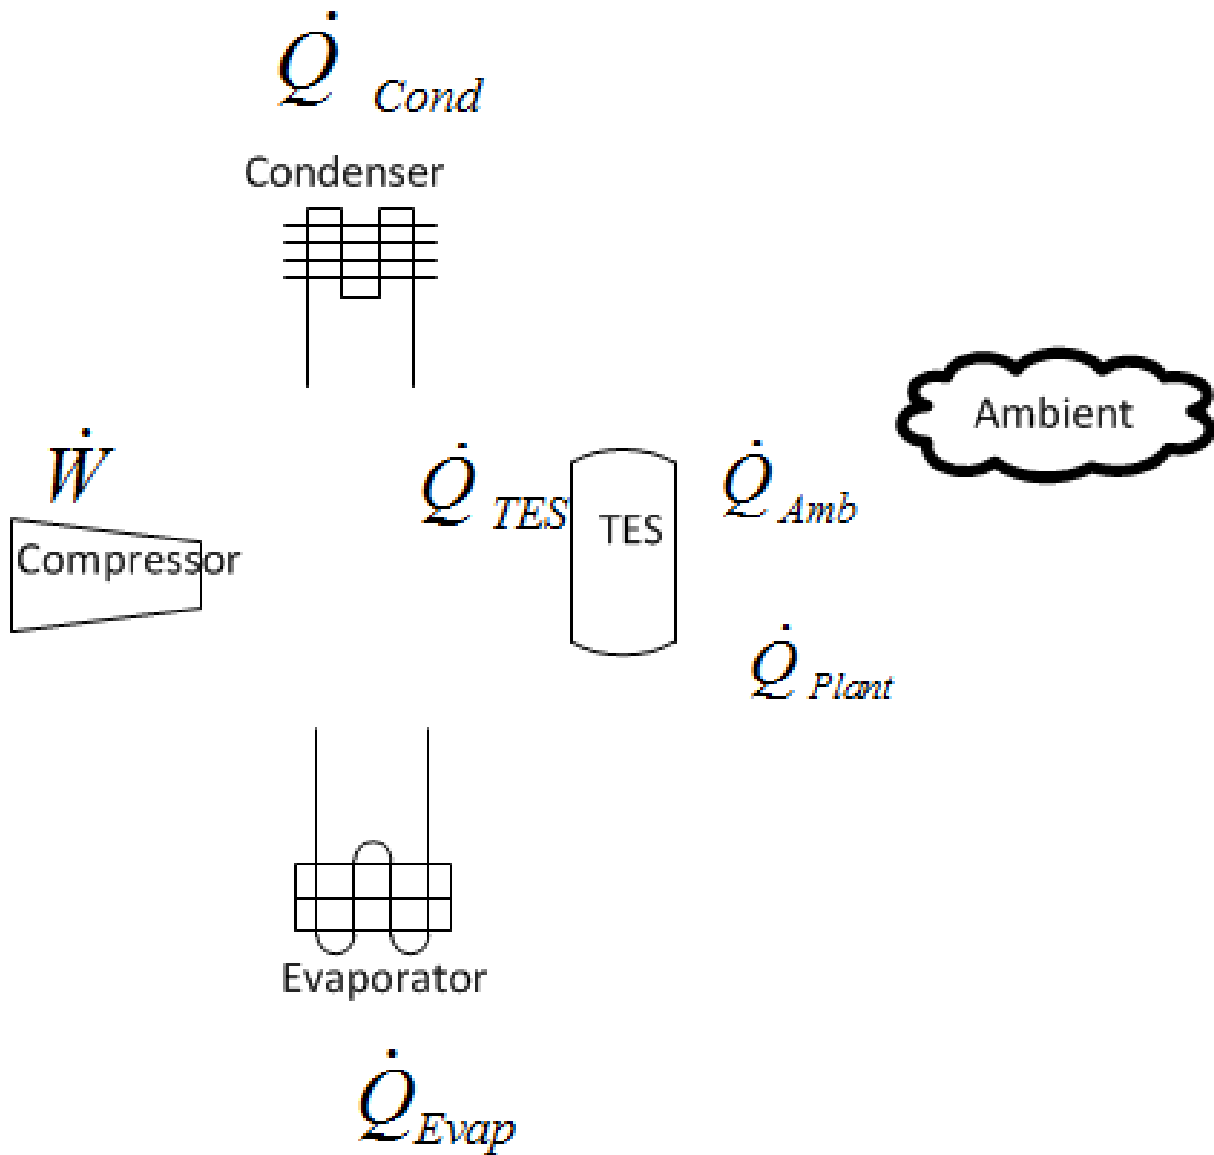

Figure 15.26: Thermal Storage Coil Cool and Charge Modes

Governing Equations for “Cool and Charge Mode”

$$-M c_p \frac{DT}{Dt} + \dot{Q}_{Amb} + \dot{Q}_{Plant} + \dot{Q}_{TES} = 0 \quad (\text{water tank}) \quad (15.623)$$

$$-M h_{fs} \frac{DF}{Dt} + \dot{Q}_{Amb} + \dot{Q}_{Plant} + \dot{Q}_{TES} = 0 \quad (\text{ice tank}) \quad (15.624)$$

$$\dot{W}_{Evap} + \dot{W}_{TES} + \dot{Q}_{Evap} + \dot{Q}_{Cond} + \dot{Q}_{TES} = 0 \quad (15.625)$$

$$\dot{Q}_{Amb} = (UA)_{Tank} (T_{TES} - T_{Amb}) \quad (15.626)$$

$$\dot{Q}_{Plant} = \dot{m} c_p \varepsilon (T_{TES} - T_{w,in}) \quad (15.627)$$

The input correlations are used in the following manner to determine cooling capacity, charge capacity, and energy consumption for a given set of operationg conditions.

One total evaporator cooling capacity modifier curve is a function of evaporator inlet wetbulb and condenser inlet drybulb temperatures and state of TES, S_{TES} (temperature of water or fraction of ice).

$$EvapCapTempModFac = f(T_{evap,wb}, T_{cond,db}, S_{TES}) \quad (15.628)$$

Another total evaporator cooling capacity modifier curve is a function of flow fraction.

$$EvapCapFlowModFac = f\left(\frac{\dot{m}_{evap,air}}{\dot{m}_{evap,air,rated}}\right) \quad (15.629)$$

One evaporator energy input ratio modifier curve, function of evaporator inlet wetbulb and condenser inlet drybulb temperatures and state of TES.

$$EIREvapTempModFac = f(T_{evap,wb}, T_{cond,db}, S_{TES}) \quad (15.630)$$

Another energy input ratio modifier curve is a function of flow fraction.

$$EIREvapFlowModFac = f\left(\frac{\dot{m}_{evap,air}}{\dot{m}_{evap,air,rated}}\right) \quad (15.631)$$

Part load degradation curve is a function of evaporator part load ratio.

$$EvapPartLoadFac = f(PLR) \quad (15.632)$$

One storage charge capacity modifier curve is a function of evaporator inlet wetbulb and condenser inlet drybulb temperatures and state of TES.

$$TESCapTempModFac = f(T_{evap,wb}, T_{cond,db}, S_{TES}) \quad (15.633)$$

Another storage charge capacity modifier curve is a function of evaporator part load ratio.

$$TESCapPartLoadFac = f(PLR) \quad (15.634)$$

The results of the performance curves are applied as follows to determine cooling capacity and energy performance:

$$\dot{Q}_{Evap} = \dot{Q}_{Evap,RatedCoolAndCharge} (EvapCapTempModFac) (EvapCapFlowModFac) \quad (15.635)$$

$$\dot{Q}_{TES} = \dot{Q}_{Charge,Rated} (TESCapTempModFac) (TESCapPartLoadFac) \quad (15.636)$$

$$\dot{W}_{Evap,elec} = \frac{(\dot{Q}_{Evap}) (EIRTempModFac) (EIRFlowModFac) (EvapPLR)}{(COP_{Rated,Cooling}) (EvapPartLoadFac)} \quad (15.637)$$

$$\dot{W}_{TES,elec} = \frac{(\dot{Q}_{TES}) (EIRStorTempModFac) (EIRStorFlowModFac) (StorPLR)}{(COP_{Rated,Charging}) (StorPartLoadFac)} \quad (15.638)$$

The sensible heat ratio (SHR) is determined by a rated SHR and two performance curves. There are two options for the SHR temperature modifying factor, it can either be a function of evaporator entering wetbulb and evaporator entering drybulb temperature or it can add a third independent variable for the state of charge of TES.

$$SHRTempModFac = \begin{cases} f(T_{evap,wb}, T_{evap,db}) \\ f(T_{evap,wb}, T_{evap,db}, S_{TES}) \end{cases} \quad (15.639)$$

The SHR flow fraction modifying factor is a function of air flow fraction through the evaporator section where air flow fraction is the ratio of current air mass flow rate to the rated air mass flow rate.

$$SHRFlowModFac = f\left(\frac{\dot{m}_{evap,air}}{\dot{m}_{evap,air,rated}}\right) \quad (15.640)$$

The results of the performance curves are applied as follows to determine SHR:

$$SHR = SHR_{rated} * SHRTempModFac * SHRFlowModFac \quad (15.641)$$

Cool and Discharge Mode is when the unit is both cooling and discharging the TES, then all the parts are active. The electric power into the compressor is split into two terms to accommodate devices that actually have dual compressors.

Governing Equations for “Cool and Discharge Mode”

$$-Mc_p \frac{DT}{Dt} + \dot{Q}_{Amb} + \dot{Q}_{Plant} + \dot{Q}_{TES} = 0 \quad (water\ tank) \quad (15.642)$$

$$-Mh_{fs} \frac{DF}{Dt} + \dot{Q}_{Amb} + \dot{Q}_{Plant} + \dot{Q}_{TES} = 0 \quad (ice\ tank) \quad (15.643)$$

$$\dot{W}_{Evap} + \dot{W}_{TES} + \dot{Q}_{Evap} + \dot{Q}_{Cond} + \dot{Q}_{TES} = 0 \quad (15.644)$$

$$\dot{Q}_{Amb} = (UA)_{Tank} (T_{TES} - T_{Amb}) \quad (15.645)$$

Figure 15.27: Thermal Storage Coil Cool and Discharge Modes

$$\dot{Q}_{Plant} = \dot{m}c_p\varepsilon (T_{TES} - T_{w,in}) \quad (15.646)$$

The input correlations are used in the following manner.

One total evaporator cooling capacity modifier curve is a function of evaporator inlet wetbulb and condenser inlet drybulb temperatures and state of TES.

$$EvapCapTempModFac = f(T_{evap,wb}, T_{cond,db}, S_{TES}) \quad (15.647)$$

Another total evaporator cooling capacity modifier curve is a function of flow fraction.

$$EvapCapFlowModFac = f\left(\frac{\dot{m}_{evap,air}}{\dot{m}_{evap,air,rated}}\right) \quad (15.648)$$

One evaporator energy input ratio modifier curve is a function of of evaporator inlet wetbulb and condenser inlet drybulb temperatures and state of TES.

$$EIREvapTempModFac = f(T_{evap,wb}, T_{cond,db}, S_{TES}) \quad (15.649)$$

Another evaporator energy input ratio modifier curve is a function of flow fraction.

$$EIREvapFlowModFac = f\left(\frac{\dot{m}_{evap,air}}{\dot{m}_{evap,air,rated}}\right) \quad (15.650)$$

Evaporator part load degradation curve is a function of evaporator part load ratio.

$$EvapPartLoadFac = f(EvapPLR) \quad (15.651)$$

One storage discharge capacity modifier curve is a function of evaporator inlet wetbulb and condenser inlet drybulb temperatures and state of TES.

$$TESCapTempModFac = f(T_{evap,wb}, T_{cond,db}, S_{TES}) \quad (15.652)$$

Another storage discharge capacity modifier curve is a function of evaporator part load ratio.

$$TESCapPartLoadFac = f(EvapPLR) \quad (15.653)$$

One storage energy input ratio modifier curve is a function of evaporator inlet wetbulb and condenser inlet drybulb temperatures and state of TES.

$$EIRStorTempModFac = f_{triquadratic}(T_{evap,wb}, T_{cond,db}, S_{TES}) \quad (15.654)$$

Another storage energy input ratio modifier curve is a function of flow fraction.

$$EIRStorFlowModFac = f\left(\frac{\dot{m}_{evap,air}}{\dot{m}_{evap,air,rated}}\right) \quad (15.655)$$

Storage part load degradation curve is a function of storage discharge part load ratio.

$$StorPartLoadFac = f(StorPLR) \quad (15.656)$$

The results of the performance curves are applied as follows to determine cooling capacity and energy performance:

$$\dot{Q}_{Evap} = \dot{Q}_{Evap,RatedCoolAndDischarge} (EvapCapTempModFac) (EvapCapFlowModFac) \quad (15.657)$$

$$\dot{Q}_{TES} = -\dot{Q}_{Discharge,Rated} (TESCapTempModFac) (TESCapPartLoadFac) \quad (15.658)$$

$$\dot{W}_{Evap,elec} = \frac{(\dot{Q}_{Evap}) (EIREvapTempModFac) (EIREvapFlowModFac) (EvapPLR)}{(COP_{Rated,Cooling}) (EvapPartLoadFac)} \quad (15.659)$$

$$\dot{W}_{TES,elec} = \frac{(\dot{Q}_{TES}) (EIRStorTempModFac) (EIRStorFlowModFac) (StorPLR)}{(COP_{Rated,Discharging}) (StorPartLoadFac)} \quad (15.660)$$

The sensible heat ratio (SHR) is determined by a rated SHR and two performance curves. There are two options for the SHR temperature modifying factor, it can either be a function of evaporator entering wetbulb and evaporator entering drybulb temperature or it can add a third independent variable for the state of charge of TES.

$$SHRTempModFac = \begin{cases} f(T_{evap,wb}, T_{evap,db}) \\ f(T_{evap,wb}, T_{evap,db}, S_{TES}) \end{cases} \quad (15.661)$$

The SHR flow fraction modifying factor is a function of air flow fraction through the evaporator section where air flow fraction is the ratio of current air mass flow rate to the rated air mass flow rate.

$$SHRFlowModFac = f\left(\frac{\dot{m}_{evap,air}}{\dot{m}_{evap,air,rated}}\right) \quad (15.662)$$

The results of the performance curves are applied as follows to determine SHR:

$$SHR = SHR_{rated} * SHRTempModFac * SHRFlowModFac \quad (15.663)$$

Charge Only Mode is when the unit is only charging, there is no heat flow at the evaporator. There is no modulation or part loading, when charging the unit charges at its nominal design rate (adjusted for conditions).

The governing equations for “Charge Only Mode”

$$-M_{c_p} \frac{DT}{Dt} + \dot{Q}_{Amb} + \dot{Q}_{Plant} + \dot{Q}_{TES} = 0 \quad (water\ tank) \quad (15.664)$$

$$-Mh_{fs} \frac{DF}{Dt} + \dot{Q}_{Amb} + \dot{Q}_{Plant} + \dot{Q}_{TES} = 0 \quad (ice\ tank) \quad (15.665)$$

$$\dot{W} + \dot{Q}_{Cond} + \dot{Q}_{TES} = 0 \quad (15.666)$$

Figure 15.28: Thermal Storage Coil Charge Only Mode

$$\dot{Q}_{Amb} = (UA)_{Tank} (T_{TES} - T_{Amb}) \quad (15.667)$$

$$\dot{Q}_{Plant} = \dot{m} c_p \varepsilon (T_{TES} - T_{w,in}) \quad (15.668)$$

The input correlations are used in the following manner.

Storage charge capacity modifier factor is a function of evaporator inlet wetbulb and condenser inlet drybulb temperatures and state of TES.

$$TESCapTempModFac = f(T_{evap,wb}, T_{cond,db}, S_{TES}) \quad (15.669)$$

Energy input ratio modifier factor is a function of evaporator inlet wetbulb and condenser inlet drybulb temperatures and state of TES.

$$EIRTempModFac = f(T_{evap,wb}, T_{cond,db}, S_{TES}) \quad (15.670)$$

$$\dot{Q}_{TES} = (\dot{Q}_{Charge,Rated}) (TESCapTempModFac) \quad (15.671)$$

$$\dot{W}_{elec} = (\dot{Q}_{TES}) \left(\frac{1}{COP_{Rated,ChargeOnly}} \right) (EIRTempModFac) \quad (15.672)$$

Discharge Only Mode is when the unit is only discharging, there is no heat flow at the condenser. The rate of discharge will modulate to meet part loading at the evaporator.

The governing equations for “Discharge Only Mode”

Figure 15.29: Thermal Storage Coil Discharge Only Mode

$$-M c_p \frac{DT}{Dt} + \dot{Q}_{Amb} + \dot{Q}_{Plant} + \dot{Q}_{TES} = 0 \quad (\text{water tank}) \quad (15.673)$$

$$-M h_{fs} \frac{DF}{Dt} + \dot{Q}_{Amb} + \dot{Q}_{Plant} + \dot{Q}_{TES} = 0 \quad (\text{ice tank}) \quad (15.674)$$

$$\dot{W} + \dot{Q}_{Evap} + \dot{Q}_{TES} = 0 \quad (15.675)$$

$$\dot{Q}_{Amb} = (UA)_{Tank} (T_{TES} - T_{Amb}) \quad (15.676)$$

$$\dot{Q}_{Plant} = \dot{m} c_p \varepsilon (T_{TES} - T_{w,in}) \quad (15.677)$$

The input correlations are used in the following manner.

One total evaporator cooling capacity modifier factor is a function of evaporator inlet wetbulb temperature and state of TES.

$$EvapCapTempModFac = f(T_{evap,wb}, S_{TES}) \quad (15.678)$$

Another total evaporator cooling capacity modifier factor is a function of flow fraction.

$$EvapCapFlowModFac = f\left(\frac{\dot{m}_{evap,air}}{\dot{m}_{evap,air,rated}}\right) \quad (15.679)$$

One energy input ratio modifier factor is a function of evaporator inlet wetbulb temperature and state of TES.

$$EIRTempModFac = f(T_{evap,wb}, S_{TES}) \quad (15.680)$$

Another energy input ratio modifier factor is a function of flow fraction.

$$EIRFlowModFac = f\left(\frac{\dot{m}_{evap,air}}{\dot{m}_{evap,air,rated}}\right) \quad (15.681)$$

Part load degradation curve is a function of evaporator part load ratio.

$$EvapPartLoadFac = f(EvapPLR) \quad (15.682)$$

$$\dot{Q}_{Evap} = \left(\dot{Q}_{Evap,RatedDischargeOnly}\right) (EvapCapTempModFac) (EvapCapFlowModFac) \quad (15.683)$$

$$\dot{W}_{elec} = \frac{\left(\dot{Q}_{evap}\right) (EIRStorTempModFac) (EIRStorFlowModFac) (EvapPLR)}{(COP_{Rated,DischargeOnly}) (EvapPartLoadFac)} \quad (15.684)$$

$$\dot{Q}_{TES} = \dot{Q}_{Evap} + \dot{W}_{elec} \quad (15.685)$$

The sensible heat ratio (SHR) is determined by a rated SHR and two performance curves. There are two options for the SHR temperature modifying factor, it can either be a function of evaporator

entering wetbulb and evaporator entering drybulb temperature or it can add a third independent variable for the state of charge of TES.

$$SHRTempModFac = \begin{cases} f(T_{evap,wb}, T_{evap,db}) \\ f(T_{evap,wb}, T_{evap,db}, S_{TES}) \end{cases} \quad (15.686)$$

The SHR flow fraction modifying factor is a function of air flow fraction through the evaporator section where air flow fraction is the ratio of current air mass flow rate to the rated air mass flow rate.

$$SHRFlowModFac = f\left(\frac{\dot{m}_{evap,air}}{\dot{m}_{evap,air,rated}}\right) \quad (15.687)$$

The results of the performance curves are applied as follows to determine SHR:

$$SHR = SHR_{rated} * SHRTempModFac * SHRFlowModFac \quad (15.688)$$

15.3 HVAC Controllers

15.3.1 Control Valve for Water-Based Air System Coils

The input object Controller:WaterCoil provides a simple controller model for adjusting water flow rates to meet the desired air side conditions. It is really a solution inverter. For a water coil the simulation cannot be inverted where the mass flow rate of the water through the coil can be solved directly given an air temperature. Thus, this “controller” will numerically step through all of the water flow possibilities by a root finding technique until the mass flow rate is determined to meet the specified outlet air temperature within a specified user tolerance.

15.3.1.1 Model Description

The figure below illustrates the use of a simple controller used with a central chilled water coil (control variable Temperature). The controller reads the desired temperature setpoint from the control node (established by a SetpointManager) and modulates the chilled water flow rate at the actuator node in order to meet the desired supply (coil outlet) air temperature.

In this case, the controller simply senses the temperature at the control node and compares this value with the desired temperature setpoint. If the sensed temperature is above the desired setpoint temperature, the chilled water flow rate is increased. This controller may be used for both chilled water and hot water coils. The action parameter input is set to REVERSE for chilled water cooling coils and NORMAL for hot water heating coils.

The simple controller may also be used to control both high temperature and high humidity levels by controlling the water flow rate through a chilled water coil. Setting the controller’s control variable to TemperatureAndHumidityRatio enables this feature. In this case, the controller monitors two setpoint values, one for temperature control and the other for high humidity control. Note that two setpoint managers must be used to establish these setpoints as shown in the figure below. The limiting case for either temperature or high humidity control (i.e., the minimum supply air temperature required to meet both setpoints) is used for controlling the water flow rate through the chilled water coil. If high humidity control is the limiting case then colder supply air will be

Figure 15.30: Controller:WaterCoil used with Central Chilled Water Coil

delivered by the cooling coil to achieve proper dehumidification and some form of air reheat may be required to avoid overcooling of the zones being served by this air loop.

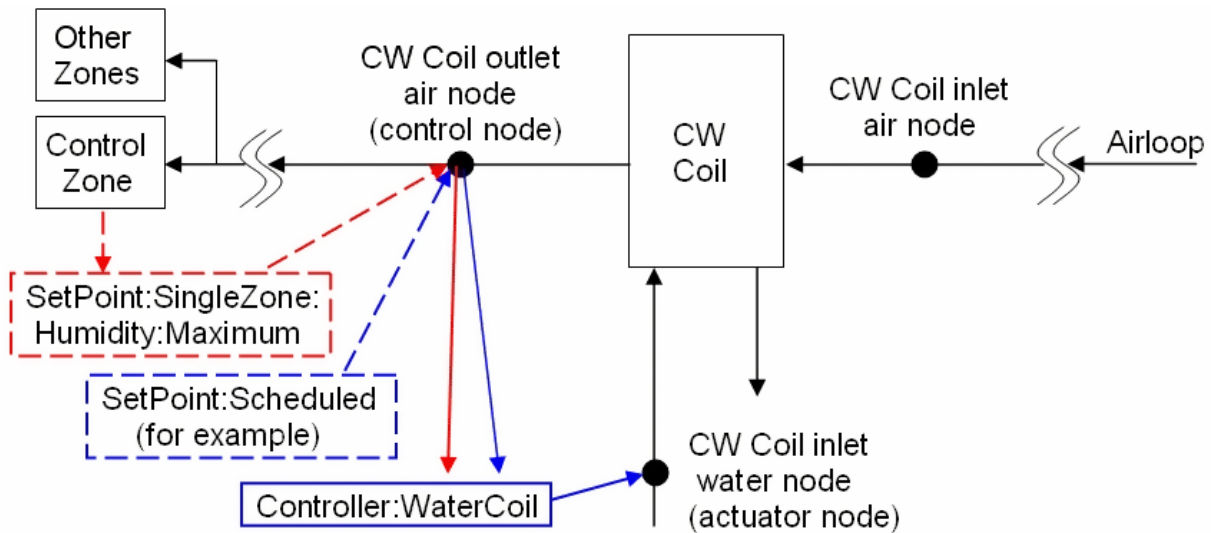

Figure 15.31: Two Setpoint managers used in Controller:WaterCoil

When the control variable `TemperatureAndHumidityRatio` is used, the controller modulates water flow through a chilled water coil to meet both a temperature and a humidity ratio setpoint. These two setpoints are placed on the control node by setpoint managers.

The model first calculates the approach temperature using the dry-bulb temperature and dew-point temperature of the air leaving the water coil:

$$T_{dp} = \text{PsyTdpFnWPb}(\omega_{SA}, P) \quad (15.689)$$

$$T_{approach} = T_{SA} - T_{dp} \quad (15.690)$$

where:

$T_{approach}$ is the approach temperature (°C)

ω_{SA} is the supply (outlet) air humidity ratio (kg/kg)

P is the outdoor barometric pressure (Pa)

T_{dp} is the supply (outlet) air dewpoint temperature (°C)

T_{SA} is the supply (outlet) air dry-bulb temperature (°C)

PsyTdpFnWPb is the EnergyPlus psychrometric function, returns dewpoint temperature given humidity ratio and barometric pressure.

The supply air dewpoint temperature required to meet the humidity ratio setpoint (placed on the control node by SetpointManager:SingleZone:Humidity:Maximum, SetpointManager:MultiZone:MaximumHumidity:Average or SetpointManager:MultiZone:Humidity:Maximum) is then calculated as a function of the humidity ratio setpoint and barometric pressure as follows:

$$T_{dp,SP} = \text{PsyTdpFnWPb}(\omega_{SP}, P) \quad (15.691)$$

where:

$T_{dp,SP}$ is the dewpoint temperature corresponding to w_{SP} (°C)

ω_{SP} is the humidity ratio setpoint (kg/kg).

In order for the dewpoint temperature of the coil's supply (outlet) air to reach $T_{dp,SP}$ the dry-bulb temperature of air leaving the cooling coil must be at $T_{dp,SP} + T_{approach}$:

$$T_{HR,SP} = T_{dp,SP} + T_{approach} \quad (15.692)$$

where: $T_{HR,SP}$ is the supply air dry-bulb temperature setpoint required to achieve the specified humidity ratio setpoint (°C).

The supply air temperature setpoint required to achieve the specified humidity ratio setpoint is then compared to the setpoint temperature required for zone temperature control, and the minimum of these two setpoint values is used as the setpoint temperature for controlling the chilled water coil.

$$T_{SP} = \text{MIN}(T_{Temp,SP}, T_{HR,SP}) \quad (15.693)$$

where:

T_{SP} = chilled water coil supply air temperature setpoint (°C)

$T_{Temp,SP}$ = supply air temperature setpoint required for zone temperature control (°C).

As described previously, the controller varies the chilled water flow rate through the coil using a root finding technique until the actual supply air temperature reaches T_{sp} within the specified tolerance:

$$T_{Actual} - T_{SP} \leq \text{Controller Convergence Tolerance} \quad (15.694)$$

where T_{Actual} is the actual air temperature leaving the cooling coil (°C).

15.3.2 Outdoor Air Damper Controller for Air Systems

When the heat exchanger assisted cooling coil is used with a furnace or unitary system (ref. AirLoopHVAC:Unitary:Furnace:HeatCool or AirLoopHVAC:UnitaryHeatCool) or DX system (ref. CoilSystem:Cooling:DX) located in an air loop (or DX system used in an outside air system), an

economizer function may be customized as necessary. For economizer control, an outdoor air controller (ref. Controller:OutdoorAir) is used to define the economizer control inputs and determine when economizer mode is active. The heat exchanger (ref. HeatExchanger:*) object provides an economizer lockout feature which disables heat recovery any time the economizer is active. This feature can be turned on and off using the heat exchanger lockout input. Heat exchanger assisted cooling coils used with the zone equipment described below disregard this economizer control feature. The heat recovery bypass control input may also be used to selectively control heat recovery.

15.3.2.1 Inputs

- Controller Name
- Relief air node
- Return air node
- Control node (the mixed air node)
- Actuated node (the outside air inlet node)
- Minimum outside air flow rate (at design) (m^3/s)
- Maximum outside air flow rate ($\dot{V}_{oa,max}$) (m^3/s)
- EconomizerChoice: *FixedDryBulb* | *FixedEnthalpy* | *DifferentialDryBulb* | *DifferentialEnthalpy* | *ElectronicEnthalpy* | *FixedDewPointAndDryBulb* | *DifferentialDryBulbAndEnthalpy* | *NoEconomizer*
- Bypasschoice: *MinimumFlowWithBypass* | *ModulateFlow*
- High temperature limit (T_{high}) ($^{\circ}\text{C}$)
- High specific enthalpy limit (h_{high}) (J/kg)
- High dewpoint temperature limit ($T_{DP,high}$) ($^{\circ}\text{C}$)
- Electronic Enthalpy limit (quadratic or cubic curve object)
- Low temperature limit (T_{low}) ($^{\circ}\text{C}$)
- Lockout: *LockoutWithHeating* | *LockoutWithCompressor*
- MinimumLimit: *FixedMinimum* | *ProportionalMinimum*
- Minimum Outdoor Air Schedule (schedule values multiply the minimum outside air flow rate)
- Minimum Fraction of Outdoor Air Schedule (schedule values sets the limit on minimum outside air fraction)
- Maximum Fraction of Outdoor Air Schedule (schedule values sets the maximum outside air fraction possible in the system)
- Name of Controller:MechanicalVentilation object

- Time-of-day economizer control schedule (economizer active when schedule values are greater than 0)
- High humidity control flag: *Yes* | *No*
- Humidstat control zone name (zone name where humidistat is located)
- Control high indoor humidity based on outdoor humidity ratio: *Yes* | *No*
- High humidity outside air flow ratio (this flow ratio is multiplied by the maximum outside air flow rate during periods of high indoor relative humidity)
- Heat Recovery Bypass Control Type: *BypassWhenWithinEconomizerLimits* | *BypassWhenOAFlowGreaterThanMinimum*

15.3.2.2 Economizer Limits

Economizer limits may be used to create single-point or multi-point controllers. The figure below shows several examples of each type of controller. Single-point economizer controllers use a single independent variable to specify the operation of the economizer. In all cases, the economizer is disabled (OFF) when the outdoor weather condition exceeds the limit. However, when a low temperature limit is used the economizer is disabled when the outdoor temperature is *below* the low dry-bulb temperature limit.

Economizer limits may also be used to create multi-point controllers where two or more limits specify the economizer operating region. The economizer is disabled (OFF) if *any single* multi-point economizer limit is exceeded.

Figure 15.32: Economizer Limit Controls

15.3.2.3 Simulation

The simulation contains 4 steps.

15.3.2.4 Step 1: Calculate the minimum outside air flow rate

The user inputs the minimum outside air flow rate (or it is automatically calculated by the program from the user's design inputs). This is converted to a mass flow rate $\dot{m}_{oa,min,des}$ using the density of dry air at 20°C. If the economizer is on an air loop then the minimum outside air flow fraction is initialized to:

$$f_{oa,min} = \dot{m}_{oa,min,des} / \dot{m}_{s,des} \quad (15.695)$$

where $\dot{m}_{s,des}$ is the design supply air mass flow rate. If the economizer is not on an air loop the minimum outside air flow fraction is initialized to:

$$f_{oa,min} = \dot{m}_{oa,min,des} / \dot{m}_{oa,max,des} \quad (15.696)$$

where $\dot{m}_{oa,max,des}$ is the user input maximum outside air volumetric flow rate converted to mass flow rate in the same manner as for the minimum outside air flow rate. If a minimum outside air schedule has been input, $f_{oa,min}$ is multiplied by the current schedule value.

15.3.2.5 Step 2: Calculate an initial outside air signal

We now define an initial outside air signal $S_{oa,init}$.

If $|T_r - T_{in}| > \Delta T_{small}$, then:

$$S_{oa,init} = (T_r - T_{mix,set}) / (T_r - T_i) \quad (15.697)$$

Otherwise:

- if $T_r < T_{mix,set}$ and $T_r \geq T_i$, $S_{oa,init}$ is set to -1;
- if $T_r < T_{mix,set}$ and $T_r < T_i$, $S_{oa,init}$ is set to 1;
- if $T_r \geq T_{mix,set}$ and $T_r \geq T_i$, $S_{oa,init}$ is set to 1;
- if $T_r \geq T_{mix,set}$ and $T_r < T_i$, $S_{oa,init}$ is set to -1.

Finally, $S_{oa,init}$ is constrained to be: $f_{oa,min} \leq S_{oa,init} \leq 1$. Basically, if the outside air can not accomplish cooling, $S_{oa,init}$ is set to $f_{oa,min}$. If it can do cooling, $S_{oa,init}$ is greater than the minimum outside air flow fraction but not greater than 1. Here:

T_r is the return air temperature (°C)

T_i is the outside air inlet temperature (°C)

$T_{mix,set}$ is the mixed air setpoint (°C)

ΔT_{small} is a small temperature difference (°C), equal to 0.00001.

15.3.2.6 Step 3: Do the on/off and limit checks

- If *EconomizerChoice* = *No Economizer*, $S_{oa,init} = f_{oa,min}$.
- If $\dot{V}_{oa,max} < \dot{V}_{small}$, $S_{oa,init} = f_{oa,min}$; \dot{V}_{small} is 0.001 m³/s.
- If the economizer is locked out, $S_{oa,init} = f_{oa,min}$.

Note: the above three checks also set the *EconomizerOperationFlag* and *HighHumidityControlFlag* to *false* (economizer and high humidity control not operating).

- If $T_i > T_{mix,set}$, $S_{oa,init} = 1$.

- If Differential dry-bulb was input as Economizer choice and $T_i > T_r$, then $S_{oa,init} = f_{oa,min}$.
- If Differential Enthalpy was input as Economizer choice and $h_i > h_r$, then $S_{oa,init} = f_{oa,min}$, where h_i and h_r are the outside air inlet and return air enthalpies.

Setpoints are checked after this which include check for Fixed dry-bulb temperature limit, Enthalpy Limit, Dewpoint Limit and Humidity ratio limit if specified.

- If Differential Enthalpy was input as Economizer choice and $h_i > h_r$, then $S_{oa,init} = f_{oa,min}$, where h_i and h_r are the outside air inlet and return air enthalpies.

Setpoints are checked after this which include check for Fixed dry-bulb temperature limit, Enthalpy Limit, Dewpoint Limit and Humidity ratio limit if specified.

- If a FixedDryBulb / FixedEnthalpy / FixedDewPointAndDryBulb / ElectronicEnthalpy was input as the economizer choice then the limits are checked as before.
- Limits are checked as follows:
 - If a high temperature limit was input and $T_{oa} > T_{high}$, $S_{oa,init} = f_{oa,min}$; where T_{oa} is the outside air temperature.
 - If an enthalpy limit was input and $h_{oa} > h_{high}$, $S_{oa,init} = f_{oa,min}$; where h_{oa} is the outside air specific enthalpy.
 - If a dewpoint temperature limit was input and $T_{DP,OA} > T_{DP,high}$, $S_{oa,init} = f_{oa,min}$; where $T_{DP,OA}$ is the outside air dewpoint temperature and $T_{DP,high}$ is the dewpoint temperature limit.
 - If an electronic enthalpy curve was input and $w_{OA} > w_{CurveOutput}$, $S_{oa,init} = f_{oa,min}$; where w_{OA} is the outside air humidity ratio and $w_{CurveOutput}$ is the curve's humidity ratio output as a function of outdoor air dry-bulb temperature.
- Another Economizer choice called DifferentialDryBulbAndEnthalpy checks the outside air temperature against return temperature and outside air enthalpy against return air enthalpy and also checks the setpoints.
- If a low temperature limit was input and $T_{oa} < T_{low}$, $S_{oa,init} = f_{oa,min}$.

Note: the above nine cases set the *EconomizerOperationFlag* to *false* (economizer not operating), otherwise the economizer is active.

- If high humidity control is specified and the zone humidistat indicates a moisture load (i.e. zone relative humidity greater than the relative humidity setpoint), the *HighHumidityOperationFlag* is set to *true*. If high humidity control is based on the outdoor humidity ratio then the *HighHumidityOperationFlag* is set to *true* only when the outdoor air humidity ratio is less than the humidistat's zone humidity ratio. A *true* HighHumidityOperationFlag also enables economizer operation in the heat exchangers as if the economizer flag used here was also set to *true* (Ref. HeatExchanger:* - field Economizer Lockout).

The economizer schedule is then checked to determine if a “push-button” type economizer control is used. When schedule values are greater than 0, the economizer is active (*EconomizerOperationFlag* = *true*). This test overrides the economizer limit checks described above in Step 3.

15.3.2.7 Step 4: Calculate the final outside air signal

If $S_{oa,init}$ is greater than $f_{oa,min}$ and less than 1 and the mixed air mass flow rate is greater than $\dot{m}_{verysmall}$ (10^{-30}) and night venting is not occurring and *HighHumidityOperationFlag* is false, then we calculate a final outside air signal S_{oa} by using the root solver method routine *SolveRegulaFalsi* to zero the residual $T_{mix,set} - T_{mix}$ by varying the outside air mass flow rate $S_{oa} \cdot \dot{m}_{mix}$. Mass and energy balance are used to obtain the mixed air humidity ratio and enthalpy from the recirculated air and outside air inlet conditions. The psychrometric function *PsyTdbFnHW* is used to obtain T_{mix} from the mixed air enthalpy and humidity ratio.

Otherwise, $S_{oa} = S_{oa,init}$.

15.3.2.8 Step 5: calculate the outside air flow rate and apply final constraints

If *BypassChoice* = *True* and *HighHumidityOperationFlag* = *false*, $S_{oa} = f_{oa,min}$.

If the *HighHumidityOperationFlag* is *true*, then:

$$S_{oa} = \max \left(f_{oa,min}, OAF_{lowRatio} \frac{\dot{m}_{oa,max,des}}{\dot{m}_{mix}} \right) \quad (15.698)$$

If night ventilation is occurring, $S_{oa} = 1$. Note that night ventilation has priority over the above constraints.

Now, the outside air flow rate is calculated:

$$\dot{m}_{oa} = S_{oa} \cdot \dot{m}_{mix} \quad (15.699)$$

Next, calculate the outside air mass flow rate:

If *EconomizerOperationFlag* is *true* and *HighHumidityOperationFlag* is *false*, then

$$\dot{m}_{oa} = S_{oa} \cdot \dot{m}_{oa,max,des} \quad (15.700)$$

Otherwise:

$$\dot{m}_{oa} = S_{oa} \cdot \dot{m}_{mix} \quad (15.701)$$

Then the following constraints are applied:

- \dot{m}_{oa} must be greater than or equal to the air primary loop total exhaust air mass flow rate ($\dot{m}_{exhaust}$).
- If *MinimumLimit* = *Fixed Minimum*, \dot{m}_{oa} must be greater than or equal to the minimum outside air mass flow rate.
- If the Minimum Fraction of Outdoor Air Schedule or the Maximum Fraction of Outdoor Air Schedule is available, outside air fraction $S_{oa} = \dot{m}_{oa} / \dot{m}_{mix}$ is checked against those fractions from the schedule.

$$S_{oa} = \text{Maximum}(\text{Minimum OA fraction}, S_{oa}) \quad (15.702)$$

$$S_{oa} = \text{Minimum}(\text{Maximum OA fraction}, S_{oa}) \quad (15.703)$$

- \dot{m}_{oa} must be \leq the maximum outside air mass flow rate.
- If there is an EMS override set $\dot{m}_{oa} = \text{EMS actuated OA mass flow rate}$.
- If there is a demand limiting override set $\dot{m}_{oa} = \text{Demand limiting OA mass flow rate}$.
- \dot{m}_{oa} must be $\leq \dot{m}_{mix}$.

If heat recovery bypass control is selected, the type of control determines how heat recovery is simulated. If `BypassWhenWithinEconomizerLimits` is selected, heat recovery is only active when the `EconomizerOperationFlag` is false. If `BypassWhenOAFlowGreaterThanMinimum` is selected *and* the `EconomizerOperationFlag` is true *and* the outside air mass flow rate is greater than the minimum flow rate, heat recovery is disabled, otherwise heat recovery is active. The heat recovery bypass control option is used to optimize heat recovery in heating mode. Heat recovery is commonly used to reduce the cooling load when outdoor conditions are higher than indoor conditions, however, when outdoor conditions are favorable the heat exchanger can be turned off and the economizer may be used to also reduce the cooling load. Economizer mode is typically involves increasing the outdoor air flow rate. At some point the outdoor air flow rate must be reduced and the heat exchanger should be turned back on to reduce or avoid an indoor heating requirement. This option will typically be used with some form of supply air temperature control used with the heat recovery equipment (Ref. `HeatExchanger`).

15.3.2.9 Step 6: Set the relief air mass flow rate

$$\dot{m}_{relief} = \max(0, \dot{m}_{oa} - \dot{m}_{exhaust}) \quad (15.704)$$

15.3.3 Outdoor Air Damper Controller for Zone Energy Recovery Ventilator

The stand alone energy recovery ventilator (ERV) controller is used solely in conjunction with a stand alone energy recovery ventilator (see figure below).

This controller object mimics virtually all of the control logic available for a conventional air-side economizer as embodied in the object `Controller:OutdoorAir`. However, this controller is only used with the stand alone energy recovery ventilator object (dedicated to serving a single zone, without a traditional air distribution system) while the `Controller:OutdoorAir` is used with systems that utilize an air loop to provide conditioned air to one or more zones. The purpose of this controller is to signal the object `HeatExchanger:AirToAir:SensibleAndLatent` that favorable conditions are available for free cooling and heat exchange should be suspended (i.e., air flow is fully bypassed around a fixed-plate heat exchanger or the rotation of a rotary heat exchanger is stopped). A time-of-day schedule may also be used to simulate a “push-button” type economizer. The air flow rate through the stand alone ERV remains the same regardless of whether the controller is signaling for economizer (free cooling) operation or not. In this way, this controller is very similar to `Controller:OutdoorAir` with the field `Economizer Control Action Type` set to “`MinimumFlowWithBypass`”. However, the supply and exhaust air flow rates may be modified in response to a high indoor humidity condition (i.e., when the zone relative humidity is “predicted” to exceed the setpoint, at times the actual zone relative humidity may be slightly below the setpoint. Ref. `Zone/Sys Moisture Load Rate Predicted`.) and works in a similar fashion to the outside air controller where the air flow rates are adjusted based on a user specified air flow *ratio*.

Figure 15.33: Schematic of the `ZoneHVAC:EnergyRecoveryVentilator` Compound Object

15.3.3.1 Controller Logic

In many ways, the logic for this controller follows that established for the object `Controller:OutdoorAir`. Nearly the same computations (source code) are used for this controller as for `Controller:OutdoorAir`, except the addition of a few calculations that are unique for this stand alone ERV controller. Refer to the *Simulation* discussion for the outdoor air controller to review the calculation procedure. In some instances local variables used in the `Controller:OutdoorAir` computations are set to specific values for `ZoneHVAC:EnergyRecoveryVentilator:Controller` to allow the same computations and logic to be used for both controllers. The logic that is being applied for `ZoneHVAC:EnergyRecoveryVentilator:Controller` is presented below.

As explained above the controller senses when air conditions are such that heat exchange by the air-to-air heat exchanger should be suspended to provide free cooling to the zone, thereby reducing the amount of mechanical cooling that needs to be provided by other equipment. The inputs for this controller specify temperature and/or enthalpy conditions that are used to trigger economizer operation. An economizer lockout input is provided in the heat exchanger object and is used for customizing heat exchanger performance during economizer operation. Heat exchange is suspended only if the heat exchanger's economizer lockout input is set to Yes.

The user can enter a high and low temperature limit for economizer operation. When the supply inlet (outdoor) air is between these two values, heat exchange is suspended while air flow rates remain unchanged. This logic represents a conventional single-point temperature economizer control. If the user wishes to model differential temperature control, EXHAUST AIR TEMP LIMIT should be specified in the proper input field. In this case, heat exchange is suspended whenever the temperature of the exhaust air is greater than the temperature of the outdoor air. The user still needs to set the low temperature limit to restart the heat exchange process when the outdoor temperature falls too low.

A high dewpoint temperature limit may also be specified. When the supply inlet (outdoor) air is below this limit, heat exchange is suspended while air flow rates remains unchanged. The user still needs to set the low temperature limit to restart the heat exchange process when the outdoor temperature falls too low.

Similar logic can be used with air enthalpy. The user can enter a high enthalpy limit, and heat exchange between the supply and exhaust air streams will be suspended when the outdoor air enthalpy falls below this value. This logic represents single-point enthalpy economizer control. If the user wishes to model differential enthalpy control, EXHAUST AIR ENTHALPY LIMIT should be specified in the proper input field. Regardless of modeling single-point enthalpy or differential enthalpy control, the user still needs to set the low temperature limit to restart the heat exchange process when the outdoor temperature falls too low.

The user may also specify an electronic enthalpy curve object to represent a variable enthalpy controller. A quadratic or cubic curve is used in this case. The output of this curve would represent the maximum outdoor humidity ratio allowed as a function of outdoor dry-bulb temperature.

The air flow rates through the stand alone ERV may also be modified based on a high indoor relative humidity condition. The change in air flow rates may occur at any time the indoor relative humidity is high or when the indoor relative humidity is high *and* the outdoor humidity ratio is lower than the indoor humidity ratio. This control mode modifies the air flow rates according to the user specified high humidity outside air flow ratio. When high humidity control is active, heat exchange is suspended in the same manner as if an economizer were used and, as with economizer operation, heat exchange is suspended only if the heat exchanger's economizer lockout input is set to Yes.

The model is flexible, and checks all limits established by the user in the object's input data. The model initially assumes that heat exchange should be suspended, and then checks each one of the limits that the user has set (single-point temperature, differential temperature, single-point enthalpy and differential point enthalpy, single-point dewpoint or electronic (variable) enthalpy). If any of the limits entered by the user is exceeded, then economizer operation is terminated and heat exchange between the supply and exhaust air streams is modeled.

15.4 Baseboard Heaters

There are five different baseboard models in EnergyPlus. Two of these models are convection only while three of these models have both radiative and convective heat transfer to the zone. The hot water and electric baseboard models with only convection provide a simple convective heat gain to the space via the baseboard unit. The models for these convection only units are fairly simple and provide convective heating to the space in an attempt to meet whatever heating load is present. The convection only models do not require iteration or resimulation of the surface heat balances because it is assumed that there is no radiation given off by the unit.

The hot water, electric, and steam baseboard models with radiation and convection allow the user to account for some of the energy given off by the unit to be via radiation. These models are both more realistic and more sophisticated. They are more realistic because most baseboard units will give off some amount of radiation, even if in many cases that fraction is small. They are more sophisticated because adding radiation to a space is more complicated than simply adding heat to the zone air heat balance directly via convection. The addition of radiation energy involves distribution of that radiation and also the need to resimulate the surface heat balances to account

for this new thermal energy incident on surfaces throughout the space. This also then means that the baseboard heaters with radiation and convection will take longer to simulate since all Zone HVAC models that have a radiant component need to iterate through the surface heat balances more than once. These iterations slow down the simulation but are necessary to correctly account for the changes to the radiation balance on the surfaces in the zone.

This section provides some of the calculation details for the five different baseboard models. More information on the input required for these models can be found in the Input/Output Reference for EnergyPlus.

15.4.1 Hot Water Baseboard Heater with Only Convection

15.4.1.1 Model Description

The convective water baseboard heater (Ref. ZoneHVAC:Baseboard:Convective:Water) is a simple model for establishing a convective-only heat addition to a space through a baseboard heater. In most situations, the baseboard heater does give a significant amount of heat off via natural convection, but some heat is given off via radiation. In this model, the radiant component is ignored and all heat is assumed to be delivered to the space via convection. The baseboard heater is supplied with hot water from the primary system which is circulated through the inside of a finned tube within the zone. Heat is transferred from the water inside the pipe, through the tube and fins, and eventually convected to the surrounding air within the zone. EnergyPlus then assumes that this heat is evenly spread throughout the zone thus having an immediate impact on the zone air heat balance which is used to calculate the mean air temperature (MAT) within the zone.

In general, the hot water baseboard heater resides in the equipment list of two different half loops—the zone equipment loop (the air side of the baseboard unit) and the plant demand loop (the water side of the baseboard unit). The model utilizes an effective UA value to handle the heat exchange between the water loop and the zone air. From there, it employs an effectiveness-NTU heat exchanger model to determine the heat transfer between the water and the zone air. This is necessary because during the simulation only the inlet water and “inlet air” (assumed to be zone air) is known. As a result, the effectiveness-NTU heat exchanger methodology is better suited to determine the performance of the system than the Log Mean Temperature Difference (LMTD) approach to characterizing heat exchangers.

15.4.1.2 Convective Water Baseboard Heater Inputs

Like many other HVAC components, the convective-only water baseboard model requires a unique identifying name, an availability schedule, and water side inlet and outlet nodes. These define the availability of the unit for providing conditioning to the zone and the node connections that relate to the primary system or the plant demand side loop. In addition, the user specifies a convergence tolerance to help define the ability of the local controls to tightly control the system output. In almost all cases, the user should simply accept the default value for the convergence tolerance unless engaged in an expert study of controls logic in EnergyPlus.

The input also requires a UA value and a maximum design flow rate for the unit. Both of these parameters can be auto-sized by EnergyPlus if the user so chooses. The UA value corresponds to the convective heat transfer from the water to the pipe, the conduction through the pipe and fin material, and the natural convection from the pipe/fins to the zone air. The maximum flow rate and UA value define the performance and maximum output of the baseboard unit.

15.4.1.3 Simulation and Control

The simulation of the convective water baseboard unit follows a standard effectiveness-NTU heat exchanger methodology. It begins by calculating the product of the specific heat and mass flow rate for both the air and water sides of the baseboard unit. In the initialization of the model, it is assumed that the air mass flow rate is equal to 2.0 times the water mass flow rate. The purpose of this calculation is to provide some reasonable estimate of the air mass flow rate so that the model can calculate system performance correctly. This calculation is kept constant throughout the rest of the simulation.

Each system time step, the baseboard attempts to meet any remaining heating requirement of the zone through the following calculations:

$$C_{water} = c_{p,water} \dot{m}_{water} \quad (15.705)$$

$$C_{air} = c_{p,air} \dot{m}_{air} \quad (15.706)$$

$$C_{max} = MAX(C_{air}, C_{water}) \quad (15.707)$$

$$C_{min} = MIN(C_{air}, C_{water}) \quad (15.708)$$

$$C_{ratio} = C_{min} / C_{max} \quad (15.709)$$

$$\varepsilon = 1 - e^{\left(\frac{NTU^{0.22}}{C_{ratio}} e^{(-C_{ratio} NTU^{0.78})} - 1 \right)} \quad (15.710)$$

Once the effectiveness is determined, the outlet conditions for the baseboard unit are determined using the following equations:

$$T_{air,outlet} = T_{air,inlet} + \varepsilon (T_{water,inlet} - T_{air,inlet}) C_{min} / C_{air} \quad (15.711)$$

$$T_{water,outlet} = T_{water,inlet} - (T_{air,outlet} - T_{air,inlet}) C_{air} / C_{water} \quad (15.712)$$

Now that the outlet conditions have been determined, the output of the baseboard unit (all convective) is calculated from:

$$Output(Convection) = C_{water} (T_{water,inlet} - T_{water,outlet}) \quad (15.713)$$

If the unit was scheduled off or there is no water flow rate through the baseboard unit, then by definition there will be no heat transfer from the unit to the zone. The model assumes no heat storage in the baseboard unit itself and thus no residual heat transfer in future system time steps due to heat storage in the water or metal of the baseboard unit.

15.4.1.4 References

The effectiveness-NTU method is taken from Incropera and DeWitt, Fundamentals of Heat and Mass Transfer, Chapter 11.4, p. 523, eq. 11.33. However, the user can always refer to any heat transfer textbook for more information on heat exchanger methodology or the ASHRAE Handbook series for general information on different system types as needed.

15.4.2 Electric Baseboard Heater with Only Convection

15.4.2.1 Model Description

The input object ZoneHVAC:Baseboard:Convective:Electric is used to define an electric baseboard heaters that assumes only convective heat addition to a zone from the unit. In most situations, the baseboard heater does give a significant amount of heat off via natural convection, but some heat is given off via radiation. In this model, the radiant component is ignored and all heat is assumed to be delivered to the space via convection. The baseboard heater provides heat to the zone via electric resistance heating and thus consumes electricity rather than be supplied with hot water. EnergyPlus then assumes that this heat is evenly spread throughout the zone thus having an immediate impact on the zone air heat balance which is used to calculate the mean air temperature (MAT) within the space.

15.4.2.2 Convective Electric Baseboard Heater Inputs

Like many other HVAC components, the convective-only electric baseboard model requires a unique identifying name and an availability schedule. The availability schedule defines when unit is available to provide heating to the zone. The input also requires a capacity and efficiency for the electric baseboard. While the efficiency is a required input that defaults to unity, the user can choose to have the capacity auto-sized by EnergyPlus.

15.4.2.3 Simulation and Control

When the unit is available and there is a heating load within a space, the electric baseboard unit will meet the entire remaining provided that it has enough capacity to do so. The energy consumption of the baseboard heat is calculated using the user-supplied efficiency and the current load on the baseboard unit as follows:

$$Energy_{electric} = Heating_{baseboard} / Efficiency \quad (15.714)$$

If the unit was scheduled off or there is no heating load for the zone, then there will be no convective heat transfer to the zone from the baseboard unit. The model assumes no heat storage in the baseboard system itself and thus no residual heat transfer in future system time steps due to heat storage in the metal of the baseboard unit.

15.4.2.4 References

While there are no specific references for this model as it is fairly intuitive, the user can always refer to the ASHRAE Handbook series for general information on different system types as needed.

15.4.3 Hot Water Baseboard Heater with Radiation and Convection

15.4.3.1 Model Description

The input object ZoneHVAC:Baseboard:RadiantConvective:Water is used to model a hot water baseboard unit that transfers heat to the zone air via convection and to the surfaces and people via radiation. The actual system impact of the baseboard heater on the zone is the sum of the convective heat transfer to the zone air, the additional convective heat transfer from the surfaces

to the zone air after they have been heated, and the radiant heat transferred to people which is assumed to be added to the zone air heat balance by convection from people to the zone air. This actual convective power is used to directly meet any remaining heating requirement in the zone based on the thermostatic controls. The model thus improves the accuracy of thermal comfort predictions by allowing the impact of radiation from the baseboard unit to people in the zone to be taken into account while better accounting for the actual effect of the radiation from the baseboard unit to surfaces.

The baseboard heater is supplied with hot water from the primary system which is circulated through the inside of a finned tube within the space. This could also be used to model a hot water radiator (convector in the UK). Heat is transferred from the water inside the pipe, through the tube and fins. It is also not only convected to the surrounding air but also radiated to the surfaces and people within the zone. The user is allowed to specify the percentage of radiant heat from the heater to the surfaces as well as how that radiation is distributed to individual surfaces through the use of radiant distribution fractions. In addition, the user has the option to define what fraction of radiation leaving the heater is incident directly on a person within the zone for thermal comfort purposes. This amount of heat is then used in the thermal comfort models in the same way that radiation from a high temperature radiant heater is utilized.

This model calculates a UA value using the log mean temperature difference (LMTD) method for heat exchangers. The calculation is based on standard conditions of both fluids inputted by the user who obtains the information in a rating document or manufacturer's literature. Overall energy balances to the hot water and air account for the heat exchange between the water loop and the zone air. Once the UA for the baseboard heater has been determined, the model employs an effectiveness-NTU heat exchanger method during simulation to determine the heat transfer between the water and zone air. This is necessary because during the simulation only the inlet water and "inlet air" (assumed to be zone air) temperatures are known. As a result, the effectiveness-NTU heat exchanger methodology is better suited to determine the performance of the system during the simulation than the Log Mean Temperature Difference (LMTD) approach to characterizing heat exchangers.

15.4.3.2 Water Baseboard Heater Inputs

Like many other HVAC components, the water baseboard model requires a unique identifying name, an availability schedule, and water inlet and outlet nodes. These define the availability of the unit for providing heating to the zone and the node connections that relate to the primary system. For the calculation of the UA value of the unit, standard conditions of both fluids are necessary. The user specifies such standard conditions based on information obtained from manufacturers directly or other documents such as the I = B = R rating guide. The information required includes the rated capacity, average water temperature, water mass flow rate, and standard inlet air temperature. However, the model also has the ability to autosize the rated capacity, which allows the user simulate a generic baseboard unit when manufacturer's data is unavailable.

The UA value characterizes the total heat transfer to the zone from the unit including the convective heat transfer from the water to the tube, the conduction through the tube and fin material, the natural convection from the tube/fins to the zone air, and radiation to the zone surfaces. In addition, a convergence tolerance is requested of the user to help define the ability of the local controls to manage the system output. In almost all cases, the user should simply accept the default value for the convergence tolerance unless engaged in an expert study of controls logic

in EnergyPlus.

Many of the inputs for the radiant heat transfer portion of the hot water baseboard model are the same as for the high temperature radiant heater model. The user inputs the fraction radiant and the fraction of radiant energy incident both on people and on surfaces as this information is required to calculate the radiant energy distribution from the heater to people and surfaces in the zone. The sum of these radiant distribution fractions (surfaces and people) must sum to unity, and each water baseboard heater is allowed to distribute radiant energy to up to 20 surfaces.

15.4.3.3 Simulation and Control

One difference between the model for this baseboard unit and the convection-only baseboard model is that this model determines the UA value of the unit based on rated heating capacities available in manufacturers' literature. Almost all baseboards or radiators are rated under standard conditions such as the water flow rate, the inlet air temperature, and the average water temperature and thus this information can be obtained from manufacturers. Based on this user supplied information, the model determines the UA value of the unit, employing the log mean temperature difference (LMTD) heat exchanger methodology. During the simulation, this UA value is then used to determine the heating output from the baseboard heater. So, EnergyPlus calculates the UA value once from standard conditions of the air and water provided by the user during initialization and uses this constant UA value throughout the simulation for this baseboard unit.

Base on manufacturer's information for the rated capacity, the rated water flow rate, and the rated average water temperature, standard conditions such as the rated heating capacity (q_{std}), the average water temperature ($T_{w,avg}$), and the water mass flow rate (\dot{m}_w) can be determined based on these user-supplied inputs. The standard water inlet temperature ($T_{w,in}$) and outlet temperature ($T_{w,out}$) are obtained from the following expressions:

$$T_{w,in} = \frac{q_{std}}{2\dot{m}_w c_{p,w}} + T_{w,avg} \quad (15.715)$$

$$T_{w,out} = 2T_{w,avg} - T_{w,in} \quad (15.716)$$

where $c_{p,w}$ is the specific heat capacity of the water (calculated based on the average water temperature).

The model then assumes the air mass flow rate is given by the following expression:

$$\dot{m}_{a,std} = 0.0062 + .0000275\dot{Q}_{design} \quad (15.717)$$

Since the inlet air temperature ($T_{a,in}$) is assumed to be 18°C and the heating capacity of the unit, i.e. the rated capacity, are known, the outlet air temperature ($T_{a,out}$) can be obtained from the following expression:

$$T_{a,out} = \frac{q_{std}}{\dot{m}_{a,std} c_{p,a}} + T_{a,in} \quad (15.718)$$

where $c_{p,a}$ is the specific heat capacity of the air at standard conditions.

At this point, all four temperatures (air inlet, air outlet, water inlet, and water outlet) are known, and the mean temperature difference (ΔT_{lm}) can be obtained from the following expressions:

$$\Delta T_1 = T_{w,in} - T_{a,out} \quad (15.719)$$

$$\Delta T_2 = T_{w,out} - T_{a,in} \quad (15.720)$$

$$\Delta T_{lm} = \frac{\Delta T_1 - \Delta T_2}{\log \left(\frac{\Delta T_1}{\Delta T_2} \right)} \quad (15.721)$$

The UA value of the baseboard unit is thus:

$$UA = \frac{q_{std}}{\Delta T_{lm}} \quad (15.722)$$

The user is able to specify both rated average water temperature and rated water mass flow rate when manufacturer's data is available. However, if this information is not available, EnergyPlus will use default values for both of these fields.

If desired, EnergyPlus will autosize the rated capacity of the baseboard unit when the user does not know this value. In this case, the model employs the design heating load and design water mass flow rate in the zone, so that the standard water inlet and outlet temperatures are estimated as:

$$T_{w,in} = \frac{q_{design}}{2\dot{m}_{w,design}c_{p,w}} + T_{w,avg} \quad (15.723)$$

$$T_{w,out} = 2T_{w,avg} - T_{w,in} \quad (15.724)$$

where q_{design} is the design zone heating load estimated by EnergyPlus.

Similarly, the model estimates the air outlet temperature using the air mass flow rate calculated above:

$$T_{a,out} = \frac{q_{design}}{\dot{m}_{a,std}c_{p,a}} + T_{a,in} \quad (15.725)$$

Temperatures at all four locations (air inlet, air outlet, water inlet, and water outlet) are now known and the UA value is determined in the same way as shown above.

Once the UA value is determined, the model employs an effectiveness-NTU heat exchanger method to determine the total overall heat transfer between the water and the zone air in the same way that the convection-only model does (see “Hot Water Baseboard Heater with Only Convection” model). For this calculation, the actual air mass flow rate is calculated from the design air mass flow rate and a ratio of the actual water mass flow rate to the maximum water mass flow rate:

$$\dot{m}_a = \dot{m}_{a,std} \frac{\dot{m}_w}{\dot{m}_{w,max}} \quad (15.726)$$

The model then determines the radiant heat addition by:

$$q_{rad} = q \cdot Frac_{rad} \quad (15.727)$$

where q_{rad} is the total radiant heat transfer from the baseboard unit, q is the lesser of the heating capacity of the unit and the zone heating load, and $Frac_{rad}$ is the user-defined radiant fraction for the baseboard unit. The radiant heat additions to people and surfaces are thus:

$$q_{people} = q_{rad} \cdot Frac_{people} \quad (15.728)$$

$$q_{surface,i} = q_{rad} \cdot Frac_{surface,i} \quad (15.729)$$

where q_{people} is the radiant heat transfer to people, $q_{surface,i}$ is the heat radiated to surface i , $Frac_{people}$ is the fraction of the heat radiated to people, and $Frac_{surface,i}$ is the fraction of the heat radiated to surface i .

Based on these above equations, the model then distributes the radiant heat additions to the appropriate surfaces and people in the zone and the convective heat addition to air in the zone. The surface heat balances are then recalculated to account for the radiant heat added to the zone surfaces by the baseboard unit. It is assumed that the radiant heat incident on people in the zone is taken into account in the thermal comfort models and then is converted to convection to the zone so that the zone heat balance includes this amount of heat which would otherwise be lost (see the High Temperature Radiant Heater Model for more information about how radiant energy added by these types of systems affect thermal comfort). The load met, the actual convective system impact for the baseboard heater, q_{req} , is calculated using the following equation:

$$q_{req} = (q_{surf,c} - q_{surf,z}) + q_{conv} + q_{people} \quad (15.730)$$

where $q_{surf,c}$ is the convection from the surfaces to the air in the zone once the radiation from the baseboard unit is taken into account; $q_{surf,z}$ is the convection from the surfaces to the air in the zone when the radiation from the baseboard unit was zero; q_{conv} is the convective heat transfer from the heater to the zone air; and q_{people} is radiant heat to the people.

The accounting of the radiant heat added to the zone (surfaces) by the water baseboard heater is very similar to the method used in the high temperature radiant system model. After all the system time steps have been simulated for the zone time step, an “average” zone heat balance calculation is done (similar to the radiant systems). If the unit was scheduled off or there is no water flow rate through the baseboard unit, then, there will be no heat transfer from the unit. The model assumes no heat storage in the unit itself and thus no residual heat transfer in future system time steps due to heat storage in the water or metal of the unit.

15.4.4 Electric Baseboard Heater with Radiation and Convection

15.4.4.1 Model Description

The input object ZoneHVAC:Baseboard:RadiantConvective:Electric is used to specify electric baseboard heaters that include both convective and radiant heat additions to a zone from a baseboard heater that uses electricity rather than hot water as a heating source. The radiant heat transfer to people as well as surfaces within a zone is determined in the same fashion as both hot water and steam baseboard heaters with radiation and convection heat transfer. The electric baseboard

heater receives energy via electric resistance heating. Radiant heat calculated by the user-defined fraction from the heating capacity of a baseboard unit impacts the surface heat balances and thermal comfort of occupants in a zone. EnergyPlus then assumes that the remaining convective gains from the unit are evenly spread throughout the space thus having an immediate impact on the zone air heat balance which is used to calculate the mean air temperature (MAT) within the space.

15.4.4.2 Convective Electric Baseboard Heater Inputs

Like many other HVAC components, the electric baseboard model requires a unique identifying name and an availability schedule. The availability schedule defines when the unit can provide heating the zone. The input also requires a capacity and efficiency for the unit. While the efficiency is a required input that defaults to unity, the capacity can be chosen to be autosized by EnergyPlus.

All inputs for the radiant heat calculation are the same as the water and steam baseboard heater with radiation and convection models in EnergyPlus. Users are required to input fractions that specify the fraction of the total radiant heat delivered directly to surfaces as well as people in a space. The sum of of these radiant distribution fractions must sum to unity, and each electric baseboard heater is allowed to distribute energy to up to 20 surfaces.

15.4.4.3 Simulation and Control

The simulation and control of this model is fairly straightforward. When the unit is available and there is a heating load within a space, the electric baseboard unit will attempt to meet the entire remaining heating load if it has enough capacity to do so. If the zone heating load is greater than the baseboard heating capacity, then the baseboard unit will run at its capacity. The model then determines the radiant heat emitted by the baseboard unit using the following equation:

$$q_{rad} = q \cdot Frac_{rad} \quad (15.731)$$

where q_{rad} is the total radiant heat transfer from the baseboard unit, q is the lesser of the heating capacity of the unit and the zone heating load, and $Frac_{rad}$ is the user-defined radiant fraction for the baseboard unit. The radiant heat additions to people and surfaces are thus:

$$q_{people} = q_{rad} \cdot Frac_{people} \quad (15.732)$$

$$q_{surface,i} = q_{rad} \cdot Frac_{surface,i} \quad (15.733)$$

where q_{people} is the radiant heat transfer to people, $q_{surface,i}$ is the heat radiated to surface i , $Frac_{people}$ is the fraction of the heat radiated to people, and $Frac_{surface,i}$ is the fraction of the heat radiated to surface i .

Based on these above equations, the model then distributes the radiant heat additions to the appropriate surfaces and people in the zone and the convective heat addition to air in the zone. The surface heat balances are then recalculated to account for the radiant heat added to the zone surfaces by the baseboard unit. It is assumed that the radiant heat incident on people in the zone is taken into account in the thermal comfort models and then is converted to convection to the zone so that the zone heat balance includes this amount of heat which would otherwise be lost (see the High Temperature Radiant Heater Model for more information about how radiant energy added by

these types of systems affect thermal comfort). The load met, the actual convective system impact for the baseboard heater, q_{req} , is calculated using the following equation:

$$q_{req} = (q_{surf,c} - q_{surf,z}) + q_{conv} + q_{people} \quad (15.734)$$

where $q_{surf,c}$ is the convection from the surfaces to the air in the zone once the radiation from the baseboard unit is taken into account; $q_{surf,z}$ is the convection from the surfaces to the air in the zone when the radiation from the baseboard unit was zero; q_{conv} is the convective heat transfer from the heater to the zone air; and q_{people} is radiant heat to the people.

The accounting of the radiant heat added to the zone (surfaces) by the electric baseboard heater is very similar to the method used in the high temperature radiant system model. After all the system time steps have been simulated for the zone time step, an “average” zone heat balance calculation is done (similar to the radiant systems).

The energy consumption of the baseboard heater is calculated using the user-supplied efficiency and the actual convective system impact calculated as

$$Q_{elec} = \frac{q}{\eta} \quad (15.735)$$

where Q_{elec} is the energy consumption and η is the efficiency of the unit.

If the unit was scheduled off or there is no heating load for the zone, then there will be no heat transfer from the unit. The model assumes no heat storage in the baseboard unit itself and thus no residual heat transfer in future system time steps due to heat storage in the metal of the baseboard unit.

15.4.4.4 References

While there are no specific references for this model as it is fairly intuitive, the user can always refer to the ASHRAE Handbook series for general information on different system types as needed.

15.4.5 Steam Baseboard Heater with Radiation and Convection

15.4.5.1 Model Description

The input object ZoneHVAC:Baseboard:RadiantConvective:Steam is used to specify steam baseboard heaters that include both convective and radiant heat additions to a zone from a baseboard heater that uses steam rather than hot water or electricity as a heating source. The radiant heat transfer to people as well as surfaces within a zone is determined in the same fashion as both hot water and electric baseboard heaters with radiation and convection heat transfer. The steam baseboard heater produces heat mostly as a result of the condensation of steam inside the baseboard unit. Some sensible heat is also extracted through subcooling of the condensed steam (water) below the phase change temperature. Since it is assumed that the steam temperature is much greater than the zone temperature, all of the heat generated by the phase change and subcooling are assumed to be transferred to the zone. Radiant heat calculated by the user-defined fraction from the heating provided by the baseboard unit impacts the surface heat balances and thermal comfort of occupants in a zone. EnergyPlus then assumes that the remaining convective gains from the unit are evenly spread throughout the space thus having an immediate impact on the zone air heat balance which is used to calculate the mean air temperature (MAT) within the space.

This model determines the heating provided by the unit from the sum of the latent heat transfer and sensible cooling of water in a similar fashion as the steam coil model in EnergyPlus does. Overall energy balances to the steam and air handle the heat exchange between the steam loop and the zone air. The mass flow rate of steam is determined based on the heating demand in the zone. The model requests the user input the desired degree of subcooling so that it determines the heating rate from the heater due to the cooling of the condensate.

15.4.5.2 Steam Baseboard Heater Inputs

The steam baseboard model requires a unique identifying name, an available schedule, and steam inlet and outlet nodes. These define the availability of the unit for providing heating to the zone and the node connections that relate to the primary system. It also requires the desired degree of subcooling to calculate the heating capacity and temperature of the condensate. A maximum design flow rate is required, and the user can request this parameter to be auto-sized by EnergyPlus. In addition, a convergence tolerance is requested of the user to control the system output. In almost all cases, the user should simply accept the default value for the convergence tolerance unless engaged in an expert study of controls logic in EnergyPlus.

All of the inputs used to characterize the radiant heat transfer are the same as for the water and electric radiant-convective baseboard heater models in EnergyPlus. User inputs for the radiant fraction and for the fraction of radiant energy incident both on people and on surfaces are required to calculate radiant energy distribution from the heater to the people and surfaces. The sum of these radiant distribution fractions must sum to unity, and each steam baseboard heater is allowed to distribute energy to up to 20 surfaces.

15.4.5.3 Simulation and Control

The algorithm for the steam baseboard model with radiation and convection is similar to the steam coil model in EnergyPlus while the simulation of radiant components is the same as the water radiant-convective baseboard model. This model initializes all conditions at the inlet node such as mass flow rate, temperature, enthalpy, and humidity ratio. The model then calculates the heating output of the steam baseboard (q) using:

$$q = \dot{m}_s(h_{fg} + c_{pw}\Delta t) \quad (15.736)$$

where \dot{m}_s is the mass flow rate of steam in kg/s, h_{fg} is the heat of vaporization of steam in J/kg, c_{pw} is the specific heat of water in J/kg.K, and Δt is the degree of subcooling in °C.

The outlet steam temperature is then calculated from:

$$T_{s,out} = T_{s,in} - \Delta t \quad (15.737)$$

The model then determines the radiant heat emitted by the baseboard unit using the following equation:

$$q_{rad} = q \cdot Frac_{rad} \quad (15.738)$$

where q_{rad} is the total radiant heat transfer from the baseboard unit, q is the lesser of the heating capacity of the unit and the zone heating load, and $Frac_{rad}$ is the user-defined radiant fraction for the baseboard unit. The radiant heat additions to people and surfaces are thus:

$$q_{people} = q_{rad} \cdot Frac_{people} \quad (15.739)$$

$$q_{surface,i} = q_{rad} \cdot Frac_{surface,i} \quad (15.740)$$

where q_{people} is the radiant heat transfer to people, $q_{surface,i}$ is the heat radiated to surface i , $Frac_{people}$ is the fraction of the heat radiated to people, and $Frac_{surface,i}$ is the fraction of the heat radiated to surface i .

Based on these above equations, the model then distributes the radiant heat additions to the appropriate surfaces and people in the zone and the convective heat addition to air in the zone. The surface heat balances are then recalculated to account for the radiant heat added to the zone surfaces by the baseboard unit. It is assumed that the radiant heat incident on people in the zone is taken into account in the thermal comfort models and then is converted to convection to the zone so that the zone heat balance includes this amount of heat which would otherwise be lost (see the High Temperature Radiant Heater Model for more information about how radiant energy added by these types of systems affect thermal comfort). The load met, the actual convective system impact for the baseboard heater, q_{req} , is calculated using the following equation:

$$q_{req} = (q_{surf,c} - q_{surf,z}) + q_{conv} + q_{people} \quad (15.741)$$

where $q_{surf,c}$ is the convection from the surfaces to the air in the zone once the radiation from the baseboard unit is taken into account; $q_{surf,z}$ is the convection from the surfaces to the air in the zone when the radiation from the baseboard unit was zero; q_{conv} is the convective heat transfer from the heater to the zone air; and q_{people} is radiant heat to the people.

The accounting of the radiant heat added to the zone (surfaces) by the steam baseboard heater is very similar to the method used in the high temperature radiant system model. After all the system time steps have been simulated for the zone time step, an “average” zone heat balance calculation is done (similar to the radiant systems). Note that if the unit was scheduled off or there is no steam flow rate through the baseboard unit, then, there will be no heat transfer from the unit. The model assumes no heat storage in the unit itself and thus no residual heat transfer in future system time steps due to heat storage in the steam or metal of the unit.

15.4.5.4 References

While there are no specific references for this model as it is fairly intuitive, the user can always refer to the ASHRAE Handbook series for general information on different system types as needed. The user can also consult information on the EnergyPlus steam coil for further details.

Chapter 16

Simulation Models – Encyclopedic Reference

The following descriptions are grouped alphabetically (as much as possible) with some also having additional tags of “Heat Balance”, “HVAC”, and “Plant”. With the integrated solution, these designations signify where the effects of these models have their first impacts.

Main Sections:

16.1 Cooling Towers and Evaporative Fluid Coolers

16.1.1 One, Two, and Variable Speed Cooling Towers and Evaporative Fluid Coolers

16.1.1.1 Overview

The input objects `CoolingTower:SingleSpeed`, `CoolingTower:TwoSpeed`, and `CoolingTower:VariableSpeed:Merkel` provide models for single-speed, two-speed, and variable-speed cooling towers that are based on Merkel’s theory (Merkel 1925), which is also the basis for the tower model included in ASHRAE’s HVAC1 Toolkit for primary HVAC system energy calculations (ASHRAE 1999, Bourdouxhe et al. 1994). Cooling tower performance is modeled using effectiveness-NTU relationships for counterflow heat exchangers. The model can be used to simulate the performance of both single speed, two speed, and variable speed mechanical-draft cooling towers. The model will also account for tower performance in the “free convection” regime, when the tower fan is off but the water pump remains on. For part-load operation, the model assumes a simple linear interpolation between two steady-state regimes without accounting for any cycling losses.

For single speed cooling towers, the capacity control can be fan cycling or fluid bypass. In fluid bypass mode, portion of the water goes through the tower media and gets cooled while the remaining water flow gets bypassed, two water flows then mix together trying to meet the tower exiting water setpoint temperature. In both the free convection cooling when fan is off and normal cooling when fan is on for the entire time step, if the tower exiting water temperature is lower than the setpoint, the tower operates in fluid bypass mode. The model determines the fluid bypass fraction by iterations until the mixed water meets the tower exiting water temperature setpoint. In the fluid bypass mode, except the free convection, the tower fan runs at full speed for the entire time step. The maximum amount of tower water that can be bypassed is bounded by the freezing point of the tower water – the tower exiting water temperature cannot be lower than the freezing setpoint.

Evaporative fluid coolers are modeled very similar to cooling towers. The main difference between the two is in the “Performance input method” input field. Cooling tower has two choices for this field namely “UFactorTimesAreaAndDesignWaterFlowRate” and “Nominal capacity”. The nominal capacity is specified for the standard conditions i.e. entering water at 35°C (95°F), leaving water at 29.44°C (85°F), entering air at 25.56°C (78°F) wet-bulb temperature and 35°C (95°F) dry-bulb temperature. On the other hand evaporative fluid cooler has three choices for “Performance input method” which are “UFactorTimesAreaAndDesignWaterFlowRate”, “StandardDesignCapacity” and “UserSpecifiedDesignCapacity”. First method is same for both tower and fluid cooler. Standard design capacity is specified for the same conditions which are used to specify nominal capacity for tower as described above. If the capacity of fluid cooler for conditions other than the standard ones is known then UserSpecifiedDesignCapacity method should be used. In this case, the conditions for which the fluid cooler capacity is known i.e. entering water temperature, entering air temperature and entering air wet bulb temperature must be specified in the input. To calculate evaporation loss for fluid cooler, spray water flow rate which is different than the process fluid flow rate must be specified for all the performance input methods. This is not required for cooling tower because cooled fluid i.e. water is in direct contact with the air so the water loss is calculated by using cooled fluid flow rate only. Unlike cooling tower, evaporative fluid cooler model does not account for free convection.

Cooling tower model is described below which holds equally good for evaporative fluid cooler. The differences are mentioned whenever required.

16.1.1.2 Model Description

Based on Merkel’s theory, the steady-state total heat transfer between the air and water entering the tower can be defined by the following equation:

$$d\dot{Q}_{total} = \frac{U dA}{c_p} (h_s - h_a) \quad (16.1)$$

where:

h_s is the enthalpy of saturated air at the wetted-surface temperature (J/kg)

h_a is the enthalpy of air in the free stream (J/kg)

c_p is the specific heat of moist air (J/kg-°C)

U is the cooling tower overall heat transfer coefficient (W/m²-°C)

A is the heat transfer surface area (m²).

Equation 16.1 is based on several assumptions:

- air and water vapor behave as ideal gases
- the effect of water evaporation is neglected
- fan heat is neglected
- the interfacial air film is assumed to be saturated
- the Lewis number is equal to 1

In this model, it is also assumed that the moist air enthalpy is solely a function of the wet-bulb temperature and that the moist air can be treated as an equivalent ideal gas with its mean specific heat defined by the following equation:

$$\bar{c}_{pe} = \frac{\Delta h}{\Delta T_{wb}} \quad (16.2)$$

where:

Δh is the enthalpy difference between the air entering and leaving the tower (J/kg)

ΔT_{wb} is the wet-bulb temperature difference between the air entering and leaving the tower (°C).

Since the liquid side conductance is much greater than the gas side conductance, the wetted-surface temperature is assumed to be equal to the water temperature. Based on this assumption and Equations 16.1 and 16.2, the expression for total heat transfer becomes:

$$d\dot{Q}_{total} = U_e dA (T_w - T_{wb}) \quad (16.3)$$

where:

$$U_e = \frac{U \bar{c}_{pe}}{cp} \quad (16.4)$$

T_{wb} is the wet-bulb temperature of the air (°C)

T_w is the temperature of the water (°C).

An energy balance on the water and air sides of the air/water interface yields the following equations:

$$d\dot{Q}_{total} = \dot{m}_w c_{pw} dT_w \quad (16.5)$$

$$d\dot{Q}_{total} = \dot{m}_a \bar{c}_{pe} dT_{wb} \quad (16.6)$$

where:

\dot{m}_w is the mass flow rate of water (kg/s)

\dot{m}_a is the mass flow rate of air (kg/s).

Assuming that the heat capacity rate ($\dot{m}c_p$) for the cooling tower water is less than that for the air, the effectiveness of the cooling tower can be defined by analogy to the effectiveness of a simple heat exchanger:

$$\varepsilon = \frac{T_{win} - T_{wout}}{T_{win} - T_{wbin}} \quad (16.7)$$

where

ε is the heat exchanger effectiveness

T_{win} is the inlet water temperature ($^{\circ}\text{C}$)

T_{wout} is the outlet water temperature ($^{\circ}\text{C}$)

T_{wbin} is the wet-bulb temperature of the inlet air ($^{\circ}\text{C}$).

Combining Equations 16.3, 16.5, and 16.6 and integrating over the entire heat transfer surface area, and combining the result with Equation 16.7 provides the following expression for cooling tower effectiveness:

$$\varepsilon = \frac{1 - \exp \left\{ -NTU \left[1 - \left(\frac{\dot{C}_w}{\dot{C}_a} \right) \right] \right\}}{1 - \left(\frac{\dot{C}_w}{\dot{C}_a} \right) \exp \left\{ -NTU \left[1 - \left(\frac{\dot{C}_w}{\dot{C}_a} \right) \right] \right\}} \quad (16.8)$$

where:

$$\dot{C}_w = \dot{m}_w c_{pw} \quad (16.9)$$

$$\dot{C}_a = \dot{m}_a \bar{c}_{pe} \quad (16.10)$$

$$NTU = \text{Number of Transfer Units} = \frac{UA_e}{\dot{C}_w} \quad (16.11)$$

This equation is identical to the expression for effectiveness of an indirect contact (i.e., fluids separated by a solid wall) counterflow heat exchanger (Incropera and DeWitt 1981). Therefore, the cooling tower can be modeled, in the steady-state regime, by an equivalent counterflow heat exchanger as shown in the following figure.

Figure 16.1: Cooling Tower Schematic

The first fluid is water and the second fluid is an equivalent fluid entering the heat exchanger at temperature T_{wbin} and specific heat \bar{c}_{pe} . The heat exchanger is characterized by a single parameter, its overall heat transfer coefficient-area product UA_e . The actual cooling tower heat transfer coefficient-area product is related to UA_e by the following expression:

$$UA = UA_e \frac{c_p}{\bar{c}_{pe}} \quad (16.12)$$

This heat transfer coefficient-area product is assumed to be a function of the air mass flow rate only and can be estimated from laboratory test results or manufacturers' catalog data.

The model for the variable speed Merkel tower also includes Scheier's modifications. Scheier has extended the Merkel model to also include terms that adjust UA with three factors that model how UA values change when the tower is operating away from its rated conditions. The first factor, $f_{UA,wetbulb}$, adjusts UA for the current outdoor wetbulb temperature. The user enters a performance curve or lookup table that is a function of one independent variable. The independent variable is the difference between the design wetbulb temperature and the current wetbulb temperature, in degrees Celsius.

$$f_{UA,wetbulb} = func((T_{des,wetbulb} - T_{current,wetbulb})) \quad (16.13)$$

The second factor, $f_{UA,airflow}$, adjusts UA for the current air flow rate. The user enters a performance curve or lookup table that is a function of one independent variable. The independent variable is the ratio of the current air flow rate to the design air flow rate at full speed.

$$f_{UA,airflow} = func(AirFlowRatio) \quad (16.14)$$

The third factor, $f_{UA,waterflow}$, adjusts UA for the current water flow rate. The user enters a performance curve or lookup table that is a function of one independent variable. The independent variable is the ratio of the current water flow rate to the design water flow rate.

$$f_{UA,waterflow} = func(WaterFlowRatio) \quad (16.15)$$

Then the UA value at any given time is calculated using:

$$UA_e = UA_{design} \bullet f_{UA,wetbulb} \bullet f_{UA,airflow} \bullet f_{UA,waterflow} \quad (16.16)$$

16.1.1.3 Method for Calculating Steady-State Exiting Water Temperature

The objective of the cooling tower model is to predict the exiting water temperature and the fan power required to meet the exiting water setpoint temperature. Since only the inlet air and inlet water temperatures are known at any simulation time step, an iterative procedure is required to determine the exiting fluid temperatures using the equations defined in the previous section. In the case of the EnergyPlus model, the iterations are performed to determine the exiting wet-bulb temperature of the air. The exiting water temperature is then calculated based on an energy balance that assumes that the energy absorbed by the air is equivalent to the energy removed from the water. The procedure for calculating the steady-state, exiting air wet-bulb temperature is outlined below.

As explained previously, it is assumed that the moist air enthalpy can be defined by the wet-bulb temperature alone. Therefore, the first step in the procedure is to calculate the enthalpy of moist air entering the cooling tower based on the ambient wet-bulb temperature from the weather

file. Since an iterative solution is required, a first guess of the outlet air wet-bulb temperature is then made and the enthalpy of this estimated outlet air wet-bulb temperature is calculated. Based on these inlet and outlet air conditions, the mean specific heat of the air is calculated based on Equation 16.2, repeated here:

$$\bar{c}_{pe} = \frac{\Delta h}{\Delta T_{wb}} \quad (16.17)$$

With the overall heat transfer coefficient-area product for the cooling tower entered by the user, the effective heat transfer coefficient-area product is calculated by rearranging Equation 16.12:

$$UA_e = UA \frac{\bar{c}_{pe}}{c_p} \quad (16.18)$$

With \bar{c}_{pe} and UA_e known, the effectiveness of the heat exchanger is then calculated:

$$\varepsilon = \frac{1 - \exp \left\{ -NTU \left[1 - \left(\frac{\dot{C}_{\min}}{\dot{C}_{\max}} \right) \right] \right\}}{1 - \left(\frac{\dot{C}_{\min}}{\dot{C}_{\max}} \right) \exp \left\{ -NTU \left[1 - \left(\frac{\dot{C}_{\min}}{\dot{C}_{\max}} \right) \right] \right\}} \quad (16.19)$$

where:

$$\dot{C}_{\min} = \text{Minimum}(\dot{C}_w, \dot{C}_a) \quad (16.20)$$

$$\dot{C}_{\max} = \text{Maximum}(\dot{C}_w, \dot{C}_a) \quad (16.21)$$

$$\dot{C}_w = \dot{m}_w c_{pw} \quad (16.22)$$

$$\dot{C}_a = \dot{m}_a \bar{c}_{pe} \quad (16.23)$$

$$NTU = \text{Number of Transfer Units} = \frac{UA_e}{\dot{C}_{\min}} \quad (16.24)$$

The heat transfer rate is then calculated as follows:

$$\dot{Q}_{total} = \varepsilon \dot{C}_{\min} (T_{win} - T_{wbin}) \quad (16.25)$$

The outlet air wet-bulb temperature is then recalculated:

$$T_{wbout} = T_{wbin} + \frac{\dot{Q}_{total}}{\dot{C}_a} \quad (16.26)$$

The iterative process of calculating T_{wbout} continues until convergence is reached. Finally, the outlet water temperature is calculated as follows:

$$T_{wout} = T_{win} + \frac{\dot{Q}_{total}}{\dot{C}_w} \quad (16.27)$$

16.1.1.4 Calculating the Actual Exiting Water Temperature and Fan Power

The previous section describes the methodology used for calculating the steady-state temperature of the water leaving the cooling tower. This methodology is used to calculate the exiting water temperature in the free convection regime (water pump on, tower fan off) and with the tower fan operating (including low and high fan speed for the two-speed tower). The exiting water temperature calculations use the fluid flow rates (water and air) and the UA-values entered by the user for each regime.

The cooling tower model seeks to maintain the temperature of the water exiting the cooling tower at (or below) a setpoint. The model obtains the target temperature setpoint from the setpoints placed on either the tower outlet node or the loop's overall setpoint node (typically set to the supply side outlet node). The model checks to see if the outlet node has a setpoint placed on it and uses that if it does. If the outlet node does not have a temperature setpoint then the model uses the loop-level outlet node specified in the input field called Loop Temperature Setpoint Node Name in the PlantLoop or CondenserLoop object. The model first checks to determine the impact of "free convection", if specified by the user, on the tower exiting water temperature. If free convection is not specified by the user, then the exiting water temperature is initially set equal to the entering tower water temperature. If the user specifies "free convection" and the steady-state exiting water temperature based on "free convection" is at or below the setpoint, then the tower fan is not turned on.

If the exiting water temperature remains above the setpoint after "free convection" is modeled, then the tower fan is turned on to reduce the exiting water temperature to the setpoint. The model assumes that part-load operation is represented by a simple linear interpolation between two steady-state regimes (e.g., tower fan on for the entire simulation time step and tower fan off for the entire simulation time step). Cyclic losses are not taken into account.

The fraction of time that the tower fan must operate is calculated based on the following equation:

$$\omega = \frac{T_{set} - T_{wout,off}}{T_{wout,on} - T_{wout,off}} \quad (16.28)$$

where:

T_{set} is the exiting water setpoint temperature (°C)

$T_{wout,off}$ is the exiting water temperature with tower fan off (°C)

$T_{wout,on}$ is the exiting water temperature with tower fan on (°C).

The average fan power for the simulation time step is calculated by multiplying ω by the steady-state fan power specified by the user.

The calculation method for the two-speed tower is similar to that for the single-speed tower example described above. The model first checks to see if "free convection" is specified and if the resulting exiting water temperature is below the setpoint temperature. If not, then the model calculates the steady-state exiting water temperature with the tower fan at low speed. If the exiting water temperature at low fan speed is below the setpoint temperature, then the average fan power is calculated based on the result of Equation 16.28 and the steady-state, low speed fan power specified by the user. If low-speed fan operation is unable to reduce the exiting water temperature below the setpoint, then the tower fan is increased to its high speed and the steady-state exiting water temperature is calculated. If this temperature is below the setpoint, then a modified version of Equation 16.28 is used to calculate runtime at high fan speed:

$$\omega = \frac{T_{set} - T_{wout,low}}{T_{wout,high} - T_{wout,low}} \quad (16.29)$$

where

T_{set} is the exiting water setpoint temperature (°C)

$T_{wout,low}$ is the exiting water temperature with tower fan at low speed (°C)

$T_{wout,high}$ is the exiting water temperature with tower fan at high speed (°C).

The average fan power for the simulation time step is calculated for the two-speed cooling tower as follows:

$$P_{fan,avg} = \omega(P_{fan,high}) + (1 - \omega)(P_{fan,low}) \quad (16.30)$$

The calculation method for the variable-speed Merkel/Scheier model is different from the one- and two-speed models. Whereas the other towers are setpoint driven, the variable speed Merkel/Scheier model is driven by the load dispatched from the plant operation scheme, such as PlantEquipmentOperation:CoolingLoad. The plant operation scheme provides the cooling tower model with a target load to meet and the tower is controlled to meet that load (as opposed to meeting a leaving setpoint). This allows complex configurations with more than one cooling tower to be properly dispatched using all the features available in the various plant operation schemes. The model first evaluates the load provided with the fans off using only free convection. If the free convection mode meets or exceeds the target load then the tower runs in free convection mode. The model then evaluates the load provided by running the fans at full speed. If the full fan speed load provided is less than or equal to the target load then the tower runs at full speed. The model then evaluates the load provided with the variable speed fan running at the minimum air speed ratio, which is a user input (default is 0.2). If the minimum fan speed load provided meets or exceeds the target load, then tower runs at the minimum fan speed. If the target load is between the load provided by minimum and maximum fans speeds, then the model solves for an airflow rate ratio that just meets the target load using root solver numerical method. The variable speed Merkel/Scheier model does not model bypass and may provided excess cooling at times when running in free convection or at the minimum fan speed. Fan power for the variable speed Merkel/Scheier model is then calculated from the airflow rate ratio using a design fan power and a performance curve or lookup table with one independent variable for the airflow ratio.

$$P_{fan} = P_{fan,des} \bullet func(AirFlowRatio) \quad (16.31)$$

16.1.1.5 Tower Basin Heater

The tower basin heater operates in the same manner as the variable speed cooling tower basin heater. Refer to the variable speed cooling tower basin heater description in the following section.

16.1.1.6 Cooling Tower Makeup Water Usage

The cooling tower makeup water usage is the same as the variable speed cooling tower makeup water usage. Refer to the variable speed cooling tower makeup water usage description in the following section.

16.1.2 Variable Speed Cooling Towers Empirical Models

16.1.2.1 Overview

The input object `CoolingTower:VariableSpeed` provides models for variable speed towers that are based on empirical curve fits of manufacturer's performance data or field measurements. The user specifies tower performance at design conditions, and empirical curves are used to determine the approach temperature and fan power at off-design conditions. The user defines tower performance by entering the inlet air wet-bulb temperature, tower range, and tower approach temperature at the design conditions. The corresponding water flow rate, air flow rate, and fan power must also be specified. The model will account for tower performance in the "free convection" regime, when the tower fan is off but the water pump remains on and heat transfer still occurs (albeit at a low level). Basin heater operation and makeup water usage (due to evaporation, drift, and blowdown) are also modeled.

The cooling tower seeks to maintain the temperature of the water exiting the cooling tower at (or below) a setpoint. The setpoint temperature is defined by the setpoints placed on either the tower outlet node or the loop's overall setpoint node (typically set to the supply side outlet node). The model checks to see if the outlet node has a setpoint placed on it and uses that if it does. If the outlet node does not have a temperature setpoint then the model uses the loop-level outlet node specified in the input field called `Loop Temperature Setpoint Node Name` in the `PlantLoop` or `CondenserLoop` object. The model simulates the outlet water temperature in four successive steps:

- The model first determines the tower outlet water temperature with the tower fan operating at maximum speed. If the outlet water temperature is above the setpoint temperature, the fan runs at maximum speed.
- If the outlet water temperature with maximum fan speed is below the setpoint temperature, then the model next determines the impact of "free convection" (water flowing through tower with fan off). If the exiting water temperature based on "free convection" is at or below the setpoint, then the tower fan is not turned on.
- If the outlet water temperature remains above the setpoint after "free convection" is modeled, then the tower fan is turned on at the minimum fan speed (minimum air flow rate ratio) to reduce the leaving water temperature. If the outlet water temperature is below the setpoint at minimum fan speed, the tower fan is cycled on and off to maintain the outlet water setpoint temperature.
- If the outlet water temperature remains above the setpoint after minimum fan speed is modeled, then the tower fan is turned on and the model determines the required air flow rate and corresponding fan speed to meet the desired setpoint temperature.

16.1.2.2 Model Description

The variable speed tower model utilizes user-defined tower performance at design conditions along with empirical curves to determine tower heat rejection and fan power at off-design conditions. Basin heater operation and makeup water usage are also modeled based on user inputs, tower entering air conditions, and tower operation. The following sections describe how each of these tower performance areas is modeled.

16.1.2.3 Tower Heat Rejection

Heat rejection by the variable speed cooling tower is modeled based on the CoolTools correlation, YorkCalc correlation, or user-defined coefficients for either the CoolTools or YorkCalc correlations. These purely-empirical correlations model the tower approach temperature using a polynomial curve fit with a large number of terms and either three or four independent variables.

The CoolTools correlation has 35 terms with four independent variables:

$$\begin{aligned}
 Approach = & Coeff(1) + Coeff(2) \cdot FRair + Coeff(3) \cdot (FRair)^2 + \\
 & Coeff(4) \cdot (FRair)^3 + Coeff(5) \cdot FRwater + \\
 & Coeff(6) \cdot FRair \cdot FRwater + Coeff(7) \cdot (FRair)^2 \cdot FRwater + \\
 & Coeff(8) \cdot (FRwater)^2 + Coeff(9) \cdot FRair \cdot (FRwater)^2 + \\
 & Coeff(10) \cdot (FRwater)^3 + Coeff(11) \cdot Twb + Coeff(12) \cdot FRair \cdot Twb + \\
 & Coeff(13) \cdot (FRair)^2 \cdot Twb + Coeff(14) \cdot FRwater \cdot Twb + \\
 & Coeff(15) \cdot FRair \cdot FRwater \cdot Twb + Coeff(16) \cdot (FRwater)^2 \cdot Twb + \\
 & Coeff(17) \cdot (Twb)^2 + Coeff(18) \cdot FRair \cdot (Twb)^2 + \\
 & Coeff(19) \cdot FRwater \cdot (Twb)^2 + Coeff(20) \cdot (Twb)^3 + Coeff(21) \cdot Tr + \\
 & Coeff(22) \cdot FRair \cdot Tr + Coeff(23) \cdot (FRair)^2 \cdot Tr + \\
 & Coeff(24) \cdot FRwater \cdot Tr + Coeff(25) \cdot FRair \cdot FRwater \cdot Tr + \\
 & Coeff(26) \cdot (FRwater)^2 \cdot Tr + Coeff(27) \cdot Twb \cdot Tr + \\
 & Coeff(28) \cdot FRair \cdot Twb \cdot Tr + Coeff(29) \cdot FRwater \cdot Twb \cdot Tr + \\
 & Coeff(30) \cdot (Twb)^2 \cdot Tr + Coeff(31) \cdot (Tr)^2 + Coeff(32) \cdot FRair \cdot (Tr)^2 + \\
 & Coeff(33) \cdot FRwater \cdot (Tr)^2 + Coeff(34) \cdot Twb \cdot (Tr)^2 + Coeff(35) \cdot (Tr)^3
 \end{aligned} \tag{16.32}$$

where:

Approach is the approach temperature (°C) which is equal to the outlet water temperature minus the inlet air wet-bulb temperature

FRair is the air flow rate ratio (actual air flow rate divided by design air flow rate)

FRwater is the water flow rate ratio (actual water flow rate divided by design water flow rate)

Tr is the range temperature (°C) which is the inlet water temperature minus the outlet water temperature

Twb is the inlet air wet-bulb temperature (°C)

Coeff(#) are the correlation coefficients.

If the user selects Tower Model Type = CoolToolsCrossFlow, then the 35 coefficients derived for the CoolTools simulation model (Benton et al. 2002) are used and these coefficients are already

defined within EnergyPlus as shown in Table 16.1. If the user specifies Tower Model Type = CoolToolsUserDefined, then the user must enter a CoolingTowerPerformance:CoolTools object to define the 35 coefficients that will be used by the CoolTools approach temperature correlation.

Similarly, the YorkCalc correlation has 27 terms with three independent variables:

$$\begin{aligned}
Approach = & Coeff(1) + Coeff(2) \cdot Twb + Coeff(3) \cdot Twb^2 + Coeff(4) \cdot Tr + \\
& Coeff(5) \cdot Twb \cdot Tr + Coeff(6) \cdot Twb^2 \cdot Tr + Coeff(7) \cdot Tr^2 + \\
& Coeff(8) \cdot Twb \cdot Tr^2 + Coeff(9) \cdot Twb^2 \cdot Tr^2 + Coeff(10) \cdot LGRatio + \\
& Coeff(11) \cdot Twb \cdot LGRatio + Coeff(12) \cdot Twb^2 \cdot LGRatio + \\
& Coeff(13) \cdot Tr \cdot LGRatio + Coeff(14) \cdot Twb \cdot Tr \cdot LGRatio + \\
& Coeff(15) \cdot Twb^2 \cdot Tr \cdot LGRatio + Coeff(16) \cdot Tr^2 \cdot LGRatio + \\
& Coeff(17) \cdot Twb \cdot Tr^2 \cdot LGRatio + Coeff(18) \cdot Twb^2 \cdot Tr^2 \cdot LGRatio + \\
& Coeff(19) \cdot LGRatio^2 + Coeff(20) \cdot Twb \cdot LGRatio^2 + \\
& Coeff(21) \cdot Twb^2 \cdot LGRatio^2 + Coeff(22) \cdot Tr \cdot LGRatio^2 + \\
& Coeff(23) \cdot Twb \cdot Tr \cdot LGRatio^2 + Coeff(24) \cdot Twb^2 \cdot Tr \cdot LGRatio^2 + \\
& Coeff(25) \cdot Tr^2 \cdot LGRatio^2 + Coeff(26) \cdot Twb \cdot Tr^2 \cdot LGRatio^2 + \\
& Coeff(27) \cdot Twb^2 \cdot Tr^2 \cdot LGRatio^2
\end{aligned} \tag{16.33}$$

where:

Approach is the approach temperature (°C) which is the outlet water temperature minus the inlet air wet-bulb temperature

Tr is the range temperature (°C) which is the inlet water temperature minus the outlet water temperature

Twb is the inlet air wet-bulb temperature (°C)

LGRatio is the liquid-to-gas ratio which is the ratio of water flow rate ratio (FRwater) to air flow rate ratio (FRair)

Coeff(#) are the correlation coefficients.

If the user selects Tower Model Type = YorkCalc, then the 27 coefficients derived for the YorkCalc simulation model (York International Corp. 2002) are used and these coefficients are already defined within EnergyPlus as shown in Table 16.1. If the user specifies Tower Model Type = YorkCalcUserDefined, then the user must enter a CoolingTowerPerformance:YorkCalc object to define the 27 coefficients that will be used by the YorkCalc approach temperature correlation.

The approach temperature correlations for the CoolTools and YorkCalc simulation models are valid for a range of conditions defined in Table 16.2. If the user defines their own model coefficients (CoolingTowerPerformance:CoolTools or CoolingTowerPerformance:YorkCalc), then they must also define in that same object the range of conditions for which the model is valid. For all of these correlation variables, the program issues warnings if the actual values are beyond the minimum/-maximum values specified for the correlation being used. For inlet air wet-bulb temperature and water mass flow rate ratio, the values of these variables used in the calculation of approach temperature are limited to be within the valid minimum/maximum range. For approach, range, and liquid-to-gas ratio the warnings are issued if the values are beyond the specified minimum/maximum range but the actual values are still used. The warnings issued do not necessarily indicate a poor estimate of tower performance at the condition(s) which caused the warning, but are provided to identify conditions outside the defined correlation limits. Exceeding the defined limits by a small amount may not introduce significant errors, but large deviations may be problematic. It is for this reason that we recommend using a very broad range of cooling tower performance data (i.e., data covering the entire range expected during the simulation) when generating user-defined coefficients for the variable speed tower model.

Table 16.2: Minimum and Maximum Limits for Approach Temperature Correlation Variables

Independent Variable Limit	CoolTools	YorkCalc
Minimum Inlet Air Wet-Bulb Temperature	-1.0°C	-34.4°C
Maximum Inlet Air Wet-Bulb Temperature	26.7°C	26.7°C
Minimum Tower Range Temperature	1.1°C	1.1°C
Maximum Tower Range Temperature	11.1°C	22.2°C
Minimum Tower Approach Temperature	1.1°C	1.1°C
Maximum Tower Approach Temperature	11.1°C	40°C
Minimum Water Flow Rate Ratio	0.75	0.75
Maximum Water Flow Rate Ratio	1.25	1.25
Maximum Liquid-to-Gas Ratio	N/A	8.0

The approach temperature correlation(s) used to simulate cooling tower heat rejection are based on water and air flow rate “ratios” and are not directly dependent on the size of the tower or the actual air and water flow rates through the tower. However, the model correlations are developed based on a reference condition. For Model Types “CoolToolsCrossFlow” and “YorkCalc”, the reference condition is a water flow rate of 0.000043 m³/s per kW of heat rejected (2.4 gal/min per ton of heat rejected) with 25.6°C (78°F) enter air wet-bulb temperature, 35°C (95°F) hot water inlet temperature, and 29.4°C (85°F) cold water outlet temperature. The reference condition may be different if the user defines tower model coefficients using CoolingTowerPerformance:CoolTools or CoolingTowerPerformance:YorkCalc.

Due to the inherent reference condition used to generate the tower performance curves, the water flow rate at the reference condition must be determined using the design performance information specified by the user and the tower model’s approach temperature correlation. This is done by

using the model's approach temperature correlation (described earlier in this section) to calculate the water flow rate ratio which yields the user-defined design approach temperature based on an air flow rate ratio of 1.0 ($FR_{air} = 1.0$), the design inlet air wet-bulb temperature, and the design range temperature. The calculated approach temperature (using the model correlation) must satisfy the following two equations:

$$T_{water,outlet,design} = T_{wb,air,design} + T_{approach,design} \quad \{FR_{air} = 1.0\} \quad (16.34)$$

$$T_{water,inlet,design} = T_{wb,air,design} + T_{approach,design} + T_{range,design} \quad \{FR_{air} = 1.0\} \quad (16.35)$$

where:

$T_{water,outlet,design}$ is the design outlet water temperature (°C)

$T_{water,inlet,design}$ is the design inlet water temperature (°C)

$T_{wb,air,design}$ is the design inlet air wet-bulb temperature (°C)

$T_{approach,design}$ is the design approach temperature (°C)

$T_{range,design}$ is the design range temperature (°C)

FR_{air} is the air flow rate ratio (actual air flow rate divided by design air flow rate).

The water flow rate ratio used in the approach temperature correlation which satisfies these two equations is the ratio of the design water flow rate (specified by the user) to the water flow rate at the reference condition. This ratio is used to calculate the reference water volumetric flow rate, which is then used throughout the simulation to determine the actual water flow rate ratio used in the approach temperature correlation for each simulation time step.

$$\dot{V}_{reference} = \frac{\dot{V}_{design}}{FR_{water,reference}} \quad (16.36)$$

where:

$\dot{V}_{reference}$ is the water volumetric flow rate at the reference condition (m³/s)

\dot{V}_{design} is the design water volumetric flow rate specified by the user (m³/s)

$FR_{water,reference}$ is the design water flow rate divided by the reference water flow rate.

The cooling tower seeks to maintain the temperature of the water exiting the cooling tower at (or below) a setpoint. The setpoint temperature is defined by the field “Condenser Loop Temperature Setpoint schedule or reference” for the CondenserLoop object. The model simulates the outlet water temperature in four successive steps:

- The model first determines the tower outlet water temperature with the tower fan operating at maximum speed. If the outlet water temperature is above the setpoint temperature, the fan runs at maximum speed.
- If the outlet water temperature with maximum fan speed is below the setpoint temperature, then the model next determines the impact of “free convection” (water flowing through tower with fan off). If the exiting water temperature based on “free convection” is at or below the setpoint, then the tower fan is not turned on.
- If the outlet water temperature remains above the setpoint after “free convection” is modeled, then the tower fan is turned on at the minimum fan speed (minimum air flow rate ratio) to reduce the leaving water temperature. If the outlet water temperature is below the setpoint

at minimum fan speed, the tower fan is cycled on and off to maintain the outlet water setpoint temperature.

- If the outlet water temperature remains above the setpoint after minimum fan speed is modeled, then the tower fan is turned on and the model determines the required air flow rate and corresponding fan speed to meet the desired setpoint temperature.

For each simulation time step, the model first calculates the outlet water temperature with the tower fan operating at maximum speed ($FR_{air} = 1.0$). The calculated approach temperature (using the correlations described above), inlet air wet-bulb temperature (weather data), and range temperature are used to determine the tower outlet water temperature as follows:

$$\begin{aligned} T_{water,outlet,fanMAX} &= T_{wb,air} + T_{approach} \quad \{FR_{air} = 1.0\} \\ &= T_{water,inlet} + T_{range} \end{aligned} \quad (16.37)$$

where:

$T_{water,outlet,fanMAX}$ is the tower outlet water temperature at maximum fan speed ($^{\circ}\text{C}$)

$T_{wb,air}$ is the tower inlet air wet-bulb temperature ($^{\circ}\text{C}$)

$T_{approach}$ is the approach temperature at current operating conditions ($^{\circ}\text{C}$)

T_{range} is the range temperature at current operating conditions ($^{\circ}\text{C}$).

Note that the approach temperature correlation as described previously is a function of range temperature, so the equations above must be solved iteratively to converge on a solution. If the resulting outlet water temperature is above the desired setpoint temperature, then the fan runs at maximum speed and does not cycle on/off (fan part-load ratio = $FanPLR = 1.0$ and $FR_{air} = 1.0$).

If the outlet water temperature with maximum fan speed is below the setpoint temperature, then the model next determines the impact of “free convection” (water flowing through tower with fan off). In the free convection regime, the outlet water temperature is calculated using a fraction of the water temperature difference through the tower when the fan is at its maximum speed. This fraction is defined by the user (Fraction of Tower Capacity in Free Convection Regime).

$$T_{water,outlet,fanOFF} = T_{water,inlet} - [Frac_{freeconv} (T_{water,inlet} - T_{water,outlet,fanMAX})] \quad (16.38)$$

where:

$T_{water,outlet,fanOFF}$ is the tower outlet water temperature in free convection regime ($^{\circ}\text{C}$)

$T_{water,inlet}$ is the tower inlet water temperature ($^{\circ}\text{C}$)

$Frac_{freeconv}$ is the fraction of tower capacity in free convection regime (user specified).

If the outlet water temperature in the free convection regime is below the setpoint temperature, the tower fan is not turned on and the fan part-load ratio is set equal to 0. In addition, the air flow rate ratio through the tower is assumed to be equal to the fraction of tower capacity in the free convection regime.

$$FanPLR = FanPLR_{freeconv} = 0.0 \quad (16.39)$$

$$FR_{air} = FR_{air,freeconv} = Frac_{freeconv} \quad (16.40)$$

where:

$FanPLR$ is the fan part-load ratio

$FanPLR_{freeconv}$ is the fan part-load ratio in free convection regime

$FR_{air,freeconv}$ is the air flow rate ratio in free convection regime.

If the outlet water temperature in the free convection regime is above the setpoint temperature, then the fan is turned on at the minimum fan speed (minimum air flow rate ratio, $FR_{air,min}$, entered by the user) and the outlet water temperature is calculated as the inlet air wet-bulb temperature plus the calculated approach temperature:

$$FR_{air} = FR_{air,min} \quad (16.41)$$

$$T_{water,outlet,fanMIN} = T_{wb,air} + T_{approach} \quad (16.42)$$

where:

$T_{water,outlet,FanMIN}$ is the outlet water temperature at minimum fan speed ($^{\circ}C$)

$FR_{air,min}$ is the air flow rate ratio at the minimum fan speed.

If the outlet water temperature at minimum fan speed is below the setpoint temperature, the cooling tower fan cycles on and off at the minimum air flow rate ratio in order to meet the setpoint temperature.

$$FanPLR = \left(\frac{T_{water,outlet,fanOFF} - T_{setpoint}}{T_{water,outlet,fanOFF} - T_{water,outlet,fanMIN}} \right) \quad (16.43)$$

where $T_{setpoint}$ is the outlet water setpoint temperature ($^{\circ}C$).

If the outlet water temperature at minimum fan speed is above the outlet water temperature setpoint, then the cooling tower fan speed (FR_{air}) is increased until the calculated approach temperature produces the required outlet water temperature to meet the setpoint.

$$T_{approach} = f(FR_{air}) \quad (16.44)$$

$$T_{water,outlet} = T_{setpoint} = T_{wb,air} + T_{approach} \quad (16.45)$$

$$FanPLR = 1.0 \quad (i.e., fan does not cycle on/off) \quad (16.46)$$

16.1.2.4 Fan Power

When the cooling tower fan is operating, fan electric power is calculated based on the air flow rate ratio required to meet the above conditions. If the user has entered a fan power curve object (cubic curve), the output of that curve is multiplied by the design fan power. Otherwise, tower fan power is assumed to be directly proportional to the cube of the air flow rate ratio. In either case, the fan part-load ratio is applied to account for times when the tower fan cycles on/off to meet the setpoint temperature. Fan energy consumption is calculated each simulation time step.

If FanPowerCurveObject is defined, then:

$$P_{fan} = (CurveOutput) (FanPLR) P_{fan,design} \quad (16.47)$$

Else:

$$P_{fan} = (P_{fan,design}) (FanPLR) (FR_{air})^3 \quad (16.48)$$

In addition:

$$E_{fan} = (P_{fan}) (TimeStepSys) 3600 \quad (16.49)$$

where:

FanPowerCurveObject is the name of fan power ratio as a function of air flow rate ratio curve

P_{fan} is the tower fan electric power (W)

E_{fan} is the tower fan electric consumption (J)

CurveOutput is the output of FanPowerCurveObject evaluated at the operating air flow rate ratio (FR_{air})

$P_{fan,design}$ is the design fan power at design (maximum) air flow through the tower (W)

TimeStepSys is the HVAC system simulation time step (hr).

16.1.2.5 Tower Basin Heater

Calculations are also made to estimate the electric power input to the tower basin heater. A schedule may be used to disable the basin heater during regular maintenance periods or other time periods (e.g., during summer). If a schedule is not provided, the basin heater is assumed to be available the entire simulation time period. The basin heater operates when it is scheduled on, the outdoor air dry-bulb temperature is below the basin heater setpoint temperature, and the cooling tower is not active (i.e., water is not flowing through the tower). The user is required to enter a basin heater capacity (Watts per degree Kelvin) and a heater setpoint temperature (°C) if they want to model basin heater electric power.

```
P_heater_basin =0.0
IF (WaterNotFlowingThroughTower) THEN
  IF (Scheduleheater_basin is Defined) THEN
    IF (CAPheater_basin > 0 AND Scheduleheater_basin = ON) THEN
      P_heater_basin = MAX(0.0,CAP_heater_basin*(T_setpoint_basin-T_db_outdoor))
    ENDIF
  ELSE
    IF (CAPheater_basin > 0) THEN
      P_heater_basin = MAX(0.0,CAP_heater_basin*(T_setpoint_basin-T_db_outdoor))
    ENDIF
  ENDIF
ENDIF
```

$$E_{heater,basin} = (P_{heater,basin}) (TimeStepSys) 3600 \quad (16.50)$$

where:

$P_{heater,basin}$ is the tower basin heater electric power (W)

$E_{heater,basin}$ is the tower basin heater electric consumption (J)

$T_{setpoint,basin}$ is the basin heater setpoint temperature (°C)

$T_{db,outdoor}$ is the outdoor air dry-bulb temperature (°C)

$CAP_{heater,basin}$ is the basin heater capacity (W/K)

$Schedule_{heater,basin}$ is the basin heater schedule (schedule value > 0 means ON).

16.1.3 Cooling Towers with Multiple Cells

Many towers are constructed to be capable of being grouped together to achieve the desired capacity. Thus, many cooling towers are assemblies of two or more individual cooling towers or “cells.” The number of cells they have, e.g., an eight-cell tower, often refers to such towers.

For the operation of multi-cell towers, the first step is to determine the number of cells n , which will be operating during the timestep using the calculation logic from DOE-2.1E.

The maximum and minimum flow rates per cell are determined according to the input fractions (*Minimum Water Flow Rate Fraction: k_{min}* and *Maximum Water Flow Rate Fraction: k_{max}*) as follows:

$$\begin{aligned}\dot{m}_{w,min} &= \frac{\dot{m}_{w,des}}{n_{tot}} \times k_{min} \\ \dot{m}_{w,max} &= \frac{\dot{m}_{w,des}}{n_{tot}} \times k_{max}\end{aligned}\tag{16.51}$$

where $\dot{m}_{w,des}$ is the design water flow rate through the entire cooling tower.

Then, we determine the minimum and maximum number of cells that can operate with this water flow rate:

$$\begin{aligned}n_{min} &= \min \left(\frac{\dot{m}_{w,tot}}{\dot{m}_{w,max}}, n_{tot} \right) \\ n_{max} &= \min \left(\frac{\dot{m}_{w,tot}}{\dot{m}_{w,min}}, n_{tot} \right)\end{aligned}\tag{16.52}$$

where n_{tot} is the total number of cells of the tower and $\dot{m}_{w,tot}$ is the water flow rate to the tower.

The number of cells operating n is set accordingly:

If the *Cell Control* method is *MinimalCell*, $n = n_{min}$.

If the *Cell Control* method is *MaximalCell*, $n = n_{max}$.

Finally, the water mass flow rate per cell (\dot{m}_w) will be:

$$\dot{m}_w = \frac{\dot{m}_{w,tot}}{n}\tag{16.53}$$

Then we simulate the performance of one cell with this flow rate per cell (calling the SimSimpleTower subroutine for single and two speed cooling tower objects). As we assume that each cell is identical, the UA of one cell is calculated dividing the UA of the whole tower (obtained from the input or from the auto sizing calculations). The air flow rate per cell is also equal to the one of the whole tower divided by the number of cells operating:

$$UA_{cell} = \frac{UA_{tot}}{n_{tot}} \quad (16.54)$$

$$\dot{m}_{air,cell} = \frac{\dot{m}_{air,tot}}{n} \quad (16.55)$$

At the end, the total fan power of the tower operating with a certain number of cells is given by:

$$FanPower = FanPower_{tot} \times \frac{n}{n_{tot}} \quad (16.56)$$

If the cells operating do not meet the loads, we increase the number of cells if spare cells are available and the water flow through each cell is within the user specified minimum and maximum water flow rate fractions range. This is an iteration process.

16.1.4 Cooling Tower Makeup Water Usage

Makeup water use for all types of cooling towers is made up of three components: evaporation, drift, and blowdown. The first is the amount of water evaporated to reduce the water's temperature as it passes through the cooling tower. There are two methods that evaporation makeup water can be modeled in EnergyPlus. The first method assumes that the tower outlet air conditions are saturated (which may not always be the case for certain operating conditions). For this "Saturated Exit" mode, the enthalpy of the tower's outlet air is calculated as the inlet air enthalpy plus the water side heat transfer divided by the air mass flow rate through the tower.

$$\dot{Q}_{water} = \dot{m}_{water} C_p (T_{water,inlet} - T_{water,outlet}) \quad (16.57)$$

$$h_{sat\ air,outlet} = h_{air,inlet} + \left(\frac{\dot{Q}_{water}}{\dot{m}_{air}} \right) \quad (16.58)$$

where:

\dot{Q}_{water} is the water-side heat transfer (W)

\dot{m}_{water} is the mass flow rate of water through the tower (kg/s)

C_p is the specific heat of water (W/kg-K)

$h_{sat\ air,outlet}$ is the saturated outlet air enthalpy (J/kg)

$h_{air,inlet}$ is the inlet air enthalpy (J/kg)

\dot{m}_{air} is the mass flow rate of air through the tower (kg/s).

The saturation temperature and humidity ratio are then calculated for the tower's outlet air.

$$T_{sat\ air,outlet} = PsyTsatFnHPb(h_{sat\ air,outlet}, OutBaroPress) \quad (16.59)$$

$$\omega_{sat\ air,outlet} = PsyWFnTdbH(T_{sat\ air,outlet}, h_{sat\ air,outlet}) \quad (16.60)$$

where:

$T_{sat\ air,outlet}$ is the saturated outlet air temperature ($^{\circ}\text{C}$)

$PsyTsatFnHPb$ is an EnergyPlus psychrometric function, returns saturation temperature given enthalpy and barometric pressure

OutBaroPress is the outdoor barometric pressure (Pa)

$\omega_{sat\ air,outlet}$ is the saturated outlet air humidity ratio ($\text{kg}_{water}/\text{kg}_{dry\ air}$)

$PsyWFndbH$ is an EnergyPlus psychrometric function, returns humidity ratio given dry-bulb temperature and enthalpy.

The makeup water quantity required to replenish the water lost due to evaporation is then calculated as the product of the air mass flow rate and the difference between the entering and leaving air humidity ratio divided by the density of water.

$$\dot{V}_{evaporation,makeup} = \frac{\dot{m}_{air} (\omega_{sat\ air,outlet} - \omega_{air,inlet})}{\rho_{water}} \quad (16.61)$$

where:

$\dot{V}_{evaporation,makeup}$ is the makeup water usage due to evaporation (m^3/s)

\dot{m}_{air} is the mass flow rate of air through tower (kg/s)

$\omega_{air,inlet}$ is the humidity ratio of tower inlet air ($\text{kg}_{water}/\text{kg}_{dry\ air}$)

ρ_{water} is the density of water evaluated at the tower inlet air temperature (kg/m^3).

The second method available for calculating water makeup for evaporation is for the user to provide a value for a loss factor. The evaporation loss is then calculated as a fraction of the circulating condenser water flow and varies with the temperature change in the condenser water. The value provided by the user is in units of percent-per-degree Kelvin. The evaporation rate will equal this value times each degree Kelvin of temperature drop in the condenser water. Typical values are from 0.15 to 0.27 [percent/K]. The default is 0.2. The rate of water makeup for evaporation is then calculated by multiplying this factor times the condenser water flow rate and the temperature decrease in the condenser water flow rate. For evaporative fluid coolers, a numerical value of loss factor can be entered in the same manner as for cooling towers. If this field is blank, an empirical correlation will be used to calculate the value based on current outdoor dry bulb temperature and relative humidity. The following correlation from Qureshi and Zubair (2007) is used to calculate the loss factor:

$$Loss\ Factor = (113 - 8.417\phi + 1.6147t_{db}) * 10^{-5} \quad (16.62)$$

where ϕ is the relative humidity of inlet air and t_{db} is the dry-bulb temperature of inlet air.

Additional makeup water usage is modeled as a percentage of design water flow rate through the tower to account for drift, and as a scheduled flow rate to model blowdown. Drift is water loss due to the entrainment of small water droplets in the air stream passing through the tower. Drift is defined by the model user as a percentage of the tower's design water flow rate, and is assumed to vary with tower air flow rate ratio as follows:

$$\dot{V}_{drift,makeup} = \dot{m}_{water,design} \left(\frac{PercentWatertoDrift}{100.0} \right) FR_{air} \quad (16.63)$$

where:

$\dot{V}_{drift,makeup}$ is the makeup water usage due to drift (m^3/s)

$\dot{m}_{water,design}$ is the design (volumetric) water flow rate (m^3/s)

PercentWatertoDrift is the percent of design water flow rate lost to drift at the tower design air flow rate

FR_{air} is the ratio of actual air flow rate to tower design air flow rate.

Blowdown is water flushed from the basin on a periodic basis to purge the concentration of mineral scale or other contaminants. There are two ways that blowdown is calculated in Energy-Plus. Blowdown water rates can be scheduled so that we have:.

If *ScheduleBlowdown* is defined, then:

$$\dot{V}_{blowdown,makeup} = ScheduleValue_{blowdown} \quad (16.64)$$

Else:

$$\dot{V}_{blowdown,makeup} = 0.0 \quad (16.65)$$

where:

$\dot{V}_{blowdown,makeup}$ is the makeup water usage due to blowdown (m³/s)

ScheduleValue_{blowdown} is the blowdown schedule value for the time step being simulated (m³/s).

The second (and default) way that blowdown can be calculated is to assume that blowdown water is continually introduced at a rate that will provide a constant concentration ratio. As water evaporates it leaves behind minerals and the like causing the concentration of water impurities to be higher in the tower than in the makeup water. Acceptable concentration ratios are in the range of 3 to 5 depending on the purity of the make up water. Water lost as drift does not evaporate and decrease the water needed for blowdown. Using the “Concentration Ratio” method, the rate of blowdown can be calculated using:

$$\dot{V}_{blowdown,makeup} = \frac{\dot{V}_{evaporation,makeup}}{R_{concentration} - 1} - \dot{V}_{drift,makeup} \quad (16.66)$$

where *R_{concentration}* is the concentration ratio or the ratio of solids in the blowdown water to solids in the makeup water.

The tower makeup water consumption (m³) for each simulation time step is calculated as the sum of the individual components of makeup water usage multiplied by the simulation time step in hours and the conversion for hours to seconds (3600 sec/hr). Makeup water usage is only calculated when the cooling tower is active and water is flowing through the cooling tower.

$$V_{water,makeup} = \left(\dot{V}_{evaporation,makeup} + \dot{V}_{drift,makeup} + \dot{V}_{blowdown,makeup} \right) \cdot TimeStepSys \cdot 3600 \quad (16.67)$$

where *V_{water,makeup}* is the tower makeup water consumption (m³).

16.1.5 One and Two Speed Fluid Coolers

16.1.5.1 Overview

The input objects FluidCooler:SingleSpeed and FluidCooler:TwoSpeed provide models for dry fluid coolers. Fluid cooler's performance is modeled using effectiveness-NTU relationships for cross flow heat exchanger with both streams unmixed. The model can be used to simulate the performance of both single speed and two speed mechanical-draft fluid coolers. For part-load operation, the model assumes a simple linear interpolation between two steady-state regimes without accounting for any cycling losses.

16.1.5.2 Model Description

The expression for fluid cooler effectiveness is as follows:

$$\varepsilon = 1 - \exp \left\{ \frac{\exp \left(\frac{-NTUC_r}{\eta} \right) - 1}{\frac{C_r}{\eta}} \right\} \quad (16.68)$$

where ε is the heat exchanger effectiveness and the following equations define terms important to this equation:

$$C_r = \frac{\dot{C}_{\min}}{\dot{C}_{\max}} \quad (16.69)$$

$$\dot{C}_a = \dot{m}_a c_{pa} \quad (16.70)$$

$$\dot{C}_a = \dot{m}_a c_{pa} \quad (16.71)$$

$$\dot{C}_w = \dot{m}_w c_{pw} \quad (16.72)$$

$$\dot{C}_{\max} = \text{Max}(\dot{C}_a, \dot{C}_w) \quad (16.73)$$

$$\dot{C}_{\max} = \text{Max}(\dot{C}_a, \dot{C}_w) \quad (16.74)$$

$$\dot{C}_{\min} = \text{Min}(\dot{C}_a, \dot{C}_w) \quad (16.75)$$

$$NTU = \frac{UA}{\dot{C}_{\min}} \quad (16.76)$$

$$\eta = NTU^{(-0.22)} \quad (16.77)$$

The first fluid is water and the second fluid is air entering the heat exchanger at temperature $T_{db,in}$ and specific heat c_{pa} . The heat exchanger is characterized by a single parameter, its overall heat transfer coefficient-area product UA.

When the user selects the nominal capacity method, the UA is calculated as follows:

The model inputs (other than the UA) and the fluid cooler load that it must meet are specified at design conditions. Then the fluid cooler model converges to a UA value, using the regula-falsi method that will enable it to meet the design fluid cooler load given at the specified inputs.

16.1.5.3 Method for Calculating Steady-State Exiting Water Temperature

The objective of the fluid cooler model is to predict the exiting water temperature and the fan power required to meet the exiting water setpoint temperature. The exiting water temperature is calculated based on an energy balance that assumes that the energy absorbed by the air is equivalent to the energy removed from the water. The procedure for calculating the steady-state, exiting air dry-bulb temperature is outlined below.

With the overall heat transfer coefficient-area product for the fluid cooler calculated by the nominal capacity information entered by the user, the effectiveness of the heat exchanger is then calculated as:

$$\varepsilon = 1 - \exp \left\{ \frac{\exp \left(\frac{-NTUC_r}{\eta} \right) - 1}{\frac{C_r}{\eta}} \right\} \quad (16.78)$$

The heat transfer rate is then calculated as follows:

$$\dot{Q} = \varepsilon \dot{C}_{\min} (T_{w,in} - T_{db,in}) \quad (16.79)$$

$$\dot{Q} = \varepsilon \dot{C}_{\min} (T_{w,in} - T_{db,in}) \quad (16.80)$$

Then the outlet air dry-bulb and outlet water temperature are calculated:

$$T_{db,out} = T_{db,in} + \frac{\dot{Q}}{\dot{C}_a} \quad (16.81)$$

$$T_{w,out} = T_{w,in} - \frac{\dot{Q}}{\dot{C}_w} \quad (16.82)$$

where:

$T_{w,in}$ is the inlet water temperature (°C)

$T_{w,out}$ is the outlet water temperature (°C)

$T_{db,in}$ is the dry-bulb temperature of the inlet air (°C)

$T_{db,out}$ is the dry-bulb temperature of the outlet air (°C).

16.1.5.4 Calculating the Actual Exiting Water Temperature and Fan Power

The previous section describes the methodology used for calculating the steady-state temperature of the water leaving the fluid cooler. This methodology is used to calculate the exiting water temperature with the fluid cooler fans operating (including low and high fan speed for the two-speed fluid cooler). The exiting water temperature calculations use the fluid flow rates (water and air) and the Nominal capacity information entered by the user for each regime.

The fluid cooler model seeks to maintain the temperature of the water exiting the fluid cooler at (or below) a setpoint. The setpoint schedule is defined by the field “Loop Temperature Setpoint Node or reference” for the CondenserLoop object.

The fluid cooler fans are turned on to reduce the exiting water temperature to the setpoint. The model assumes that part-load operation is represented by a simple linear interpolation between two steady-state regimes (e.g., Fluid cooler fans on for the entire simulation time step and fluid cooler fans off for the entire simulation time step). Cyclic losses are not taken into account. If the outlet water temperature is less than the set-point then the fraction of time for which the fluid cooler must operate to meet the set-point is calculated by using the following equation:

$$\omega = \frac{T_{set} - T_{wout,off}}{T_{wout,on} - T_{wout,off}} \quad (16.83)$$

where:

T_{set} is the exiting water setpoint temperature (°C)

$T_{wout,off}$ is the exiting water temperature with all fluid cooler fans off (°C)

$T_{wout,on}$ is the exiting water temperature with all fluid cooler fans on (°C).

The average fan power for the simulation time step is calculated by multiplying ω by the steady-state fan power specified by the user.

The calculation method for the two-speed fluid cooler is similar to that for the single-speed fluid cooler example described above. The model first calculates the steady-state exiting water temperature with the fluid cooler fans at low speed. If the exiting water temperature at low fan speed is below the setpoint temperature, then the average fan power is calculated based on the result of previous equation and the steady-state, low speed fan power specified by the user. If low-speed fan operation is unable to reduce the exiting water temperature below the setpoint, then the fluid cooler fans' speed is increased to high speed and the steady-state exiting water temperature is calculated. If this temperature is below the setpoint, then a modified version of previous equation is used to calculate runtime at high fan speed:

$$\omega = \frac{T_{set} - T_{wout,low}}{T_{wout,high} - T_{wout,low}} \quad (16.84)$$

where:

T_{set} is the exiting water setpoint temperature (°C)

$T_{wout,low}$ is the exiting water temperature with fluid cooler fans at low speed (°C)

$T_{wout,high}$ is the exiting water temperature with fluid cooler fans at high speed (°C).

The average fan power for the simulation time step is calculated for the two-speed fluid cooler as follows:

$$P_{fan,avg} = \omega(P_{fan,high}) + (1 - \omega)(P_{fan,low}) \quad (16.85)$$

16.2 Demand Controlled Ventilation

ASHRAE Standard 62.1, Ventilation for Acceptable Indoor Air Quality, contains provisions that allow building ventilation systems to vary the amount of outdoor ventilation air delivered to occupied zones based on feedback from sensors that monitor various indoor air contaminants (ASHRAE 2007). Although not a contaminant of concern in most buildings, carbon dioxide (CO₂) levels can be monitored as an indicator of building occupancy and the associated human bioeffluent concentration. Demand controlled ventilation (DCV) is being increasingly used to modulate outdoor ventilation air based on real-time occupancy (Emmerich and Persily 1997, Schell et al. 1998, Schell and Int-Hout

2001). Modulating the outdoor ventilation air while maintaining proper indoor air quality has the potential for large energy savings compared to constant rate ventilation systems that are typically designed to provide outdoor ventilation air based on maximum anticipated occupancy.

EnergyPlus can model DCV by the ventilation rate procedure (VRP) defined in ASHRAE Standard 62.1-2007/2010 for single and multiple path systems, and the indoor air quality procedure (IAQP) defined in Standard 62. The VRP first calculates the breathing-zone outdoor air flow rate based on two components – the zone occupant component and the zone floor area component, then it calculates the zone supply outdoor air flow rate considering the zone air distribution effectiveness and secondary recirculation (for multi-path systems only), and finally calculates the system outdoor air flow rate considering the zone diversity and system ventilation efficiency. The user must include the following five objects in their input data file in order to model DCV (using VRP or IAQP):

- **AirLoopHVAC:OutdoorAirSystem** to simulate the mixed air box of the air loop
- **Controller:MechanicalVentilation** with the DCV flag set to ‘Yes’ to determine the minimum outdoor air flow rate to be provided by the mixed air box
- **Controller:OutdoorAir** to control the outside air flow rate introduced via the mixed air box
- **DesignSpecification:OutdoorAir** to describe the outdoor air requirements for each zone
- **DesignSpecification:ZoneAirDistribution** to describe air distribution effectiveness and secondary recirculation (for multi-path ventilation systems) for each zone

The outdoor air system (**AirLoopHVAC:OutdoorAirSystem**) is a subsystem of an **AirLoopHVAC** which handles the mixed air portion of the primary air system: the system relief air, the outside air inlet, and any components and controllers associated with the system relief air and outside air streams. The inputs for this object are fully described in the EnergyPlus Input Output Reference. Determining the outdoor air ventilation rate and introducing this ventilation via the mixed air box are accomplished by the mechanical ventilation and outdoor air controller objects.

The VRP currently requires outdoor air ventilation rates to be determined based on the floor area of each occupied zone plus the number of people in each zone. The number of people varies based on the setting of the DCV flag in the **Controller:MechanicalVentilation** object. For using occupancy at every time step, the DCV flag must be set to ‘Yes’. The outdoor air ventilation rate can then be reset dynamically as operating conditions change (e.g., variations in occupancy). The **Controller:MechanicalVentilation** object simplifies the procedure for calculating these outdoor air ventilation requirements and resetting them based on varying occupancy levels. This is particularly useful for large air distribution systems that serve a number of different zone types with varying occupancy levels.

The IAQP (ASHRAE 2007) is a design procedure in which outdoor air intake and other system design parameters are based on an analysis of contaminant sources, and contaminant concentration targets. Although carbon dioxide is not considered as an indoor contaminant but is considered as an indicator of indoor air quality in buildings, EnergyPlus uses IAQP to control carbon dioxide. In addition, a generic contaminant may be introduced. The current IAQP in EnergyPlus allows credit to be taken for controls that can be reliably demonstrated to result in indoor carbon dioxide and generic contaminant concentrations equal to or lower than those achieved using the VRP. The IAQP may also be used where the design is intended to attain specific target carbon dioxide and generic contaminant levels.

16.2.1 Ventilation Rate Procedure

16.2.1.1 Calculation of zone minimum outdoor air flow

For the i -th zone, first the breathing-zone outdoor air flow is calculated:

$$V_{bz,i} = R_{p,i} \times P_i + R_{a,i} \times A_i \times SchedFrac_i \quad (16.86)$$

where:

$V_{bz,i}$ is the breathing-zone outdoor air flow (m^3/s)

$R_{p,i}$ is the ventilation rate per person ($\text{m}^3/\text{s-person}$)

P_i is the number of occupants for the zone

$R_{a,i}$ is the ventilation rate per floor area ($\text{m}^3/\text{s-m}^2$)

A_i is the floor area of the zone (m^2)

$SchedFrac_i$ is the Outdoor Air Schedule value for the zone, if specified in the corresponding DesignSpecification:OutdoorAir object (defaults to 1.0)

i is the index of the zone or zone list.

Next, the i -th zone outdoor air flow is calculated:

$$V_{oz,i} = V_{bz,i} / E_i \quad (16.87)$$

Where:

$V_{oz,i}$ is the zone outdoor air flow (m^3/s)

E_i is the zone air distribution effectiveness, see following figure for ASHRAE recommended values.

16.2.1.2 Calculation of system minimum outdoor air flow

Occupant diversity, D , is the expected peak system population, Ps , divided by the sum of the design zone population for all the zones attached to the air system, $Pzsum$. In EnergyPlus, D , Ps , and $Pzsum$ are determined by a side calculation, in the routine DetermineSystemPopulationDiversity. This routine loops over each airloop in the model and processes the People descriptions in each zone attached to a given airloop. The design level is summed and includes zone multipliers. The concurrent system peak population is calculated by stepping through a full year of zone timesteps and multiplying the people schedules (input field Number of People Schedule Name) to the design level and summing up a total people concurrent at each timestep. The largest value for the total concurrent people on a system is used for $Pzsum$. For single zone air systems, D is forced to be 1.0 because there is no diversity that could come from serving multiple zones.

For single zone systems, the system outdoor air flow:

$$V_{ot} = V_{oz} \quad (16.88)$$

For 100% outdoor air multi-zone systems, the system outdoor air flow:

$$V_{ot} = \sum_{i=1}^{allzones} V_{oz,i} \quad (16.89)$$

For non 100% outdoor air multi-zone systems, the system outdoor air flow:

Air Distribution Configuration	E_z
Ceiling supply of cool air.	1.0
Ceiling supply of warm air and floor return.	1.0
Ceiling supply of warm air 15°F (8°C) or more above space temperature and ceiling return.	0.8
Ceiling supply of warm air less than 15°F (8°C) above space temperature and ceiling return provided that the 150 fpm (0.8 m/s) supply air jet reaches to within 4.5 ft (1.4 m) of floor level. <i>Note:</i> For lower velocity supply air, $E_z = 0.8$.	1.0
Floor supply of cool air and ceiling return provided that the 150 fpm (0.8 m/s) supply jet reaches 4.5 ft (1.4 m) or more above the floor. <i>Note:</i> Most underfloor air distribution systems comply with this proviso.	1.0
Floor supply of cool air and ceiling return, provided low-velocity displacement ventilation achieves unidirectional flow and thermal stratification.	1.2
Floor supply of warm air and floor return.	1.0
Floor supply of warm air and ceiling return.	0.7
Makeup supply drawn in on the opposite side of the room from the exhaust and/or return.	0.8
Makeup supply drawn in near to the exhaust and/or return location.	0.5

1. "Cool air" is air cooler than space temperature.
2. "Warm air" is air warmer than space temperature.
3. "Ceiling" includes any point above the breathing zone.
4. "Floor" includes any point below the breathing zone.
5. As an alternative to using the above values, E_z may be regarded as equal to air change effectiveness determined in accordance with ANSI/ASHRAE Standard 129¹⁷ for all air distribution configurations except unidirectional flow.

Figure 16.2: Zone Air Distribution Effectiveness Typical Values (Source: ASHRAE Standard 62.1-2010)

$$V_{ot} = V_{ou}/E_v \quad (16.90)$$

For non 100% outdoor air multi-zone systems, and when the “Standard62.1VentilationRateProcedureWithLimit” option is used, the system outdoor air flow:

$$V_{ot} = \min(V_{ot_{design}}, V_{ou}/E_v) \quad (16.91)$$

The “Standard62.1VentilationRateProcedureWithLimit” option should be used when the system outdoor air intake must stay at or below the design minimum outdoor air flow rate. This option can be used to meet the “Multiple-Zone VAV System Ventilation Optimization Control” requirements in ASHRAE Standards 90.1-2010 (and onwards) as well as the “Outdoor Airflow Set Point for ASHRAE Standard 62.1-2016 Ventilation” in Section 5.16.3.1 in the ASHRAE Guideline 36-2018.

where:

V_{ou} is the uncorrected system outdoor air flow (m^3/s)

$$V_{ou} = \sum_{i=1}^{allzones} (R_{p,i} \times P_i \times SchedFrac_i) + \sum_{i=1}^{allzones} (R_{a,i} \times A_i \times SchedFrac_i) \quad (16.92)$$

X_s is the uncorrected system outdoor air fraction

$$X_s = V_{ou}/V_{ps} \quad (16.93)$$

V_{ps} is the system supply air flow (m^3/s)

$Z_{d,i}$ is the zone outdoor air fraction

$$Z_{d,i} = V_{oz,i}/V_{dz,i} \quad (16.94)$$

$V_{dz,i}$ is the zone supply air flow (m^3/s)

E_v is the system ventilation efficiency, determined as the minimum of the zone ventilation efficiency among all ventilation zones served by the air handler

E_v is the minimum of (E_{vz})

E_{vz} is the zone ventilation efficiency, determined differently for single-path and multi-path systems.

For single-path systems:

$$E_{vz} = 1 + X_s - Z_{d,i} \quad (16.95)$$

For multi-path systems:

$$E_{vz} = (Fa + X_s \cdot Fb - Z_{d,i} \cdot Ep \cdot Fc)/Fa \quad (16.96)$$

where system air fractions Fa , Fb , and Fc are determined as follows:

$$Fa = Ep + (1 - Ep) \cdot Er \quad (16.97)$$

$$Fb = Ep \quad (16.98)$$

$$Fc = 1 - (1 - Ez) \cdot (1 - Er) \cdot (1 - Ep) \quad (16.99)$$

where:

Ep is the zone primary air fraction. For dual-fan dual-duct systems, the zone primary air is the air from the cold duct. This can be expressed as: $Ep = V_{pz}/V_{dz,i}$

Er is the zone secondary recirculation fraction.

Single-path systems are special cases of multi-path systems where $Er = 0$, $Ep = 1$, $Fa = Fb = Fc = 1.0$

The zone secondary recirculation fraction Er is determined by the designer based on system configuration. For plenum return systems with secondary recirculation (e.g., fan-powered VAV with plenum return) Er is usually less than 1.0, although values may range from 0.1 to 1.2 depending upon the location of the ventilation zone relative to other zones and the air handler. For ducted return systems with secondary recirculation (e.g., fan-powered VAV with ducted return), Er is typically 0.0, while for those with system-level recirculation (e.g., dual-fan dual-duct systems with ducted return) Er is typically 1.0. For other system types, Er is typically 0.75.

The program then calculates the minimum outdoor air flow fraction based on the information provided in the object `Controller:MechanicalVentilation` and the maximum branch air flow rate as follows:

$$MechVentOutsideAirMinFrac = V_{ot}\rho_{std}/\dot{m}_{maxbranch} \quad (16.100)$$

where `MechVentOutsideAirMinFrac` is the outdoor air minimum fraction based on all zones specified in the `Controller:MechanicalVentilation` object.

`Controller:OutdoorAir` controls the amount of outdoor ventilation air introduced via the mixed air box based on several user inputs. The user can define the minimum outdoor air flow rate as a percentage of the system's supply air flow rate (e.g., for a variable-air volume system) or a fixed minimum outdoor air flow rate (not as a percentage but a fixed value) (field `MinimumLimit`). DCV, using the `Controller:MechanicalVentilation` object in conjunction with the `Controller:OutdoorAir` object, allows a third option for setting the minimum outdoor air flow. Economizer operation can also be specified to increase the outdoor air flow above the minimum flow rate to provide free cooling when conditions permit (`Controller:OutdoorAir`, field `Economizer Control Type`).

EnergyPlus uses the *largest* outdoor air flow rate calculated by the various methods described above when modeling system performance (as long this rate doesn't exceed the maximum flow rate specified for the main air loop branch or for the outdoor air controller itself).

The method used to calculate the outdoor ventilation air flow rate for each system simulation time step is described in more detail below. The figure below schematically illustrates air flow paths used in the calculation of outdoor air flow rate.

The minimum outdoor air flow rate is first calculated based on the minimum outdoor air flow rate and the minimum outdoor air schedule value as defined by the user inputs for the object `Controller:OutdoorAir`:

$$\dot{m}_{minOA} = \dot{V}_{minOA} \cdot MinOAScheduleValue \cdot \rho_{std} \quad (16.101)$$

where:

\dot{m}_{minOA} is the minimum outdoor air flow rate for this time step (kg/s)

\dot{V}_{minOA} is the minimum outdoor air flow rate defined in `Controller:OutdoorAir` (m³/s)

`MinOAScheduleValue` is the minimum outdoor air schedule value defined by the schedule identified in `Controller:OutdoorAir`

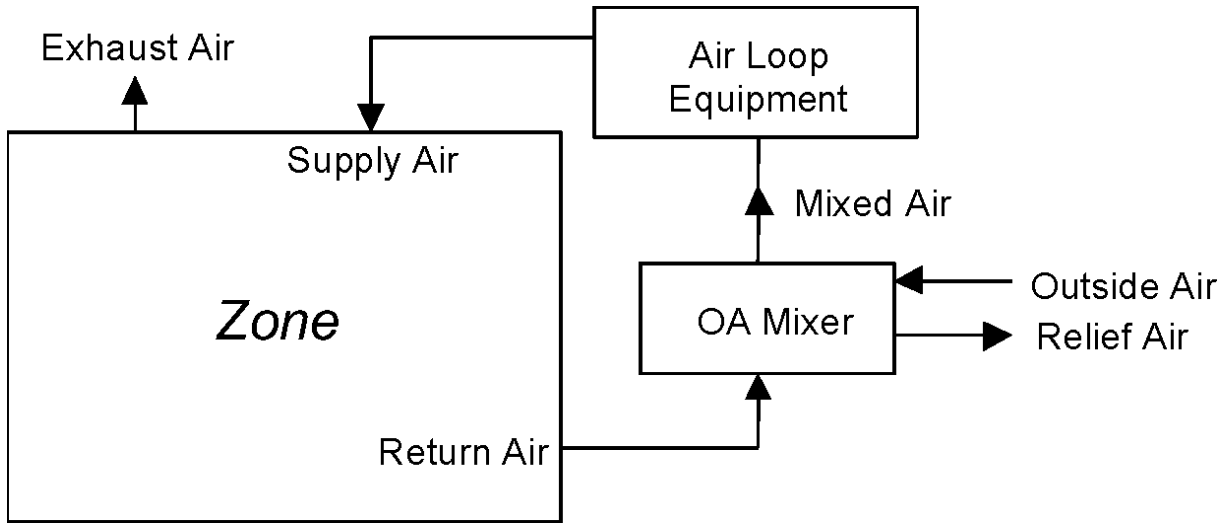

Figure 16.3: Demand Control Ventilation – Air Flow Paths

ρ_{std} is the standard air density (1.204 kg/m^3) adjusted for the local barometric pressure (standard barometric pressure corrected for altitude, ASHRAE 1997 HOF pg. 6.1).

The outdoor air minimum fraction is then calculated as the ratio of the minimum outdoor air flow rate calculated above to the maximum air flow rate defined in the Branch statement for the main air loop (converted to mass flow rate).

$$OutAirMinFrac = \frac{\dot{m}_{minOA}}{\dot{m}_{max,branch}} \quad (16.102)$$

where \dot{m}_{minOA} is the maximum branch air volume flow rate times ρ_{std} (kg/s).

The program then calculates the minimum outdoor air flow fraction (*MechVentOutsideAirMinFrac*) according to the VRP based on the information provided in the object Controller:MechanicalVentilation and the maximum branch air flow rate.

The algorithm then uses the larger of these outdoor air minimum fractions in subsequent calculations, and also makes sure that the resulting fraction is between 0 and 1.

$$OutAirMinFrac = MAX(OutAirMinFrac, MechVentOutsideAirMinFrac) \quad (16.103)$$

$$OutAirMinFrac = MIN(MAX(OutAirMinFrac, 0.0), 1.0) \quad (16.104)$$

The algorithm goes on to determine if economizer operation is possible based on the user inputs and the current conditions of the outdoor air and return air. If conditions permit economizer operation, the outdoor air flow fraction is increased beyond the minimum fraction to meet the mixed air setpoint temperature (setpoint temperature assigned to the node defined in field “Control_Node” of Controller:OutdoorAir).

$$OAFrac = MAX(OutAirMinFrac, EconomizerOAFrac) \quad (16.105)$$

The mass flow rate of outdoor air is then calculated based on the outdoor air fraction determined above and the mixed (supply) air mass flow rate:

$$\dot{m}_{OA} = OAFrac * \dot{m}_{MixedAir} \quad (16.106)$$

where:

\dot{m}_{OA} is the mass flow rate of outdoor air (kg/s)

$OAFrac$ is the fraction of outdoor air in the mixed (supply) air stream

$\dot{m}_{MixedAir}$ is the mass flow rate of the mixture of return air and outdoor ventilation air (kg/s).

The algorithm checks to make sure the calculated outdoor air mass flow rate is greater than or equal to the air flow rate being exhausted.

$$\dot{m}_{OA} = MAX(\dot{m}_{OA}, \dot{m}_{ExhaustAir}) \quad (16.107)$$

If a fixed minimum outdoor air flow rate is specified (field Minimum Limit Type in Controller:OutdoorAir) for a continuous air flow system, the program makes sure that the outdoor air mass flow rate is greater than or equal to the minimum outdoor air flow rate specified by the user.

$$\dot{m}_{OA} = MAX(\dot{m}_{OA}, \dot{m}_{minOA}) \quad (16.108)$$

The outdoor air mass flow rate should be less than or equal to the mixed (supply) air flow rate, and the outdoor air flow rate is reset if necessary.

$$\dot{m}_{OA} = MIN(\dot{m}_{OA}, \dot{m}_{MixedAir}) \quad (16.109)$$

The outdoor air mass flow rate should also be less than or equal to the maximum outdoor air flow rate specified by the user, and the outdoor air flow rate is reset if necessary.

$$\dot{m}_{OA} = MIN(\dot{m}_{OA}, \dot{m}_{MaxOA}) \quad (16.110)$$

where \dot{m}_{MaxOA} is the maximum outdoor air mass flow rate which is equal to the maximum outdoor air volume flow rate from Controller:OutdoorAir times ρ_{std} (kg/s).

Finally, the relief air flow rate is calculated as the difference between the outside and exhaust air mass flow rates.

$$\dot{m}_{ReliefAir} = MAX(\dot{m}_{OA} - \dot{m}_{ExhaustAir}, 0.0) \quad (16.111)$$

16.2.2 Indoor Air Quality Procedure

Like VRP, the user must include the following three objects in their input data file in order to model CO₂-based DCV with IAQP:

- **AirLoopHVAC:OutdoorAirSystem** to simulate the mixed air box of the air loop
- **Controller:MechanicalVentilation** to determine the minimum outside air flow rate to be provided by the mixed air box
- **Controller:OutdoorAir** to control the outside air flow rate introduced via the mixed air box

The outdoor air mass flow rate provided by the air loop is calculated as below:

$$\dot{m}_{OA} = \sum_i^N \dot{m}_{OA,z,i} \times SchedFrac_i \quad (16.112)$$

where:

$\dot{m}_{OA,z,i}$ is the outdoor air mass flow rate for the i th zone as calculated according to section Carbon Dioxide Prediction located elsewhere in this document.

$SchedFrac_i$ is the Outdoor Air Schedule value for the zone, if specified in the corresponding DesignSpecification:OutdoorAir object (defaults to 1.0)

N is the number of zones served by the air loop, which is provided in the input for a Controller:MechanicalVentilation object.

16.2.3 Proportional Control

The control has three choices: ProportionalControlBasedOnOccupancySchedule, ProportionalControlBasedOnDesignOccupancy, and ProportionalControlBasedOnDesignOARate. The difference is occupancy level in the first two choices. The former uses real time occupancy, while the latter uses design occupancy level. The third choice is used to calculate the outdoor airflow rate based on design outdoor air flow rate, specified in the DesignSpecification:OutdoorAir object. Like Ventilation Rate Procedure and the Indoor Air Quality Procedure, the following three objects must be included in the input data file in order to model CO₂-based DCV with Proportional Control:

- **AirLoopHVAC:OutdoorAirSystem** to simulate the mixed air box of the air loop
- **Controller:MechanicalVentilation** to determine the minimum outside air flow rate to be provided by the mixed air box
- **Controller:OutdoorAir** to control the outside air flow rate introduced via the mixed air box

For the i -th zone, the outdoor air mass flow rate provided by the air loop is calculated as below:

1. The required intake flow of outdoor air for the design zone population, $P_{z,i}$

$$V_{ot-design,i} = \frac{(R_{p,i} \cdot P_{z,i} \times SchedFrac_i) + (R_{a,i} \cdot A_{z,i} \times SchedFrac_i)}{E_i} \quad (16.113)$$

If ProportionalControlBasedOnDesignOARate is specified, the required intake flow rate will be revised as:

$$V_{ot-design,i} = \frac{DesignOutdoorAirFlowRate_i}{E_i} \quad (16.114)$$

The Design Outdoor Air Flow Rate is determined in the DesignSpecification:OutdoorAir object.

2. The required intake flow of outdoor air when the zone is unoccupied i.e. $P_{z,i} = 0$

$$V_{ot-min,i} = \frac{(R_{a,i} \cdot A_{z,i} \times SchedFrac_i)}{E_i} \quad (16.115)$$

If ProportionalControlBasedOnDesignOARate is specified, the required intake flow rate will be revised as:

$$V_{ot-min,i} = \frac{DesignOutdoorAirFlowRate_i \times SchedPropMin_i}{E_i} \quad (16.116)$$

3. The target indoor CO₂ concentration at $V_{ot-design,i}$

$$C_{s-design,i} = C_o + \frac{N}{(V_{ot-design,i}/P_{z,i})} \quad (16.117)$$

When the field of Maximum Carbon Dioxide Concentration Schedule Name is entered, the schedule value is used for $C_{s-design,i}$ instead of the calculated value.

4. The target indoor CO₂ concentration at V_{ot-min} is either a user input in the object ZoneControl:ContaminantController or equal to the outdoor CO₂ concentration. The default is outdoor CO₂ concentration.

$$C_{s-min,i} = C_o \quad (16.118)$$

When the indoor CO₂ concentration equals $C_{s-design,i}$, V_{ot} should equal $V_{ot-design,i}$. When the indoor CO₂ concentration equals $C_{s-min,i}$, V_{ot} should equal $V_{ot-min,i}$. When the indoor CO₂ concentration is between $C_{s-min,i}$ and $C_{s-design,i}$, a controller should adjust outdoor air intake flow V_{ot} proportionally between $V_{ot-min,i}$ and $V_{ot-design,i}$:

$$V_{ot,i} = V_{ot-min,i} + (V_{ot-design,i} - V_{ot-min,i}) \frac{(C_{s-actual,i} - C_{s-min,i})}{(C_{s-design,i} - C_{s-min,i})} \quad (16.119)$$

where:

$R_{p,i}$ is the required outdoor air flow rate per person ((m³/s)/person)

$R_{a,i}$ is the required outdoor air flow rate per unit area ((m³/s)/m²)

$P_{z,i}$ is the design zone population (number of people)

$SchedFrac_i$ is the outdoor Air Schedule value for the zone, if specified in the corresponding DesignSpecification:OutdoorAir object (defaults to 1.0)

$SchedPropMin_i$ is the Proportional Control Minimum Outdoor Air Flow Rate Schedule value for the zone, if specified in the corresponding DesignSpecification:OutdoorAir object (defaults to 1.0). When ProportionalControlBasedOnDesignOccupancy is specified, number of people is equal to the design occupancy times the current schedule value. When ProportionalControlBasedOnDesignOccupancy is specified, the number of people equals the design occupancy.

$A_{z,i}$ is the zone floor area (m²)

E_i is the zone air distribution effectiveness

N is the CO₂ generation rate specified in the People object ((m³/s)/person)

C_o is the CO₂ concentration in the outdoor air (ppm)

$C_{s-design,i}$ is the CO₂ concentration in the space for the design conditions (ppm)

$C_{s-min,i}$ is the minimum CO₂ concentration in the space (ppm)

$C_{s-actual,i}$ is the actual CO₂ concentration in the space (ppm)

$V_{ot-design,i}$ is the required intake of outdoor air flow rate at $C_{s-design}$ (m³/s)

$V_{ot-min,i}$ is the required intake of outdoor air flow rate at C_{s-min} (m³/s)

$V_{ot,i}$ is the required intake of outdoor air flow rate at $C_{s-actual}$ (m³/s)

Except for $C_{s-min,i}$ above, all other variables are already available in EnergyPlus (See Engineering Reference for “Ventilation Rate Procedure” above for further details). C_{s-min} can be specified in the ZoneControl:ContaminantController object as a schedule. If C_{s-min} is not specified in the ZoneControl:ContaminantController object, then outdoor air CO₂ concentration will be used as the minimum. In order for “ProportionalControl” to be active, the following conditions must be met, otherwise default “VentilationProcedure” will be modeled and a warning will be issued during runtime:

1. “Carbon Dioxide Control Availability Schedule Name” input field in the ZoneControl:ContaminantController object must be greater than zero.
2. CO₂ gain from people in the zone must be greater than zero.
3. “Outdoor air flow per person” and “Outdoor air flow per zone floor area” in the corresponding “DesignSpecification:OutdoorAir” object must be greater than zero.

16.2.4 Simplified Procedure

16.2.4.1 System Ventilation Efficiency

The Simplified Procedure (SP) introduced in ASHRAE Standard 62.1-2019 provides an alternative way to determine the ventilation efficiency of a system (E_v). The efficiency is calculated using equation 16.120 when the occupant diversity, D , is less than 0.6 and equation 16.121 otherwise. E_v is then used in the same manner as in the VRP to determine the system design outdoor air intake.

$$E_v = 0.88D + 0.22 \text{ for } D < 0.60 \quad (16.120)$$

$$E_v = 0.75 \text{ for } D \geq 0.60 \quad (16.121)$$

16.2.4.2 Zone Minimum Air Flow

When set to autosize, the minimum (primary) air flow (or fraction) for these terminals will be calculated using equation 16.122: *AirTerminal:SingleDuct:VAV:NoReheat* (Constant Minimum Air Flow Fraction or Fixed Minimum Air Flow Fraction), *AirTerminal:SingleDuct:VAV:Reheat* (Constant Minimum Air Flow Fraction or Fixed Minimum Air Flow Fraction), *AirTerminal:SingleDuct:SeriesPIU:Reheat*, *AirTerminal:SingleDuct:ParallelPIU:Reheat*.

$$V_{pz_{min}} = 1.5 * V_{oz} \quad (16.122)$$

16.3 Evaporative Coolers

This section describes the evaporative coolers models for HVAC in EnergyPlus.

16.3.1 Direct Evaporative Cooler

The input object `EvaporativeCooler:Direct:CelDekPad` provides a model of a direct stage evaporative cooler, shown in the figure below, that consists of a rigid media evaporative pad, with water recirculated from a reservoir. The water is pumped from the reservoir to a water distribution header, for water feed by gravity from above the media. The evaporative pad provides the area for the adiabatic saturation of the air. While the process provides a lower dry-bulb temperature, the moisture content of the leaving air is higher than the entering condition. The direct stage is used for comfort cooling in a building where adding humidity to the air can be tolerated.

The thermodynamic process is a simultaneous heat and mass transfer, or adiabatic cooling, and follows a constant enthalpy line on the psychrometric chart; it is shown in the figure below as a process from A to B. Since the deviation of the constant wet-bulb line and the constant enthalpy line is small, it is assumed that the wet-bulb temperature is constant across the direct evaporative stage.

If the direct evaporative process were 100% efficient, the leaving dry-bulb temperature would equal the entering wet-bulb temperature. The efficiency of the direct evaporative process is less than 100% and by defining saturation efficiency (ε_{se}) for the direct stage or evaporative pad, the leaving dry-bulb temperature can be expressed by the following equation.

$$T_{dbsupout} - T_{dbsupin} = \varepsilon_{se} \cdot (T_{odb} - T_{owb}) \quad (16.123)$$

16.3.1.1 Saturation Efficiency

Since the evaporative process is not 100% efficient the saturation efficiency is defined by.

Figure 16.4: Direct Stage Evaporative Cooler

Figure 16.5: Psychrometric Chart – Constant Enthalpy

$$\varepsilon_{se} = \frac{T_{dbsupin} - T_{dbsupout}}{T_{odb} - T_{owb}} \quad (16.124)$$

The saturation efficiency is determined from manufacturer's data, and the least squares curve fit is discussed in Curve Fitting Evaporative Media section.

Using the saturation efficiency (ε_{se}) for the direct stage evaporative pad, the leaving dry-bulb temperature can be determined directly. The evaporative process approximately follows a constant wet-bulb line. Therefore, with the leaving dry-bulb temperature and assuming adiabatic heat transfer across the direct stage, the outlet conditions for the direct stage are known.

The saturation efficiency of the direct evaporative cooler is a function of the pad geometry and airflow rate. The pad geometry is constant throughout the simulation, but the airflow rate can change from hour to hour when the evaporative cooler is used with an air economizer. The saturation efficiency would then be determined from the flow for that hour with the geometry of the direct evaporative cooler. This gives the dry-bulb temperature leaving the evaporative cooler. Assuming adiabatic heat transfer across the direct stage, the evaporative process follows the constant wet-bulb line or the constant enthalpy line on the psychrometric chart, therefore the wet-bulb temperature is constant from inlet to outlet.

Some things that can cause departure from the ideal adiabatic saturation process in the direct evaporative cooler are:

- makeup water entering the sump,
- friction from water re-circulation,
- heat transfer from surroundings,
- solar radiation (sun upon a cooler).

Thus, adiabatic saturation in evaporative cooling is only an approximation, however the adiabatic saturation assumption in the rigid-media cooler is good, since the water recirculates rapidly and approximates the wet-bulb temperature at steady state operation.

16.3.1.2 Curve Fitting Evaporative Media

The saturation efficiency is usually reported as a function of airflow, pad face velocity, and pad thickness. The Figure below shows a typical graph of manufacturer's data for the saturation efficiency. A multi-variate least squares curve fit of the data was used to generate saturation efficiency functions for the evaporative models that use the CelDek rigid media pad.

The curve fit for saturation efficiency was obtained using the functions listed below. The model uses the air velocity (*Airvel*) through the pad and the depth of the media (*Depth*). The least squares routine produced the following model that is used for the evaporative cooling rigid media pad. The least squares routine produced an eleven-term multi-variate fit using a third order quadratic.

$$\begin{aligned} \varepsilon_{se} = & 0.792714 + 0.958569(\text{Depth}) - 0.25193(\text{Airvel}) - 1.03215(\text{Depth}^2) \\ & + 0.0262659 (\text{Airvel}^2) + 0.914869(\text{Depth} * \text{Airvel}) \\ & - 1.48241(\text{Airvel} * \text{Depth}^2) - 0.018992(\text{Airvel}^3 * \text{Depth}) \\ & + 1.13137(\text{Depth}^3 * \text{Airvel}) + 0.0327622 (\text{Airvel}^3 * \text{Depth}^2) \\ & - 0.145384(\text{Depth}^3 * \text{Airvel}^2) \end{aligned} \quad (16.125)$$

Figure 16.6: Graph of Saturation Efficiency

where $Airvel$ is in meters per second and $Depth$ is in meters. This curve fit is used for the rigid media in the `EvapCooler:Direct:CelDekPad` and `EvapCooler:InDirect:CelDekPad`.

16.3.2 Dry Coil Indirect Evaporative Cooler

The input object `EvaporativeCooler:Indirect:CelDekPad` provides a model of a dry coil indirect evaporative cooler, shown in the figure below, that has a rigid media pad, similar to the direct evaporative stage, where the adiabatic cooling takes place. The secondary air leaves the rigid media pad and enters an air-to-air heat exchanger where it cools the supply air flowing through the heat exchanger tubes. The moist secondary air is then exhausted to the environment. The secondary air stream has its own fan and includes consists of a rigid media evaporative pad, with water recirculated from a reservoir. The water is pumped from the reservoir to a water distribution header, for water feed by gravity from above the media. The evaporative pad provides the area for the adiabatic saturation of the air.

The process that the secondary air goes through, A to C to D, is shown by the dashed lines in the following figure. Process A to C is adiabatic cooling in the rigid media pad. Then the air enters the shell side of the heat exchanger and is sensibly heated from C to D by the warm supply air passing through the tube side.

The advantage of the dry coil heat exchanger is that the heat exchanger does not have the evaporation taking place on the outside of the tubes, thus no mineral deposits are left on the heat exchange surface to reduce the efficiency of the heat exchanger. The rigid media pads are designed to flush the mineral deposits to the sump, so the saturation efficiency of the pad stays relatively constant.

The following equations are used to determine the dry-bulb temperature leaving the evaporative

Figure 16.7: Evaporative Cooler – Indirect Dry Coil

Figure 16.8: Secondary Air Process – Indirect Dry Coil Evap Cooler

media, given pad geometry and secondary airflow information. The heat transfer in the heat exchanger can be determined with the effectiveness of the heat exchanger according.

$$T_{db,sup,out} = T_{db,sup,in} - \varepsilon_{se} * (T_{odb} - T_{owb}) \quad (16.126)$$

$$Q_{Hx} = \varepsilon_{Hx} * \text{Min}(CFM_{sec}, CFM_{supply}) * \rho_{air} * c_{p,air} * (T_{odb} - T_{db,sec,out}) \quad (16.127)$$

After the heat transfer for the heat exchanger has been determined, an energy balance is done on the supply airside to determine the dry-bulb temperature leaving the indirect evaporative cooler. This assumes all the energy for is provided by the primary air stream so the effectiveness value includes the air-to-air effectiveness of the heat exchanger.

$$T_{db,sup,out} = T_{db,sup,in} - \frac{Q_{Hx}}{\rho_{air} * c_{p,air} * CFM_{supply}} \quad (16.128)$$

The wet-bulb temperature is determined from psychrometric routines using the leaving dry-bulb temperature, humidity ratio, and barometric pressure, since humidity ratio is constant for the supply air across the indirect stage. The effectiveness of the heat exchanger is determined from a parameter estimation using manufacturer's performance data. For the indirect evaporative cooler it was found that a value of 0.67 represented reasonable default effectiveness.

16.3.3 Wet Coil Indirect Evaporative Cooler

The input object EvaporativeCooler:Indirect:WetCoil provides a model for a wetted coil evaporative cooler, shown in the figure below, that has water sprayed directly on the tubes of the heat exchanger where latent cooling takes place. The vaporization of the water on the outside of the heat exchanger tubes allows the simultaneous heat and mass transfer which removes heat from the supply air on the tube side. Then the moist secondary air is exhausted. The secondary air stream has its own fan.

The process that the secondary air goes through, A to C on the following figure, is a path of simultaneous heat and mass transfer, but it does not follow a line of constant enthalpy as in the direct stage. The process is not adiabatic due to the heat gain from the supply air flowing through the tubes of the heat exchanger.

The wet coil heat exchanger can have a higher stage efficiency than the dry coil due to a higher heat transfer rate on the outside of the heat exchanger tubes. Over the operating lifetime of the heat exchanger, the vaporization taking place on the heat exchange surface can leave mineral deposits that will decrease the effectiveness of the heat exchanger.

16.3.3.1 Efficiencies of the Indirect Stage

In an indirect stage of an evaporative cooler, the secondary or wet side air stream acts as a heat sink for the supply air. The efficiency of the indirect stage is given as the effectiveness of the sensible heat exchange, ε_{Hx} , and the saturation efficiency on the wet streamside, ε_{se} . These are expressed as:

$$\varepsilon_{Hx} = \frac{q}{q_{max}} = \frac{C_{sup}(T_{sup,in} - T_{sup,out})}{C_{min}(T_{sec,in} - T_{sec,out})} \quad (16.129)$$

Figure 16.9: Wet Coil Indirect Evaporative Cooler

Figure 16.10: Secondary Air Process – Indirect Wet Coil Evaporative Cooler

$$\varepsilon_{se} = \frac{T_{dbsecin} - T_{dbsecout}}{T_{odb} - T_{owb}} \quad (16.130)$$

where $T_{db,sup,in} = T_{db,sec,in}$ for the indirect cooler. The maximum heat transfer possible would be obtained if the supply stream was cooled all the way to the wet-bulb temperature. So the efficiency of the indirect evaporative cooler is defined by:

$$\varepsilon_{ind} = \frac{(T_{db,sup,in} - T_{db,sup,out})}{(T_{odb} - T_{owb})} \quad (16.131)$$

Using the combination of the effectiveness and saturation efficiency, the total efficiency of the indirect stage can be expressed by:

$$\varepsilon_{ind} = \varepsilon_{Hx} \varepsilon_{se} \frac{C_{sup}}{C_{min}} \quad (16.132)$$

In many cases, $C_{sup} = C_{min}$ and the efficiency of the indirect stage reduces to:

$$\varepsilon_{ind} = \varepsilon_{Hx} \varepsilon_{se} \quad (16.133)$$

An intuitive model determining the performance of the wet coil indirect model was developed. This model can be used for all indirect models by curve fitting data from the evaporative cooler of interest. The model development starts with the total efficiency of the indirect evaporative cooler:

$$\varepsilon_{ind} = \frac{(T_{dbsupin} - T_{dbsupout})}{(T_{odb} - T_{owb})} \quad (16.134)$$

Solving for $T_{db,sup,out}$ gives the leaving conditions of the supply air at a constant humidity ratio:

$$T_{db,sup,out} = T_{db,sup,in} - \varepsilon * (T_{odb} - T_{owb}) \quad (16.135)$$

A form for the efficiency of the indirect stage was devised using a maximum efficiency with a coefficient to reduce the efficiency depending on the ratio of the airflows.

$$\varepsilon_{ind} = \varepsilon_{max} - C_1 * \frac{CFM_{sup}}{CFM_{sec}} \quad (16.136)$$

where C_1 is the “Flow Efficiency Ratio” and is determined from performance data.

A check of limits will verify that it makes physical sense. As the magnitude of the secondary flow increases, the second term of equation above becomes smaller. This would make the efficiency tend to go to the maximum efficiency. Physically this would be true since the convective terms for heat and mass transfer would increase on the outside of the tube with the additional mass flow rate. Similarly, if the supply air flow goes to zero with a constant secondary air flow, the second term of the equation above again becomes small, and the overall efficiency of the stage would approach the maximum. The constant C_1 tells how quickly the efficiency of the stage would decrease with a mismatch of the supply and secondary flows.

The maximum efficiency of the stage is a combination of the efficiency due to the simultaneous heat and mass transfer on the outside of the tube and the efficiency of the heat exchanger. This value can be higher than the dry coil overall efficiency since the convective coefficients on the outside of the tube are larger. For example, a least squares fit for the maximum efficiency showed this

value was approximately 0.8 compared to the dry coil indirect value of approximately 0.65 ($0.67 * 0.97$). (The maximum efficiency for the dry coil indirect was determined at the condition where flow through the evaporative pad in the secondary air stream approached zero, for a 12-inch thick pad.) It should be noted again that over the operating life of the wet coil heat exchanger, the mineral deposits that are left can decrease the effectiveness of the heat exchanger unless appropriate maintenance has taken place. Therefore, if modeling an older system, the manufacturer's data may no longer describe the equipment effectiveness.

16.3.4 Two Stage Direct/Indirect Evaporative Cooler

A two stage cooler can be modeled by combining either a wet coil or the dry coil indirect evaporative cooler staged with a direct evaporative cooler. The figure below shows a dry coil indirect evaporative cooler with a direct evaporative cooler. This configuration is mainly used for total comfort cooling for a building and would not normally be used as a pre-cooler for a refrigeration coil, since the direct stage would increase the latent load on a refrigeration coil.

Figure 16.11: Two Stage Evaporative Cooler

The thermodynamic process for the supply air is shown below, going from A to B to C. The process from A to B is sensible cooling in the indirect stage. The process from B to C is simultaneous heat and mass transfer following a constant enthalpy line. The air leaving the final stage has a lower dry-bulb and wet-bulb temperature, and an increase in moisture from the direct stage.

Two stage evaporative coolers can be accomplished by putting the `EvaporativeCooler:Direct:CelDekPad`, `EvaporativeCooler:Indirect:CelDekPad`, `EvaporativeCooler:Indirect:WetCoil` in series in any combination the user desires in the supply air loop.

16.3.5 Indirect Evaporative Cooler Special Research Model

This section summarizes the model implemented in the component `EvaporativeCooler:Indirect:ResearchSpecial`. Examples of this evaporative cooler are shown in the following figures, without and with a relief valve. This model differs from the other indirect evaporative coolers in that, under part

Figure 16.12: Thermodynamic Process for Supply Air Through Two Stage Evaporative Cooler

load conditions, it can modulate so that the air leaving the cooler just meets a drybulb temperature setpoint.

The indirect research special evaporative cooler (IEC) machine provides improved modeling features needed for data center and other hybrid cooling applications. The new model includes performance curves for variable effectiveness, fan power, and pump power. It is intended to be able to model IEC machines that have 1) variable speed secondary fans, 2) variable speed pumps for water recirculation and spraying, and 3) ability to operate in a dry mode. Such IEC machines can modulate the cooling power during operation by varying either the secondary side fan speed or the intensity of water spray or both. To simplify the model it is assumed that the device's internal controls are such that, when it is operating as a “Wet” evaporative cooler, secondary fan and spray pump operation are linked together so that there is a one-to-one mapping between them at any given part load situation. This allows formulating the fan and pump power performance curves to be based on the same independent variable, secondary air flow fraction.

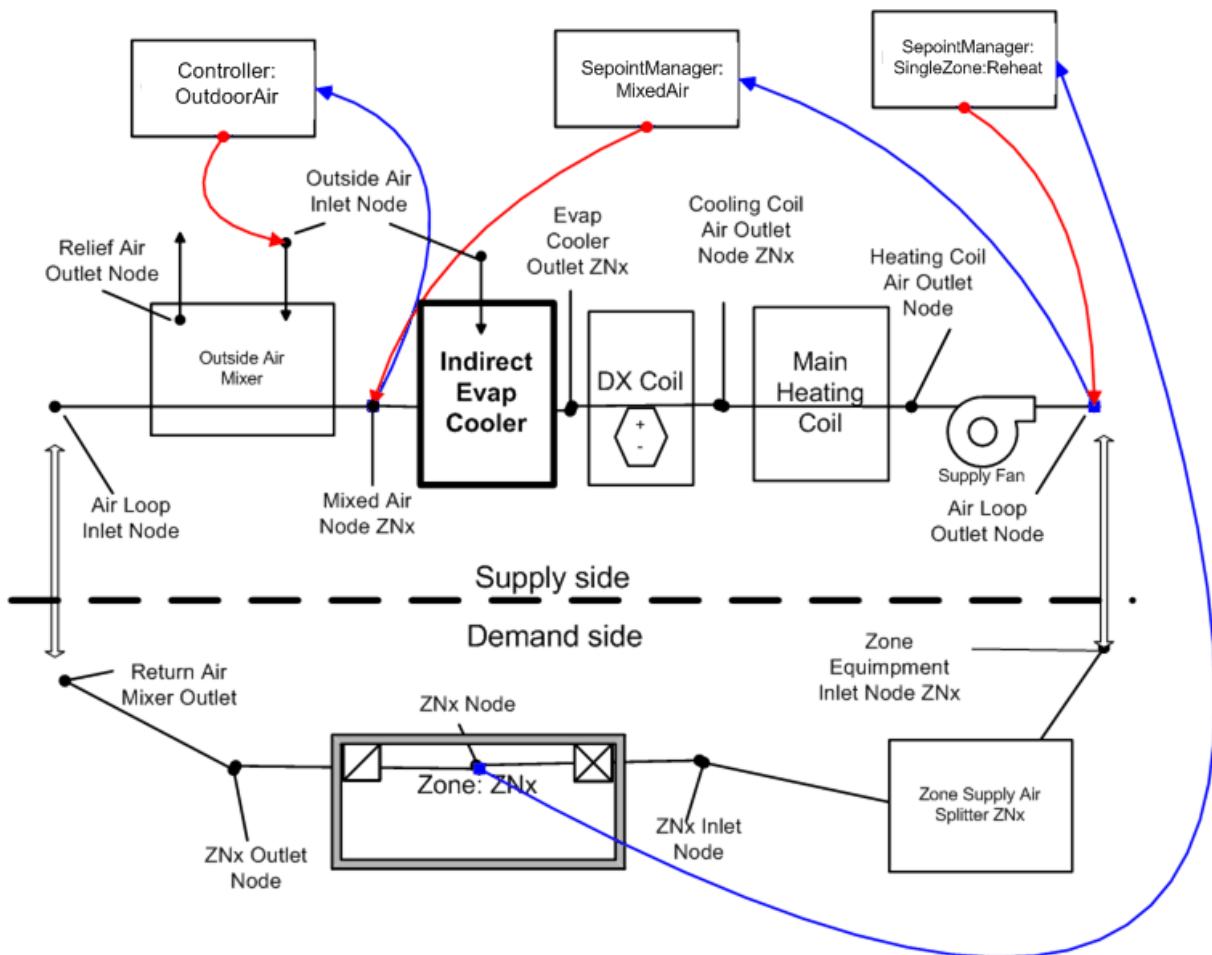

Figure 16.13: Research Special Indirect Evaporative Cooler

16.3.5.1 Model Formulation

Each time the model is called it takes the inputs on the left and produces the outputs on the right as shown in Figure 16.14. “sys” is primary air stream and typically sits on an AirLoop HVAC

branch. “sec” is secondary purge air stream and is typically outdoor air. The model will set node flow rates and “out_sec” state variables on the secondary outlet.

Figure 16.14: Research Special Indirect Evaporative Cooler Input/Output Model

Figure: Illustration of Inputs-Outputs of Indirect Evaporative Cooler Research Special

The model runs either in dry mode or wet mode depending entering air conditions of the primary and secondary air sides. Different effectiveness values are used depending on the operating modes.

16.3.5.2 Wet Mode Operation

If running “wet,” use wet bulb effectiveness and wet bulb temperature depression for delta T:

$$\begin{aligned}\varepsilon_{wb,op} &= \varepsilon_{wb,design} \cdot f_{wb,mod}(\text{flowRatio}) \\ \text{flowRatio} &= \frac{\dot{m}_{sec}}{\dot{m}_{sys}}\end{aligned}\quad (16.137)$$

where:

$\varepsilon_{wb,op}$ is the current operation effectiveness with respect to wet bulb temperature depression

$\varepsilon_{wb,design}$ is the user input for effectiveness at design air flow rates and full spray power

$f_{wb,mod}$ is the normalized wet mode operation effectiveness modifier performance curve as a function of flow fraction. The curve value describes how effectiveness varies at different flow rates. When conditions are appropriate, this curve is numerically inverted to find a FlowRatio that just meets a setpoint.

\dot{m}_{sys} is the primary air current time step mass flow rate (kg/s)

\dot{m}_{sec} is the secondary air current time step mass flow rate (kg/s).

The leaving primary air dry bulb temperature in wet operating mode is calculated as follows:

$$T_{db,out,sys} = T_{db,in,sys} - \varepsilon_{wb,op} (T_{db,in,sys} - T_{wb,in,sec}) \quad (16.138)$$

Then check that there is sufficient heat capacitance flux (mcT) in the secondary air stream to provide the conditioning. The following steps are for checking and adjusting for non-physical outcomes that could happen with low secondary flow rates.

1. Calculate heat transfer rate

The secondary air entering wet-bulb temperature would be the lowest limit allowed, although this temperature cannot be attained in most practical situations. This is checked as a limiting case.

$$\begin{aligned} T_{db,out,sys} &= \max(T_{db,out,sys}, T_{db,out,setpoint}) \\ \dot{Q}_{HX} &= (\dot{m}c_p)_{sys,in} \cdot (T_{db,in,sys} - T_{db,out,sys}) \end{aligned} \quad (16.139)$$

2. Calculate outlet enthalpy of the secondary air

$$\text{enthalpy}_{out,sec} = \text{enthalpy}_{in,sec} + \frac{\dot{Q}_{HX}}{\dot{m}_{sec}} \quad (16.140)$$

One approximation that can be made is the outlet condition of the temperature and humidity ratio combination that produces the outlet enthalpy of the secondary air calculated above. A conservative approach is that the secondary air leaves with water added at such a rate that it results in the secondary air to leave at the same dry bulb temperature and all the total heat transfer results in humidity ratio increases, i.e., latent heat transfer. Following this assumption the secondary air outlet humidity ratio can be calculated in step 3.

3. Calculate outlet humidity ratio of the secondary air

$$\begin{aligned} T_{db,out,sec} &= T_{db,in,sec} \\ \text{HumRat}_{out,sec} &= \text{PsyWFnTbH}(T_{db,out,sec}, \text{enthalpy}_{out,sec}) \\ \dot{V}_{water} &= \frac{\dot{Q}_{HX} / [(\text{HumRat}_{out,sec} - \text{HumRat}_{in,sec}) \cdot h_{fg,in,sec}]}{\rho_{water, Tdb,in,sec}} \\ \text{or} &= \\ \dot{V}_{water} &= \frac{\dot{Q}_{HX} / [\text{enthalpy}_{out,sec} - \text{enthalpy}_{in,sec}]}{\rho_{water, Tdb,in,sec}} \end{aligned} \quad (16.141)$$

16.3.5.3 Dry Mode Operation

Similarly, if running “dry” use dry bulb effectiveness and dry bulb based delta T

$$\varepsilon_{db,op} = \varepsilon_{db,design} \cdot f_{db,mod}(\text{flowRatio}) \quad (16.142)$$

where:

$\varepsilon_{db,op}$ is the current operation effectiveness with respect to dry bulb temperature depression

$\varepsilon_{db,design}$ is the user input for effectiveness at design air flow rates and dry operation mode (no water spray on the secondary air side)

$f_{db,mod}$ is the normalized dry mode operation effectiveness modifier performance curve as a function of flow fraction. The curve value describes how the dry mode effectiveness varies with different flow rates. When conditions are appropriate, this curve is numerically inverted to find a FlowRatio that just meets a setpoint.

The leaving primary air dry bulb temperature in dry operating mode is calculated as follows:

$$T_{db,out,sys} = T_{db,in,sys} - \varepsilon_{db,op} (T_{db,in,sys} - T_{db,in,sec}) \quad (16.143)$$

Then check that there is sufficient heat capacitance flux (mcT) in the secondary air stream to provide the conditioning. For dry operation, it should be sufficient to simply use inlet moist air

properties for density and specific heat. The following steps are for checking and adjusting for non-physical outcomes that could happen with low secondary flow rates.

1. Calculate heat transfer

$$\dot{Q}_{HX} = (\dot{m}c_p)_{sys,in} (T_{db,in,sys} - T_{db,out,sys}) \quad (16.144)$$

2. Calculate secondary/scavenger leaving dry-bulb

$$T_{db,out,sec} = T_{db,in,sec} + \frac{\dot{Q}_{HX}}{(\dot{m}c_p)_{sys,in}} \quad (16.145)$$

3. Check for energy imbalance and adjust if needed

$$IF (T_{db,out,sec} > T_{db,in,sys}), THEN T_{db,out,sec} = T_{db,in,sys} - 0.2^\circ C \quad (16.146)$$

4. Recalculate heat transfer limit if imbalance found in step 3 using new secondary outlet drybulb

$$\dot{Q}_{HX,lim} = (\dot{m}c_p)_{sec,in} \cdot (T_{db,out,sec} - T_{db,in,sec}) \quad (16.147)$$

5. Recalculate leaving supply air drybulb using new heat transfer rate from step 4

$$T_{db,out,sys} = T_{db,in,sec} + \frac{\dot{Q}_{HX}}{(\dot{m}c_p)_{sys,in}} \quad (16.148)$$

The IEC in dry and wet operating mode transfers no moisture to the primary system air, so the humidity ratio remains the same:

$$\text{HumRat}_{out,sys} = \text{HumRat}_{in,sys} \quad (16.149)$$

16.3.5.4 Secondary Air Flow Fraction

The secondary air mass flow rate will either be set to \dot{m}_{sec} or solved for numerically as described below. The secondary side flow fraction, ff_{sec} , is defined as. (Note this is another flow ratio that differs from the one used above which combined both streams into one ratio in effectiveness modifier curves.)

$$ff_{sec} = \frac{\dot{m}_{sec}}{\dot{m}_{sec,design}} \quad (16.150)$$

And secondary air fan electric power $p_{sec,fan}$ is calculated as.

$$P_{sec,fan} = P_{sec,fan,design} \cdot f_{sec,fan,mod}(ff_{sec}) \quad (16.151)$$

where:

$P_{sec,fan}$ is the secondary air fan electric power value at current secondary air flow rate (W)

$P_{sec,fan,design}$ is the secondary air fan electric power value at design air flow rate (W)

$f_{sec,fan,mod}$ is the secondary air fan power modifier normalized performance curve as a function of secondary air flow fraction

$\dot{m}_{sec,design}$ is the secondary air design mass flow rate (kg/s)

Recirculation and spray pump electric power is calculated using design pump electric power and a normalized pump power modifier performance curve that describes how power varies as a function of the secondary air flow fraction is given by:

$$P_{pump} = P_{pump,design} \cdot f_{pump,mod}(ff_{sec}) \quad (16.152)$$

where:

P_{pump} is the recirculation and spray pump power value at current operation (W)

$P_{pump,design}$ is the recirculation and spray pump power value at design air flow rate (W)

$f_{pump,mod}$ is the recirculation and spray pump power modifier normalized performance curve as a function of secondary air flow fraction.

Three user specified operating temperature limits are included in the model. These allow controlling when operation should shift from wet to dry and when the cooler should just be shut down because the outdoor conditions are too warm or too wet to do anything beneficial. The three temperature limits are:

- $T_{db,evapMinLimit}$ is the Evaporative Operation Minimum Limit Outdoor Drybulb Temperature, user input. Shut down wet mode with outdoor temperature is lower than this limit, typically shifting to dry mode.
- $T_{wb,evapMaxLimit}$ is the Evaporative Operation Maximum Limit Outdoor Wetbulb Temperature, user input. Shut down fan and pump and don't operate when outdoor Wetbulb is higher than this limit. The wet bulb is maybe warmer than the return air and attempting evaporative cooling is wasteful.
- $T_{db,evapMaxLimit}$ is the Dry Operation Maximum Limit Outdoor Drybulb Temperature, user input. Shut down dry operation attempts and don't operate secondary fan when outdoor dry bulb is higher than this limit. The dry bulb is maybe warmer than the return air and attempting to do heat exchange is wasteful.

Algorithm to determine cooler operation proceeds as follows:

1. Retrieve leaving setpoint, $T_{db,out,setpoint}$
2. Calculate leaving dry bulb for max cooling power available at full secondary air flow rate for dry operation, $T_{db,out,sys,dry,min}$
3. Check if dry operation limit (input field called Evaporative Operation Minimum Limit Outdoor Dry-Bulb Temperature) reached, $T_{db,in,sec} < T_{db,evapMinLimit}$
4. If dry limit not exceeded, then leaving dry bulb for max cooling power available at full secondary air flow rate for wet operation, $T_{db,out,sys,wet,min}$

5. Compare setpoint temperature needed to temperatures available, evaluate limits and choose which case for operation is called for. The following table outlines the six cases in order of increasing cooling power.

Case	Criteria
Off	$T_{db,in,sec} < T_{db,out,setpoint}$ or $(T_{db,in,sec} > T_{db,dryMaxLimit}$ and $T_{wb,in,sec} > T_{wb,evapMaxLimit})$
Dry Op Modulated	$T_{db,in,sec} < T_{wb,evapMinLimit}$; $T_{db,in,sec} < T_{db,dryMaxLimit}$ $T_{db,out,sys,dry,min} < T_{db,out,setpoint}$
Dry Op Max	$T_{db,in,sec} > T_{wb,evapMinLimit}$; $T_{db,in,sec} < T_{db,dryMaxLimit}$ $T_{db,out,setpoint} < T_{db,out,sys,dry,min}$
Dry or Wet Op Modulated	$T_{db,in,sec} > T_{wb,evapMinLimit}$; $T_{db,in,sec} < T_{db,dryMaxLimit}$ $T_{wb,in,sec} < T_{wb,evapMaxLimit}$ $T_{db,out,sys,wet,min} < T_{db,out,setpoint}$
Wet Op Modulated	$T_{db,in,sec} > T_{wb,evapMinLimit}$; $T_{wb,in,sec} < T_{wb,evapMaxLimit}$ $T_{db,out,sys,wet,min} < T_{db,out,setpoint}$
Wet Op Max	$T_{db,in,sec} > T_{wb,evapMinLimit}$; $T_{wb,in,sec} < T_{wb,evapMaxLimit}$ $T_{db,out,setpoint} < T_{db,out,sys,wet,min}$

“Modulated” cases solve for a secondary flow rate using numerical method, such as root solver. Residual is formulated by a difference between the dry bulb temperature leaving the cooler and the setpoint. As the solver progress it varies flow rate on the secondary side until the setpoint is met. For each iteration, a new effectiveness is calculated as a function of Flow Ratio. The new flow is used for the $(\dot{m}_p)_{min}$ term and the new effectiveness is used to calculate a result for leaving drybulb. The numerical method is the same for dry and wet operation, only the functions will use different curves and state variables to describe performance. The root solver solver can vary secondary flow rate, \dot{V}_{sec} , to drive the following residual to zero:

$$\text{residual} = T_{db,out,sys} - T_{db,out,setpoint} \quad (16.153)$$

“Dry or Wet Op Modulated” is the most complex situation. There is an overlap and the cooler could deliver the setpoint air using either dry operation or wet operation. The model proceeds separately to calculate both wet and dry operation, with separate numerical solvers for modulation in each mode. Then the fan and pump power is calculated for each mode. Select the lowest power mode as the preferred choice. (This doesn’t really count the value of water, could bring in a source factor but ...). Discard results for the unused mode.

The purge air, or secondary airside, is the stream that evaporates water and indirectly cools the primary, or system air. The result from Equation 16.143 is then compared to a lower bound, $T_{db,out,bound}$, determined from the dewpoint of the incoming purge air using Equation 16.154.

$$T_{db,out,bound} = T_{db,in,sys} - \beta(T_{db,in,sys} - T_{dew,in,purge}) \quad (16.154)$$

where:

$T_{dew,in,purge}$ is the dewpoint of purge air entering the wet side of cooler [°C]

β is a factor for how close to dewpoint is possible (eg. 0.9)

The final result (for $PLF = 1$) is the larger of the results from Equations 16.143 and 16.154.

The indirect cooler has the ability to overcool the air and therefore needs some form of modulation. A Part Load Fraction, PLF, is used to model the implications of controlling the amount of cooling. It is assumed that through on/off cycling that the cooling power can be varied to exactly meet the desired temperature when PLF is less than unity.

$$\dot{Q}_{Full} = \dot{m} (h_{out,sys} - h_{in,sys}) \quad (16.155)$$

$$\dot{Q}_{Required} = \dot{m} (h_{out,desired} - h_{in,sys}) \quad (16.156)$$

$$PLF = \frac{\dot{Q}_{Required}}{\dot{Q}_{Full}} \quad (16.157)$$

where PLF is the Part Load Fraction. When PLF is less than 1.0, it is assumed that the cooler will deliver the desired temperature air (as long as it is less than the inlet; it doesn't need heating). The PLF is used along with secondary side flow fraction to modify the auxiliary fan power when the fan power modifier curve is not specified and find when the unit will overcool.

$$P_{fan} = \Delta P \cdot \dot{V} \cdot e \cdot PLF \cdot ff_{sec} \quad (16.158)$$

Water pump power is also derated using the PLF and ff_{sec} .

A third air stream input to the cooler was implemented in order to allow mixing building exhaust air with outdoor air on the purge/secondary side of the cooler. The assumption when relief/tertiary air is used is that all of the available relief zone air is used and the remainder made up with outdoor air. Moisture and energy balances are drawn to compute humidity ratio and enthalpy of mixed secondary air. The volume is determined by the design volume flow rate (from secondary fan size).

16.3.5.5 Water Consumption

Water consumption is an important consideration when evaluating evaporative coolers. Water consumption of the evaporative cooler is modeled using Equation 16.159.

$$\dot{V}_{water} = \dot{V}_{evap} + \dot{V}_{drift} + \dot{V}_{blowdown} \quad (16.159)$$

The three components of water consumption are evaporation, drift, and blowdown. Evaporation is the water evaporated as the normal part of the evaporative cooler thermodynamic process and is calculated using:

$$\dot{V}_{evap} = \frac{\dot{Q}_{IEC}}{\rho_{water} h_{fg}} \quad (16.160)$$

where:

\dot{V}_{evap} is the volume flow rate of useful water evaporation (m^3/s)

h_{fg} is the heat of vaporization of water (taken as 2,500,000 J/kg)

\dot{Q}_{IEC} is the rate of heat transfer of the indirect evaporator cooler or \dot{Q}_{HX} as shown in Equation 16.144 (W)

ρ_{water} is the density of water (kg/m^3).

Drift is water that leaves the secondary side as droplets and does not contribute to the evaporative cooling process in a useful manner. It is calculated using a user input factor that describes drift as a fraction of \dot{V}_{evap} .

$$\dot{V}_{drift} = \dot{V}_{evap} * f_{drift} \quad (16.161)$$

Blowdown is water drained from the sump to counter the build up of solids in the water that would otherwise occur because of evaporation. It is calculated using a user input factor for the blowdown concentration ratio, $R_{concentration}$, which is the ratio of solids in the blowdown water compared to the solids in the fresh makeup water and is limited to values of 2 or higher. The make up water needed for blowdown is calculated using:

$$\dot{V}_{blowdown} = \frac{\dot{V}_{evap}}{(R_{concentration} - 1.0)} - \dot{V}_{drift} \quad (16.162)$$

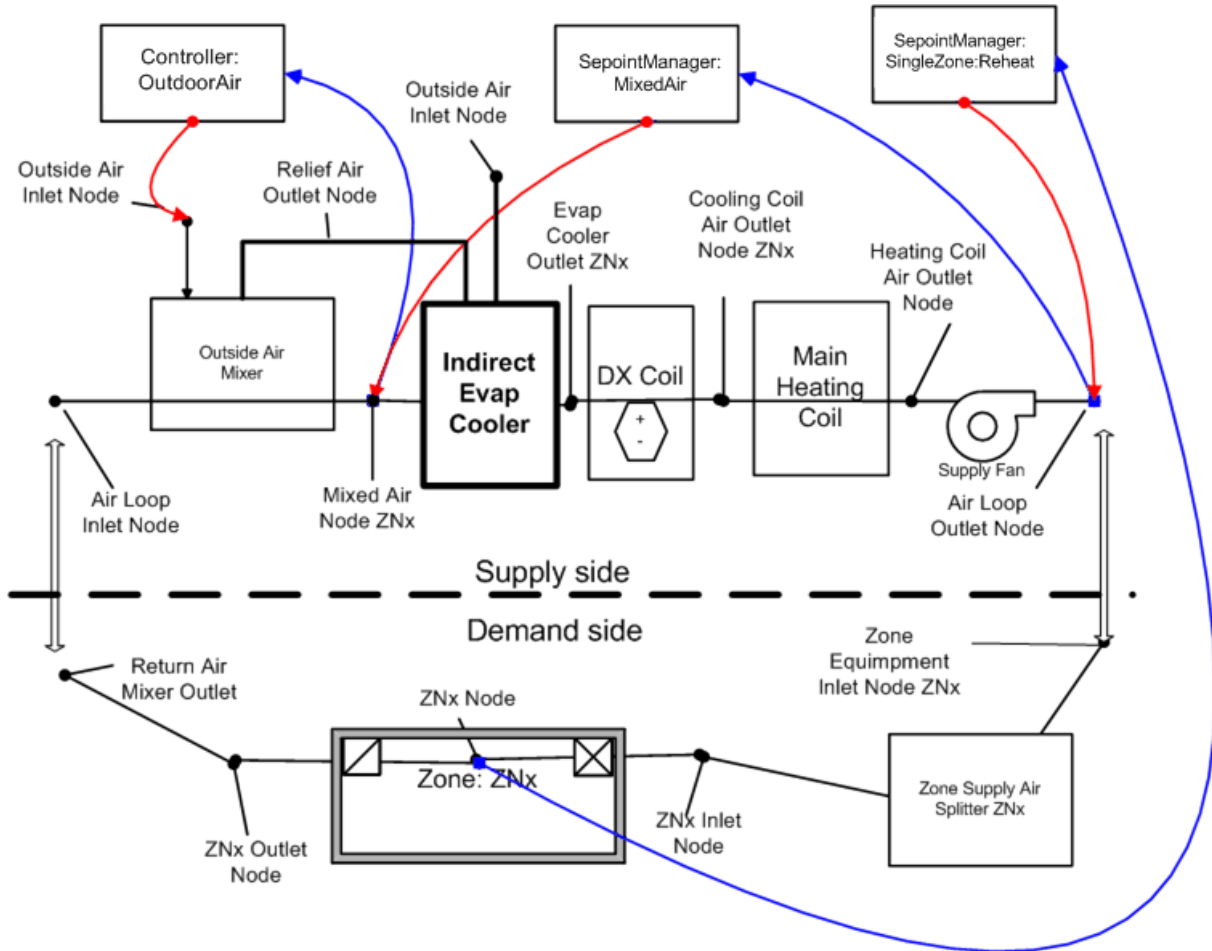

Figure 16.15: Research Special Indirect Evaporative Cooler Using Relief Air

16.3.5.6 Indirect Evaporative Cooler Sizing

The model for the object called `EvaporativeCooler:Indirect:ResearchSpecial` has a field for the secondary fan flow rate that can be autosized.

16.3.5.6.1 Secondary Air DesignFan Flow Rate

The secondary air design flow rate fan is not part of an airstream that is directly modeled in EnergyPlus. Because the primary side air flows can be autosized as part of the air system, it is convenient to also scale the size of the secondary flow. If the cooler is part of the main loop of a central air system, then the secondary fan flow rate is sized to equal to the main design flow rate.

User inputs for autosizing scaling factors are included so that when modeling an autosized IEC, all the design values can be scaled off of Primary Design Air Flow Rate. User input for Secondary Air Flow Sizing Factor is multiplied by $\text{DesMainVolFlow}_{sys}$ as follows:

$$\dot{V}_{sec,design} = \text{DesMainVolFlow}_{sys} \cdot \text{SecAirFlowScalingFactor} \quad (16.163)$$

If the cooler is part of the outdoor air path of a central air system, then the secondary air design flow rate is sized to be the maximum of either the design minimum outdoor air flow rate or one-half of the main design flow rate.

$$\dot{V}_{sec,design} = \max(\text{DesOutAirVolFlow}, 0.5 \cdot \text{DesMainVolFlow}_{sys}) \cdot \text{SecAirFlowScalingFactor} \quad (16.164)$$

16.3.5.6.2 Secondary Fan Design Power

The Secondary Fan Design Power is outsized from secondary air design flow rate and user input for Secondary Fan Sizing Specific Power in units of W/(m³/s) as follows:

$$P_{sec,fan,design} = \dot{V}_{sec,design} \cdot \text{FanPowerScalingFactor} \quad (16.165)$$

16.3.5.6.3 Recirculating Water Design Pump Power

The Recirculating Water Design Pump Power is sized from secondary air design flow rate and user input for recirculating and spraying Water Pump Power Sizing Factor in units of W/(m³/s) or W-s/m³ and is given by:

$$P_{pump,design} = \dot{V}_{sec,design} \cdot \text{PumpPowerScalingFactor} \quad (16.166)$$

where:

$\dot{V}_{sys,design}$ is the primary air design volume flow rate in (m³/s)

$\dot{V}_{sec,design}$ is the secondary air design volume flow rate in (m³/s)

SecAirFlowScalingFactor is the user specified secondary air flow sizing factor in units of W/(m³/s) for secondary design air flow rate calculation

FanPowerScalingFactor is the user specified secondary air fan sizing specific power in units of W/(m³/s) for design fan power calculation

PumpPowerScalingFactor is the user specified recirculating and spraying water pump power sizing factor in units of W/(m³/s) for design pump power calculation.

16.3.6 Direct Evaporative Cooler Special Research Model

This section summarizes the model implemented in the component EvaporativeCooler:Direct:ResearchSpecial. This model can use a simple constant effectiveness or a variable effectiveness model that, under part load conditions, can modulate so that the air leaving the cooler just meets a drybulb temperature setpoint. The algorithm used to determine the changes to the system air proceeds in four steps:

1. Calculate the current operation effectiveness using effectiveness modifying curve.
2. Calculate full load performance using a part load fraction (PLF) = 1 and Equation 16.167.
3. Calculate PLF using Equations 16.168, 16.169, and 16.170.
4. Recalculate cooler performance using the PLF.

$$\begin{aligned}
\varepsilon_{op} &= \varepsilon_{design} \cdot f_{mod}(flowRatio) \\
T_{db,out,sys} &= T_{db,in,sys} - \varepsilon_{op} \cdot (T_{db,in,sys} - T_{wb,in,sys}) \\
T_{db,out} &= T_{db,in} - \varepsilon_{op} (T_{db,in} - T_{wb,in})
\end{aligned} \tag{16.167}$$

where:

$T_{db,out,sys}$ is the drybulb temperature of the air leaving the cooler (°C) $T_{db,in,sys}$ is the drybulb temperature of the air entering the cooler (°C) $T_{wb,in,sys}$ is the wetbulb temperature of the air entering the cooler (°C) ε_{design} is the cooler design effectiveness ε_{op} is the cooler current operation effectiveness f_{mod} is the effectiveness modifier curve as a function of system air flow fraction.

The wetbulb temperature of air leaving a direct cooler is the same as the wetbulb temperature entering the cooler. The leaving humidity ratio of the air is calculated using psychrometric functions with leaving drybulb and wetbulb temperatures and outdoor air pressure as inputs. The leaving enthalpy of air is calculated using psychrometric functions with leaving drybulb temperature, leaving humidity ratio, and outdoor air pressure as inputs.

The direct cooler sometimes has the ability to overcool the air and therefore some form of modulation is useful for analysis. The special research model includes a Part Load Fraction, PLF, used to model the implications of controlling the amount of cooling. It is assumed that through some sort of on/off cycling or wetness control that the cooling electric power can be varied to exactly meet the desired temperature when PLF is less than unity. The auxiliary water pump power is then derated using user specified pump power modifier curve or linearly using a Part Load Fraction and a fan flow fraction when the pump power modifier curve is not specified.

$$FullOutput = T_{db,out} - T_{db,in} \tag{16.168}$$

$$RequiredOutput = T_{db,desired} - T_{db,in} \tag{16.169}$$

$$PLF = \frac{RequiredOutput}{FullOutput} \tag{16.170}$$

16.3.6.1 Water Consumption

Water consumption is an important consideration when evaluating evaporative coolers. Water consumption of the evaporative cooler is modeled using the following equation:

$$\dot{V}_{water} = \dot{V}_{evap} + \dot{V}_{drift} + \dot{V}_{blowdown} \tag{16.171}$$

The three components of water consumption are evaporation, drift, and blowdown. Evaporation is the water evaporated as the normal part of the evaporative cooler thermodynamic process and is calculated using:

$$\dot{V}_{evap} = \frac{\dot{m}(w_{out} - w_{in})}{\rho_{water}} \tag{16.172}$$

where:

\dot{V}_{evap} is the volume flow rate of useful water evaporation (m³/s)
 w_{out} is the humidity ratio of the air leaving the cooler (kg/kg)
 w_{in} is the humidity ratio of air entering the cooler (kg/kg)

\dot{m} is the mass flow rate of air moving through the cooler (kg/s)

ρ_{water} is the density of water (kg/m³).

Drift is water that leaves the cooler (and supply air duct) as droplets and does not contribute to the evaporative cooling process in a useful manner. It is calculated using a user input factor that describes drift as a fraction of \dot{V}_{evap} .

$$\dot{V}_{drift} = \dot{V}_{evap} * f_{drift} \quad (16.173)$$

Blowdown is water drained from the sump to counter the build up of solids in the water that would otherwise occur because of evaporation. It is calculated using a user input factor for the blowdown concentration ratio, $R_{concentration}$, which is the ratio of solids in the blowdown water compared to the solids in the fresh makeup water and is limited to values of 2 or higher. The make up water needed for blowdown is calculated using:

$$\dot{V}_{blowdown} = \frac{\dot{V}_{evap}}{(R_{concentration} - 1.0)} - \dot{V}_{drift} \quad (16.174)$$

16.4 Air System Fans

16.4.1 Overview

Four input objects (Fan:SystemModel, Fan:ConstantVolume, Fan:VariableVolume, and Fan:OnOff) provide models for fans – the prime movers in most of the air loop and zonal air conditioning systems in EnergyPlus. The *Fan:SystemModel* input object was added for version 8.7 with the intent that it provide a single versatile input object that could eventually replace Fan:ConstantVolume, Fan:VariableVolume, and Fan:OnOff. For these input objects, EnergyPlus uses a simple polynomial-based curve-fit model to describe the relation between the volume flow rate and the fan electric power, with no explicit modeling of fan pressure rise. Consequently, duct-static-pressure reset strategies can only be modeled using curves that have been specially developed to approximate static reset. For CAV and VAV central air-handling systems, a fifth input object (Fan:ComponentModel) provides a simple physics-based model for flow-dependent fan pressure rise and detailed models for fan, belt, motor, and variable-frequency-drive efficiencies and energy use. This latter input object provides the capability to analyze the effects of duct-static-pressure reset strategies, as well as changes in fan system element performance. All of these fan models calculate the fan energy usage, which is often a large fraction of HVAC energy use and a significant portion of the building energy consumption. They also calculate the temperature rise in the air stream caused by the static pressure increase as the air goes through the fan. If the motor and belt are in the air stream, waste heat from the motor and belt also acts to raise the air stream temperature.

16.4.2 Model

Each of the five fan models is a forward type: the model inputs describe the fan characteristics and the conditions of the air at the fan inlet; the outputs are the fan electrical power consumption and the conditions of the air at the fan outlet. The model algorithms and data for Fan:ConstantVolume, Fan:VariableVolume, Fan:OnOff and Fan:ComponentModel are contained in the *Fans.cc* and *Fans.hh* files in EnergyPlus. The source code for the Fan:SystemModel added for version 8.7 is contained in the *HVACFan.cc* and *HVACFan.hh* files.

16.4.2.1 Inputs and Data

For the Fan:SystemModel model (added for version 8.7), the user describes the fan by entering values for the design pressure rise across the fan, the design volume flow rate, the design electric power consumption, and the fan motor efficiency. The user also needs to specify the fraction of the fan motor's waste heat that will enter the air stream (usually 0 or 1). If the fan is indoors, the name of a Zone and a fraction for the split between thermal radiation and convection can be entered so that the portion of fan motor waste heat that does not enter the air stream can be added to the thermal zone surrounding the fan. The user enters a choice for fan speed control method to be either Continuous (for VAV) or Discrete (for constant volume, on-off, two-speed, or multi-speed). A performance curve or lookup table defined separately can be referenced by the fan to describe the variation in fan power as a function of flow rate. This curve is required for continuous speed control. However, for discrete speed control the user has the option of directly entering a power modification factor for each discrete speed and a curve is not necessary. For two- or multi-speed fans, the number of speeds is entered and pairs of values for the flow fraction and power fraction at each speed level are entered in increasing order. The design electric power consumption can be autosized using input values for one of three available scaling factors: fan total efficiency, electric power per unit flow rate, or electric power per unit flow rate per unit pressure. Except for these sizing and control features, the fan (system) model itself is based on the original fan models (Fan:VariableVolume, Fan:OnOff, and Fan:ConstantVolume) and uses the same basic mathematical formulation.

For the Fan:ConstantVolume, Fan:VariableVolume, and Fan:OnOff models, the user describes the fan by entering values for the design pressure rise across the fan, the design volume flow rate, the fan total efficiency, and the fan motor efficiency. The user also needs to specify the fraction of the fan waste heat that will enter the air stream (usually 0 or 1). For the Fan:VariableVolume model, the user must also enter the coefficients of a 4th order polynomial that relates the fan mass flow rate to the fan power consumption. The independent variable is the volumetric flow fraction; the dependent variable is the fan power part load ratio. For multi-speed fans, the user must enter a fan power ratio as a function of speed ratio performance curve name. Multi-speed fans can only be simulated in a parent object which allows multiple fan speeds (e.g., AirLoopHVAC:Unitary:Furnace:HeatCool, ZoneHVAC:PackagedTerminalAirConditioner, etc.). An optional efficiency curve may also be used when simulating multi-speed fans to adjust the fan total efficiency as the fan speed changes.

For the Fan:ComponentModel object, the user describes the fan in more detail, and also describes the duct system characteristics as seen by the fan. In particular, the user specifies a pressure rise curve with four coefficients that relates the fan total pressure rise to the volumetric flow through the fan, the duct-static-pressure set-point, and the static pressure of the spaces surrounding the ducts. If duct-static-pressure reset is used, the user enters a linear curve with two coefficients that relates the pressure set-point to the volumetric flow through the fan. For the fan itself, the user specifies the fan geometry (wheel diameter and outlet area), maximum efficiency, the Euler number corresponding to the maximum efficiency, the maximum dimensionless flow, the names of four curves with several coefficients that describe the variation of fan efficiency and dimensionless flow with the Euler number in the normal and stall operation regions of the fan, and a sizing factor (applied to the maximum flow through the fan). For the belt, the user specifies the maximum efficiency (or a curve with five coefficients that defines the maximum efficiency as a function of maximum fan shaft input power), three curves with three coefficients each that relate the belt part-load efficiency to belt fractional output torque, the motor/fan pulley diameter ratio, the belt output torque capacity, and a sizing factor (applied to the maximum output torque of the belt). For the motor, the user specifies

the maximum efficiency (or a curve with three coefficients that define the maximum efficiency as a function of maximum belt input power), a curve with three coefficients that relate the motor part-load efficiency to motor fractional output power, and a sizing factor (applied to the maximum output power of the motor). For the variable-frequency-drive (VFD), the user specifies a curve with three coefficients that relate the VFD part-load efficiency to motor fractional input power or to motor fractional speed, and a sizing factor (applied to the maximum output power of the VFD).

16.4.2.2 Control

The models must decide whether the fan is on or off. The primary on/off trigger is the fan availability schedule. This is an on/off schedule associated with each fan: a value of 1 indicates the fan is on; a value of 0 indicates the fan is off. The fan schedule can be overruled by flags set by system availability managers. If the flag *TurnFansOn* is true, a zero fan schedule value will be overridden and the fan will be turned on. If the flag *TurnFansOff* is true the fan will be forced off. The inlet air mass flow rate must be greater than zero for the fan to be on.

Generally the fan is a passive component: it accepts the mass flow on its inlet node, uses it in its calculations of energy consumption and temperature rise, and passes it to the outlet node. However the fan maximum and minimum airflow rates act as absolute limits on the airflow rate.

For multi-speed fans, the parent object determines the fan speed ratio (i.e., the selected speed of the fan motor) and uses this value to determine flow rate and electric power consumption. For a *Fan:SystemModel* operating with the Discrete choice for speed control, the fan model determines the fraction of time spent at the discrete speeds that bound it and will produce the average flow requested by the parent object. Then the fan electric power consumption is determined for each speed level and combined using a time-weighted average. For a fan operating with Continuous speed control and a fan modeled with the *Fan:OnOff* object, the electric power is evaluated using the power ratio performance curve at the (average) flow fraction requested by the parent object.

16.4.2.3 Simulation

For the *Fan:SystemModel* model based on design electric power consumption, the fan's total efficiency is determined at the beginning of the simulation using:

$$\varepsilon_{tot,max} = \frac{(\dot{V}_{design,max} \cdot \Delta P)}{\dot{Q}_{tot,design}} \quad (16.175)$$

For a fan with discrete speed control with more than one speed and input data for Speed x Electric Power Fraction, the fan's total efficiency at each speed x is determined and stored using:

$$e\varepsilon_{tot,x} = \frac{(f_{flow,x} \cdot \dot{V}_{design,max} \cdot \Delta P)}{(f_{power,x} \cdot \dot{Q}_{tot,design})} \quad (16.176)$$

For a fan with discrete speed control and no data for the power fraction at a speed, the power performance curve (or table) is evaluated first using the flow fraction for the speed:

$$f_{power,x} = func_{powercurve}(f_{flow,x}) \quad (16.177)$$

The fan model and EnergyPlus's modeling of flow at air system nodes is actually calculated using mass flow rates. User input for design maximum volume flow rate is converted to a design

mass flow rate using a design density of air that is adjusted for altitude above sea level and dry air at 20°C drybulb.

$$\dot{m}_{design,max} = \dot{V}_{design,max} \cdot \rho_{air,design} \quad (16.178)$$

For a fan with discrete speed control with more than one speed, the design mass flow rate at each speed is determined and stored using:

$$\dot{m}_{design,x} = f_{flow,x} \cdot \dot{V}_{design,max} \quad (16.179)$$

Simple (Single Speed) Fan Model

The following equations define the model for this fan:

$$\dot{Q}_{tot} = \dot{m} \cdot \Delta P / (\varepsilon_{tot,max} \cdot \rho_{air}) \quad (16.180)$$

$$\dot{Q}_{shaft} = \varepsilon_{motor} \cdot \dot{Q}_{tot} \quad (16.181)$$

$$\dot{Q}_{toair} = \dot{Q}_{shaft} + (\dot{Q}_{tot} - \dot{Q}_{shaft}) \cdot f_{motortoair} \quad (16.182)$$

$$h_{out} = h_{in} + \dot{Q}_{toair} / \dot{m} \quad (16.183)$$

$$w_{out} = w_{in} \quad (16.184)$$

$$T_{out} = PsyTdbFnHW(h_{out}, w_{out}) \quad (16.185)$$

Fan Model for Changing Flow Rates

The fan will operate at a flow fraction that is determined by other HVAC equipment in the air system. A parent object will control the air flow rates and the fan flow fraction is defined as the ratio of the current mass flow rate divided by the design mass flow rate.

$$f_{flow,cur} = \frac{\dot{m}_{cur}}{\dot{m}_{design,max}} \quad (16.186)$$

The determination of electric power consumed at a flow fraction depends on if the speed control method is discrete or continuous.

Discrete Speed Control

For the *Fan:SystemModel* using discrete speed control, with the number of fan speeds set at 1, and the flow fraction is less than one, then the fan will be modeled as cycling between "off" and "on" over the timestep. The time fraction is equal to the flow fraction so that:

$$RTF_{On} = f_{flow,cur} \quad (16.187)$$

$$\dot{Q}_{tot,elec} = RTF_{On} \cdot \left(\frac{\dot{m} \cdot \Delta P}{\varepsilon_{tot} \cdot \rho_{air}} \right) \quad (16.188)$$

Similarly, for two-speed and multi-speed fans, the current flow fraction will be used to find the run time fraction for each of the adjacent speed levels x and $x+1$ that bracket the flow fraction such that

$$f_{flow,x} \leq f_{flow,cur} \leq f_{flow,x+1} \quad (16.189)$$

The runtime fraction spent at each speed is determined using

$$RTF_x = \left(\frac{(f_{flow,x+1} - f_{flow,cur})}{(f_{flow,x+1} - f_{flow,x})} \right) \quad (16.190)$$

$$RTF_{x+1} = \left(\frac{(f_{flow,cur} - f_{flow,x})}{(f_{flow,x+1} - f_{flow,x})} \right) \quad (16.191)$$

The electric power consumption is calculated using the design mass flow rates and the total efficiency stored for each speed and combined using the runtime fraction at each speed.

$$\dot{Q}_{tot,elec} = RTF_x \cdot \left(\frac{\dot{m}_{design,x} \cdot \Delta P}{\epsilon_{tot,x} \cdot \rho_{air}} \right) + RTF_{x+1} \cdot \left(\frac{\dot{m}_{design,x+1} \cdot \Delta P}{\epsilon_{tot,x+1} \cdot \rho_{air}} \right) \quad (16.192)$$

The temperature of the air stream leaving the fan is calculated as above using this result for total power.

Continuous Speed Control

For the *Fan:SystemModel* using Continuous speed control the flow fraction is used to evaluate the power performance modification factor which is defined in a separate curve or table.

$$f_{power,cur} = func_{powercurve}(f_{flow,cur}) \quad (16.193)$$

$$\epsilon_{tot,cur} = \frac{(\dot{m}_{cur} \cdot \Delta P)}{(f_{power,cur} \cdot \dot{Q}_{tot,design} \cdot \rho_{air})} \quad (16.194)$$

Fan:OnOff Fan Model

The on/off fan model is similar to the simple fan model with the exception that the on/off fan may cycle on and off during a simulation time step. The cycling rate of the fan is known as the run time fraction. The calculation of run time fraction accounts for the part-load losses of other equipment used in the HVAC system. A part-load factor (a.k.a. part-load ratio) is first calculated for the fan as the ratio of the actual operating mass flow rate to the maximum fan mass flow rate. The run time fraction is then calculated as the part-load factor divided by the part-load fraction. The part-load fraction is determined by other HVAC equipment in the simulation (Ref. DX coil) for use by this specific fan model.

$$f_{flow} = \frac{\dot{m}}{\dot{m}_{max}} \quad (16.195)$$

$$RTF = \frac{f_{flow}}{PLF} \quad (16.196)$$

The total fan power is then calculated as the maximum fan power multiplied by the run time fraction.

$$\dot{Q}_{tot} = RTF [\dot{m} \cdot \Delta P / (\epsilon_{tot} \cdot \rho_{air})] \quad (16.197)$$

The remaining calculations are the same as those described in the simple single-speed fan mode.

Multi-Speed Fan Model

The model used to simulate a multi-speed fan relies on the general fan laws to correct for speed changes in the fan's motor and the corresponding change in fan power and fan total efficiency. Two performance curves are used to define the change in power and efficiency as shown below. The power ratio curve must be used to simulate a multi-speed fan. The power ratio curve modifies the fan power based on a change in fan speed according to the cubic fan law. Exponents other than 3 are allowed. The efficiency ratio curve is used to correct for changes in nominal efficiency at alternate fan speeds. If either or both of these curves are not provided, the ratio is assumed to be 1.

The power ratio term is evaluated using an exponent performance curve. The form of the exponent curve equation is shown below.

$$ExponentCurveOutput = C1 + C2 * x^{C3} \quad (16.198)$$

The exponent performance curve is used to evaluate the power ratio as a function of speed ratio (x in the equation above). For typical fan performance, coefficient C1 = 0 and coefficient C2 = 1. The exponent (C3) is typically equal to 3 (cubed fan law) but other values are allowed.

$$PowerRatio = f(N_{ratio})^n = ExponentCurveOutput \quad (16.199)$$

The efficiency ratio curve is a quadratic or cubic curve used to evaluate the efficiency ratio as a function of speed ratio (x in the following equation). The cubic equation form is shown below.

$$EfficiencyCurveOutput = C1 + C2(x)^2 + C3(x)^3 \quad (16.200)$$

The curve coefficients are determined by correlating the normalized fan total efficiency (i.e., the actual fan total efficiency divided by the nominal fan total efficiency at a speed ratio of 1) to the speed ratio (i.e., the ratio of actual air flow rate through the fan to the maximum fan air flow rate).

$$EfficiencyRatio = f(N_{ratio}) = EfficiencyCurveOutput \quad (16.201)$$

To account for the change in fan speed and to ensure that the run time fraction is accurately calculated, an adjustment to the previous calculation for run time fraction is made. This adjusts the calculated run time fraction to account for times when the fan speed has been reduced and the new speed is now considered the fan's maximum speed. The speed adjusted run time fraction is then used in the fan power calculation.

$$RTF = \frac{RTF}{N_{ratio}} \quad (16.202)$$

$$\dot{Q}_{tot} = RTF \left[\frac{\dot{m}\Delta P}{\varepsilon_{tot}\rho_{air}} \right] \left(\frac{PowerRatio}{EfficiencyRatio} \right) \quad (16.203)$$

Each of the performance curves described above may be used to model the performance of a multi-speed fan motor, however, the power ratio curve must be used to invoke the multi-speed simulation. These curves are used when the fan is used in an HVAC system having multiple flow rates (i.e., different flow rates in cooling and heating mode). If an HVAC system operates at the same speed in either cooling or heating mode, these curves are not required. When these curves

are not used, the associated ratio term in the equation above is assumed to be 1. The remaining calculations are identical to the simple single-speed fan model described above.

Variable Speed Fan Model

The model for the variable speed fan is similar to the simple single-speed fan model except for a part load factor that multiplies the fan power consumption.

$$f_{flow} = \dot{m} / \dot{m}_{design} \quad (16.204)$$

$$f_{pl} = c_1 + c_2 \cdot f_{flow} + c_3 \cdot f_{flow}^2 + c_4 \cdot f_{flow}^3 + c_5 \cdot f_{flow}^4 \quad (16.205)$$

$$\dot{Q}_{tot} = f_{pl} \cdot \dot{m}_{design} \cdot \Delta P / (\varepsilon_{tot} \cdot \rho_{air}) \quad (16.206)$$

The rest of the calculation is the same as for the simple fan.

The nomenclature for all of the simple models is as follows:

\dot{Q}_{tot} is the fan power (W)

\dot{m} is the air mass flow (kg/s)

$\dot{m}_{design,max}$ is the design (maximum) air flow (kg/s)

ΔP is the fan design pressure increase (Pa)

ε_{tot} is the fan total efficiency

ρ_{air} is the air density at standard conditions (kg/m³)

ε_{motor} is the motor efficiency

\dot{Q}_{shaft} is the fan shaft power (W)

\dot{Q}_{toair} is the power entering the air (W)

N_{ratio} is the ratio of actual fan flow rate (or speed) to maximum fan flow rate (or speed)

h_{in}, h_{out} are the inlet and outlet air stream specific enthalpies (J/kg)

w_{in}, w_{out} are the inlet and outlet air stream humidity ratios

T_{out} is the outlet air temperature (°C)

$PsyTdbFnHW$ is an EnergyPlus psychrometric routine relating enthalpy and humidity ratio to temperature

f_{flow} is the flow fraction or part-load ratio

f_{pl} is the part load factor.

Component Fan Model

The Fan:ComponentModel object is based upon combining: modified forms of fan, belt, motor, and variable-frequency-drive (VFD) element models (Stein and Hydeman 2004); a simplified fan pressure rise model with distribution system leakage, duct static pressure, and conditioned space pressure control effects included (Sherman and Wray 2010); and a diagnostic-based simplified duct static-pressure reset (SPR) scheme for air-handling systems (Federspiel 2004, 2005).

Fan *electric* power depends on fan *air* power (product of the airflow through and pressure rise across the fan), mechanical efficiencies (fan and belt), and electrical efficiencies (motor and drive). For systems with variable flows, none of these parameters is constant and all are interrelated. For example, Figure 16.16 shows that fan efficiency strongly depends on fan flow *as well as* pressure rise, although this is not obvious from the manufacturer's power and speed performance map (top left). Fan efficiency maps can be derived from the manufacturer's performance map using a commercially-available software-based data extraction tool such as DigitizeIt and by applying the following equation to the extracted data:

$$\eta_{fan} = \frac{\Delta P_{fan} \cdot Q_{fan}}{H_{fan}} \quad (16.207)$$

where ΔP_{fan} is the fan pressure rise (Pa), Q_{fan} is the fan flow at standard conditions (m^3/s), and H_{fan} is the fan shaft power (W). Fan speed values also can be derived from the manufacturer's performance map using a similar software-based data extraction tool.

Fan pressure rise must be sufficient to overcome the air-handling system pressure drop, which depends on duct static pressure, on duct and equipment leakage, and on pressure drops across duct and duct-like elements (e.g., dampers, fittings), coils, and filters that are connected to the fan. Duct and duct-like pressure drops increase approximately as the square of the flow through them. However, pressure drops across coils and filters behave differently: they are proportional to the flow raised to a power n , which can approach one for high-efficiency filters and wet coils (Liu et al. 2003, Trane 1999).

The relation between system pressure drop and flow defines what is commonly called a “system curve”. When system characteristics change, such as when the duct static pressure set point is varied, a family of system curves results. The intersections of these curves with fan curves (e.g., power as a function of pressure rise and flow) on a pressure versus flow plot define one or more loci of unique fan operating points. Each of these points has an associated fan efficiency, power, and speed.

Fan Pressure Rise Model: To calculate fan pressure rise based on flow through the fan, Sherman and Wray (2010) have developed a simple physics-based data-driven four parameter duct system model for the purpose of simulating its system curve. The embodiment of the model for a fixed outdoor air fraction that can be applied to constant- or variable-volume central air-handling systems is:

$$\Delta P_{fan,tot} = A_{fpr} Q_{fan}^2 + B_{fpr} Q_{fan} + C_{fpr} Q_{fan} \sqrt{P_{sm} - P_o} + D_{fpr} (P_{sm} - P_o) \quad (16.208)$$

where $\Delta P_{fan,tot}$ is the fan total pressure rise (Pa), Q_{fan} is the fan flow at standard conditions (m^3/s), P_{sm} is the duct static pressure set point (Pa), P_o is the static pressure of the spaces surrounding the ducts (Pa), and A_{fpr} , B_{fpr} , C_{fpr} , and D_{fpr} are constant coefficients that represent different aspects of the fan pressure rise model as described below.

Fan static pressure rise is determined from the total pressure rise by subtracting the outlet velocity pressure:

$$\Delta P_{fan} = \Delta P_{fan,tot} - \frac{\rho}{2} \left(\frac{Q_{fan}}{A_{fan,out}} \right)^2 \quad (16.209)$$

where $A_{fan,out}$ is the fan outlet area (m^2) and ρ is the air density at the fan inlet (kg/m^3).

The first term in Equation 16.208 looks like the common system curve in which the fan pressure rise is proportional to the square of the fan flow, but here it also depends implicitly on supply and return pressure losses, and in part on the fraction of the fan flow that is outdoor air (essentially “leaks” into and out of the return side of the system). Very often it is the only term considered, but that would only be correct with fixed-position dampers, no distribution system leakage, no linear resistance components, and no duct static pressure control.

The second term accounts for significant flow resistances in the system where the pressure difference is linearly proportional to the flow. Some filters and coils in the return may need this

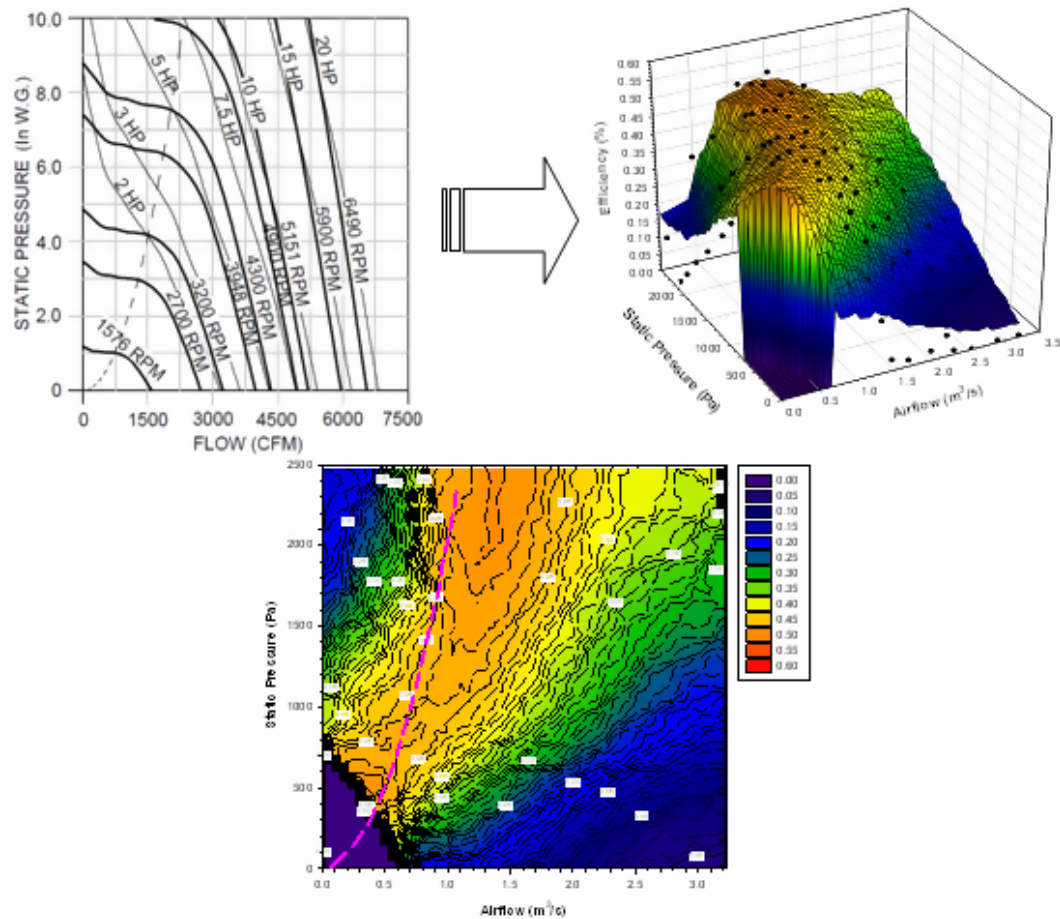

Figure 16.16: Example Fan Performance Maps - Manufacturer's Data from Loren Cook Company, plus Derived Static Efficiency (Three-Dimensional and Contours) (Dashed Parabolic Curve is "Do Not Select Line")

term to be adequately described. This term could be ignored if there are no linear components or if their pressure drops are very small compared to the other terms.

The third term, which depends on the fan flow and square root of the supply duct pressure P_{sm} , accounts in part for air leakage from the supply system when damper positions are fixed or are changed independently of static pressure or fan flow. In this case, reducing or eliminating supply leakage results in a different system curve. This, however, might be only a minor “correction” to the simple system curves generally used. The third term is zero when VAV box dampers are modulated to control flow. Consequently, with variable-position supply dampers, reducing or eliminating supply leakage does not change the system curve.

The last term also accounts in part for leakage from the supply system when damper positions are fixed or are changed independently of static pressure or fan flow. This term indicates that the same fan pressure rise can be achieved by raising the duct pressure and closing dampers. The only change in the system in such a case is that the leakage flow may increase. The coefficient for this term is equal to one when the VAV box dampers are modulated to control flow. In both cases, this term may be the most important “correction” to the simple system curves generally used, especially at low flows.

In principle, especially for research applications of Energy Plus, the four individual fan pressure rise coefficients can be determined using duct design calculation tools for the entire system (e.g., Right-CommDuct, UNI-DUCT, Ductsize, Varitrane Duct Designer, T-Duct). In practice, however, especially for existing buildings, the necessary details may not be known sufficiently. In that case, one can make active measurements at different combinations of fan flows, outside air fractions, damper positions (if they are variable), and duct static pressures and then use non-linear system identification techniques to fit the data and determine the coefficients. If passive measurements can be made over a sufficiently long time so that a wide range of outside air settings, damper positions, and fan flows is obtained, one could instead regress the data to find all of the parameters in the equation. Unfortunately, there are no standardized test procedures available to draw upon, even though some standards appear to be related (e.g., ASHRAE 1999, 2008). Consequently, field test protocols need to be developed to determine the parameters for the new duct system model. These protocols then need to be integrated into standardized data collection and analysis tools such as Pacific Gas and Electric’s “Universal Translator” tool. The California Energy Commission is funding such a project; data, procedures, and tools from this project will support the EnergyPlus implementation of the fan and duct system models described here.

SPR Model: The model for duct-static-pressure reset (SPR) is based on a simple diagnostic procedure and a linear correlation between duct static pressure and supply fan airflow (Federspiel 2004, 2005). The diagnostic method involves measuring the static pressure at the duct static pressure sensor and the velocity pressure at the fan inlet (represents the fan flow) at multiple points over the fan’s operating range, while the VAV box dampers attempt to control flow in response to a constant thermostat setpoint. The goal of the test is to define the lowest duct static pressure where all VAV boxes are still in control (dampers modulating). In the model, the correlation between P_{sm} and Q_{fan} is as follows for $Q_{fan,min} \leq Q_{fan} \leq Q_{fan,max}$:

$$P_{sm} = P_{sm,min} + (P_{sm,max} - P_{sm,min}) * \frac{(Q_{fan} - Q_{fan,min})}{(Q_{fan,max} - Q_{fan,min})} = C_1 + C_2 * Q_{fan} \quad (16.210)$$

where:

$$C_1 = P_{sm,min} - C_2 * Q_{fan,min} \quad (16.211)$$

$$C_2 = \frac{(P_{sm,max} - P_{sm,min})}{(Q_{fan,max} - Q_{fan,min})} \quad (16.212)$$

For $Q_{fan} < Q_{fan,min}$, $P_{sm} = P_{sm,min}$; for $Q_{fan} > Q_{fan,max}$, $P_{sm} = P_{sm,max}$.

Fan Efficiency and Shaft Input Power Model: A dimensionless parameter in the form of an Euler number can be used to simplify the description of fan static efficiency variations:

$$Eu = \frac{(\Delta P_{fan} * D_{fan}^4)}{(\rho * Q_{fan}^2)} \quad (16.213)$$

where ΔP_{fan} is the fan static pressure rise (Pa), D_{fan} is the fan wheel outer diameter (m), ρ is the air density at the fan inlet (kg/m^3), and Q_{fan} is the fan flow at standard conditions (m^3/s). Eu is nominally the ratio of pressure forces across the fan to inertial forces at the fan wheel exit.

By plotting the normalized fan static efficiency (*static efficiency / maximum static efficiency*) versus the logarithm base 10 of the normalized Euler number ($Eu / Eu \text{ at maximum static efficiency}$), the dimensionless performance of various fan sizes is very similar (as one might expect from the “fan laws”), but so also is the dimensionless performance of different *types* of fans (e.g., single-inlet plenum fans, double-inlet housed centrifugal fans, mixed flow fans, vane axial fans, fans with backward or forward curved blades). An example of this correlation for the “normal operation” (non-stall) and stall regions of eight fans is shown in Figure 16.17.

This model uses a continuous function to represent the normalized fan efficiency (η_{fan}) variation. The normalized exponential-conditioned skew-normal functional relationship is:

$$\frac{\eta_{fan}(x_{fan})}{\eta_{fan,max}} = \frac{e^{(-0.5*Z_1^2)}[1 + \frac{Z_2}{|Z_2|} \bullet \text{erf}\left(\frac{|Z_2|}{\sqrt{2}}\right)]}{e^{(-0.5*Z_3^2)}[1 + \frac{Z_3}{|Z_3|} \bullet \text{erf}\left(\frac{|Z_3|}{\sqrt{2}}\right)]} \quad (16.214)$$

where:

$$x_{fan} = \log_{10}(Eu/Eu_{max}) \quad (16.215)$$

$$Z_1 = (x_{fan} - a_{fan})/b_{fan} \quad (16.216)$$

$$Z_2 = ((e^{(c_{fan}*x_{fan})} * d_{fan} * x_{fan}) - a_{fan})/b_{fan} \quad (16.217)$$

$$Z_3 = -a_{fan}/b_{fan} \quad (16.218)$$

For conceptual design when only rough estimates are needed, a generic curve (also shown in Figure 16.17) can be used and then one only needs to know the maximum efficiency ($\eta_{fan,max}$) and Eu at that maximum (Eu_{max}) to entirely model the fan efficiency and hence fan power. The dimensionless coefficients for the generic normalized fan efficiency curve are as follows:

$$a_{fan} = -2.732094 \quad (16.219)$$

Figure 16.17: Normalized Efficiency Curves for Eight Fans in Dimensionless Space *(BC = backward curved, FC = forward curved; SI = single inlet, DI = double inlet)*

$$b_{fan} = 2.273014 \quad (16.220)$$

$$c_{fan} = 0.196344 \quad (16.221)$$

$$d_{fan} = 5.267518 \quad (16.222)$$

In this case, the coefficient of determination R^2 is 0.994. Also, the average and RMS differences between the efficiency values based on extracted data and the fitted generic curve are, respectively, about 0.5% and 1.4%; maximum differences are about $\pm 9\%$.

If more accuracy is needed for a specific fan, a similarly shaped curve can be developed for that fan (using extracted data, Equation 16.214, and least-squares regression techniques), segmented into normal operation and stall regions with specific coefficients fitted for each region. Figure 16.18 shows an example, using the data from Figure 16.16.

Figure 16.18: Example Normalized Efficiency Data for One Fan

For this specific fan, the coefficients are:

Table 16.4: Normalized Fan Efficiency Coefficients for Specific Backward-Curved Plenum Fan

Operating Region	a	b	c	d
Normal (Non-Stall)	0.072613	0.833213	0	0.013911
Stall	-2.354091	2.117493	0	2.753264

In this case, the average and RMS differences between the efficiency values based on extracted data and fitted specific curve (R^2 is 0.999) are, respectively, about -0.1% and 0.3%; maximum differences are about $\pm 0.7\%$. Field tests are especially needed to determine the coefficients for installed fans because fans are susceptible to “system effects” (e.g., inlet obstructions) that are not included in the manufacturer test data (AMCA 1990a).

To determine fan efficiency and fan shaft power at a particular time step, first calculate the fan pressure rise (ΔP_{fan}) using the time step fan flow (Q_{fan}) and Equation 16.208 (and also using Equation 16.210 if there is SPR). Next, calculate Eu using Equation 16.213 and then x_{fan} (\log_{10} normalized Eu), which is based on Eu and the specified Eu_{max} (Eu at maximum efficiency) for the fan. The corresponding normalized efficiency ($\eta_{fan}(x_{fan})/\eta_{fan,max}$) is obtained using Equation 16.214. The fan efficiency ($\eta_{fan}(x_{fan})$) therefore is:

$$\eta_{fan}(x_{fan}) = \eta_{fan,max} \left[\frac{\eta_{fan}(x_{fan})}{\eta_{fan,max}} \right] \quad (16.223)$$

The fan shaft input power (mechanical, W) is:

$$H_{fan} = \frac{\Delta P_{fan} \cdot Q_{fan}}{\eta_{fan}(x_{fan})} \quad (16.224)$$

Fan Shaft Speed and Torque Modeling: For rotating elements, power (H) is the product of torque τ and rotational speed ω , or conversely, torque is power divided by rotational speed $\tau = H/\omega$.

The Stein and Hydeman variable-frequency-drive (VFD) component model correlates VFD efficiency as a linear function of VFD fractional output power (i.e., motor input power). Available data for about 50 drives from Safronics were apparently used to develop their model, but those data represent VFD efficiency as a function of motor fractional speed ($\omega_{motor}/\omega_{motor,max}$, or nominally, drive output frequency divided by maximum output frequency, if motor slip is ignored).

To make use of the available data, the Stein and Hydeman linear correlation must intrinsically make an assumption that motor speed and torque have some fixed relationship. Although not documented, their assumption might be the common belief that fractional torque (τ/τ_{max}) for a motor is simply the square of its fractional speed. For fans serving duct systems with components such as filters and coils, with relatively low pressure drops elsewhere in the system, and for systems that have a non-zero controlled duct static pressure, this assumption may be inappropriate. Consequently, to make use of the available data and to avoid such assumptions, one needs to know the fraction of full speed at which fan components operate.

For the fan, dimensionless flow (φ) can be defined as (ASHRAE 1993):

$$\varphi = \frac{Q_{fan}}{\omega_{fan} \cdot D_{fan}^3} \quad (16.225)$$

where ω_{fan} is the fan speed (rad/s). This parameter can be calculated for each operating point on the fan manufacturer's performance map that represents fan speed as a function of flow and fan pressure rise. To simplify the data representation to a single curve (as we have done for fan efficiency), one can plot normalized dimensionless flow (dimensionless flow divided by maximum dimensionless flow, $(\varphi(x_{fan})/\varphi_{max})$ as a function of the log base 10 of the normalized Euler (Eu) parameter (x_{fan}). Figure 16.19 shows an example plot derived from the manufacturer's data in Figure 16.16.

Figure 16.19: Example Normalized Dimensionless Flow Data for One Fan

The following equation describes the sigmoidal functional form for normalized φ :

$$\frac{\varphi(x_{fan})}{\varphi_{max}} = (A_{spd} + B_{spd} / ((1 + e^{[(C_{spd} - x_{spd}) / D_{spd}]})^{E_{spd}})) \quad (16.226)$$

where A_{spd} , B_{spd} , C_{spd} , D_{spd} , and E_{spd} are coefficients for the fan. Separate sets of coefficients for the normal operation and stall regions can be specified. For the curve shown in Figure 16.19, these coefficients are:

Table 16.5: Dimensionless Flow Coefficients – Specific Backward-Curved Fan

Operating Region	A_{spd}	B_{spd}	C_{spd}	D_{spd}	E_{spd}
Normal (Non-Stall)	0	1.001423	0.123935	-0.476026	1

Table 16.5: Dimensionless Flow Coefficients – Specific Backward-Curved Fan

Operating Region	A_{spd}	B_{spd}	C_{spd}	D_{spd}	E_{spd}
Stall	0	5.924993	-1.916316	-0.851779	1

For a generic centrifugal fan with backward-curved blades, the coefficients are:

Table 16.6: Dimensionless Flow Coefficients – Generic Backward-Curved Fan

Operating Region	A_{spd}	B_{spd}	C_{spd}	D_{spd}	E_{spd}
Normal (Non-Stall)	-0.551396	1.551467	-0.442200	-0.414006	0.234867
Stall	0.000608	0.586366	0.021775	-0.063218	0.072827

For any operating point of flow (Q_{fan}) and fan pressure rise (ΔP_{fan}), one can calculate the corresponding Euler number (Eu) for the given fan, and then determine the corresponding normalized dimensionless flow ($\varphi x_{fan}/\varphi_{max}$) from the sigmoidal dimensionless flow function (Equation 16.226). With $\varphi x_{fan}/\varphi_{max}$ determined and knowing φ_{max} for the fan, the dimensionless flow is:

$$\varphi(x_{fan}) = \varphi_{max} \left[\frac{\varphi(x_{fan})}{\varphi_{max}} \right] \quad (16.227)$$

With φx_{fan} determined, the fan rotational speed (rad/s) is:

$$\omega_{fan} = \frac{Q_{fan}}{(\varphi(x_{fan}) * D_{fan}^3)} \quad (16.228)$$

Fan shaft torque (N m), which the belt drive must supply to the fan shaft, is then:

$$\tau_{fan} = \frac{H_{fan}}{\omega_{fan}} \quad (16.229)$$

The fraction of full-load driven torque for the belt ($\tau_{fan}/\tau_{belt,max}$), which is typically called “belt load”, is thus τ_{fan} divided by the belt torque capacity ($\tau_{belt,max}$). For a particular belt type and cross-section, belt torque capacity can be determined from manufacturer’s information such as a shaft speed versus power chart.

Ignoring belt slip, motor shaft speed (ω_{motor} , rad/s) can then be determined using the fan speed (ω_{fan}) and the motor/fan pulley diameter ratio ($D_{pulley,motor} / D_{pulley,fan}$), which is typically called the “drive” ratio:

$$\omega_{motor} = \frac{\omega_{fan}}{\left(\frac{D_{pulley,motor}}{D_{pulley,fan}} \right)} \quad (16.230)$$

Belt, Motor, and Variable-Frequency-Drive Efficiency and Input Power Models – Overview: The models for belt drives, motors, and VFDs that Stein and Hydeman included in their air-handling system model represent maximum efficiency as a function of power input to the adjacent downstream

component (e.g., the power input to a fan shaft by a belt drive), but they do not include part-load models. The part-load models are needed, because part-load efficiency for these components can fall off rapidly at low load (e.g., to zero at zero load) and many systems operate occasionally (and some much of the time) at low loads, in part because of current practices that result in substantial oversizing of components.

Belt Efficiency and Input Power Model: Figure 16.20 shows three maximum efficiency ($\eta_{belt,max}$) curves for belts (low, medium, and high) as a function of maximum fan shaft torque. This set of efficiency curves is based on belt drive loss data from AMCA Publication 203 (1990b), which reportedly is an aggregation of data from over 400 tests.

To determine $\eta_{belt,max}$ if data for a specific belt are not available, first use the maximum fan shaft input power ($H_{fan,max}$) for the load spectrum to calculate the natural logarithm of belt power capacity:

$$x_{belt,max} = \ln(H_{fan,max}) \quad (16.231)$$

where $H_{fan,max}$ is expressed in terms of hp.

Then, use the next two equations along with a choice of low, medium, or high efficiency coefficients from Table 16.7, to calculate $\eta_{belt,max}$.

Figure 16.20: Belt Maximum Efficiency vs. Fan Shaft Power Input

The quadratic polynomial curves in Figure 16.20 and their coefficients are as follows:

$$\eta_{belt,max,ln} = c_1 + c_2 \cdot x_{belt,max} + c_3 \cdot x_{belt,max}^2 + c_4 \cdot x_{belt,max}^3 + c_5 \cdot x_{belt,max}^4 \quad (16.232)$$

Table 16.7: Belt Maximum Efficiency Curve Coefficients

Efficiency Class (Loss)	c_1	c_2	c_3	c_4	c_5
High (Low Loss)	-6.502E-2	2.475E-2	-6.841E-3	9.383E-4	-5.168E-5
Medium (Medium Loss)	-9.504E-2	3.415E-2	-8.897E-3	1.159E-3	-6.132E-5
Low (High Loss)	-1.422E-1	5.112E-2	-1.353E-2	1.814E-3	-9.909E-5

The belt maximum efficiency is therefore:

$$\eta_{belt,max} = e^{\eta_{belt,max,ln}} \quad (16.233)$$

The normalized *part-load* belt efficiency model is provided to modify the maximum efficiency of the belt. This model is based on part-load data for belts in ACEEE's handbook on motor systems (Nadel et al. 2002). To determine the normalized belt efficiency at part-load ($\eta_{belt}x_{belt}/\eta_{belt,max}$), use the fan shaft (belt output) fractional torque ($x_{belt} = \tau_{belt}/\tau_{belt,max}$; $\tau_{belt} = \tau_{fan}$) as the belt fractional load in Equation 16.234 or 16.235 (select the equation for the region that contains x_{belt}) and use coefficients from Table 16.8 that correspond to that region and the belt type: V-Belt or synchronous (toothed). Figure 16.21 shows a graphical representation of the curves defined by these equations and coefficients.

The belt normalized (part-load) efficiency curves in Figure 16.21 for Regions 1 and 3 (single rectangular hyperbola type 2) and Region 2 (exponential decay), respectively, and their coefficients are as follows:

Region 1 ($0 < = x_{belt} < x_{belt,trans}$) and Region 3 ($x_{belt} > 1$):

$$\frac{\eta_{belt}(x_{belt})}{\eta_{belt,max}} = \left[\frac{a_{belt} \cdot x_{belt}}{b_{belt} + x_{belt}} \right] + c_{belt} \cdot x_{belt} \quad (16.234)$$

Region 2 ($x_{belt,trans} < = x_{belt} < = 1$):

$$\frac{\eta_{belt}(x_{belt})}{\eta_{belt,max}} = a_{belt} + b_{belt} \cdot e^{(c_{belt} \cdot x_{belt})} \quad (16.235)$$

where $x_{belt} = \tau_{belt} / \tau_{belt,max}$

Belt efficiency therefore is:

$$\eta_{belt}(x_{belt}) = \eta_{belt,max} \left[\frac{\eta_{belt}(x_{belt})}{\eta_{belt,max}} \right] \quad (16.236)$$

Belt input power (mechanical, W) at the motor shaft is:

$$H_{belt} = \frac{H_{fan}}{\eta_{belt}(x_{belt})} \quad (16.237)$$

Figure 16.21: Belt Normalized Efficiency vs. Belt Fractional Load)

Table 16.8: Belt Normalized Efficiency Curve Coefficients

Belt Type	$x_{belt,trans}$	Region	a_{belt}	b_{belt}	c_{belt}
V-Belt	0.167	1	0.920797	0.026269	0.151594
		2	1.011965	-0.339038	-3.43626
		3	1.037778	0.010307	-0.026815
Synchronous	0.137	1	0.982167	0.049135	0.158164
		2	1.002134	-0.531885	-5.295707
		3	1	0	0

Motor Efficiency and Input Power Model: Figure 16.22 shows three maximum efficiency ($\eta_{motor,max}$) curves for motors (low, medium, and high) as a function of rated motor output power (belt input power). This set of efficiency curves is based on maximum efficiency data in DOE's MotorMaster+ database (2003) from about 800 tests. It is provided for use in the absence of manufacturer's data.

Figure 16.22: Maximum Motor Efficiency vs. Belt Power Input (Motor Output)

To determine $\eta_{motor,max}$ if data for a specific motor are not available (e.g., as listed in Table 16.10), first use the maximum belt input power ($H_{belt,max}$) for the load spectrum (multiplied by whatever oversizing factor may be desired) to calculate the natural logarithm of belt power capacity:

$$x_{motor,max} = \ln(H_{belt,max}) \quad (16.238)$$

where $H_{belt,max}$ is expressed in terms of hp.

Then, use Equation 16.239, along with a choice of low, medium, or high efficiency coefficients from Table 16.9, to calculate $\eta_{motor,max}$.

The maximum motor efficiency curves in Figure 16.22 (single rectangular hyperbola type 1) and their coefficients are as follows:

$$\eta_{motor,max} = \left[\frac{a_{motor,max} \cdot x_{motor,max}}{b_{motor,max} + x_{motor,max}} \right] + c_{motor,max} \quad (16.239)$$

Table 16.9: Motor Maximum Efficiency Curve Coefficients

Case	$a_{motor,max}$	$b_{motor,max}$	$c_{motor,max}$
High-Efficiency	0.196205	3.653654	0.839926
Mid-Efficiency	0.292280	3.368739	0.762471
Low-Efficiency	0.395895	3.065240	0.674321

The normalized *part-load* motor efficiency model is provided to modify the maximum efficiency of the motor. This model is based on part-load data for motors from DOE's MotorMaster+ database (2003). To determine the normalized motor efficiency at part-load ($\eta_{motor}(x_{motor})/\eta_{motor,max}$), use the motor fractional power output ($x_{motor} = H_{belt} / H_{belt,max}$) as the fraction of motor output power in Equation 16.240 and use coefficients from Table 16.10, or for a specific motor, determined from DOE MotorMaster+ data or from manufacturer's data. Figure 16.23 shows a graphical representation of eight example curves defined by these equations and coefficients.

The example motor normalized efficiency curves (single rectangular hyperbola type 2) and their coefficients as a function of motor load fraction in Figure 16.23 are determined from DOE MotorMaster+ data and are as follows:

$$\frac{\eta_{motor}(x_{motor})}{\eta_{motor,max}} = \left[\frac{a_{PLmotor} \cdot x_{motor}}{b_{PLmotor} + x_{motor}} \right] + c_{PLmotor} \cdot x_{motor} \quad (16.240)$$

Table 16.10: Example Motor Normalized Efficiency Curve Coefficients

Poles	Motor Rated Output (hp)	Maximum Efficiency	$a_{PLmotor}$	$b_{PLmotor}$	$c_{PLmotor}$
8	1	0.6675	1.096694	0.097126	0.002011
4	1	0.7787	1.092165	0.08206	-0.0072
	5	0.84	1.223684	0.08467	-0.135186
	10	0.8745	1.146258	0.045766	-0.110367

Table 16.10: Example Motor Normalized Efficiency Curve Coefficients

Poles	Motor Rated Output (hp)	Maximum Efficiency	$a_{Plmotor}$	$b_{Plmotor}$	$c_{Plmotor}$
	25	0.8991	1.137209	0.050236	-0.08915
	50	0.9129	1.088803	0.029753	-0.064058
	75	0.9259	1.07714	0.029005	-0.04935
	100	0.9499	1.035294	0.012948	-0.024708
	125	0.9527	1.030968	0.010696	-0.023514

Motor efficiency therefore is:

$$\eta_{motor}(x_{motor}) = \eta_{motor,max} \left[\frac{\eta_{motor}(x_{motor})}{\eta_{motor,max}} \right] \quad (16.241)$$

Motor input power (electrical, W) is:

$$H_{motor} = \frac{H_{belt}}{\eta_{motor}(x_{motor})} \quad (16.242)$$

VFD Efficiency and Input Power Model: For VFDs, published performance data are limited. Data from DOE (2008) suggest using a functional relation similar to that used for motors to represent VFD efficiency (η_{VFD}) as a function of the fraction of full-load motor input power ($x_{VFD} = H_{motor} / H_{motor,max}$), as shown in Figure 16.24, or as a function of the fraction of full-load speed ($x_{VFD} = \omega_{motor} / \omega_{motor,max}$), as shown in Figure 16.25.

The performance curve (single rectangular hyperbola type 2) used here for VFD efficiency is:

$$\eta_{VFD} = \left[\frac{a_{VFD} \cdot x_{VFD}}{b_{VFD} + x_{VFD}} \right] + c_{VFD} \cdot x_{VFD} \quad (16.243)$$

Example coefficients derived from the DOE data as a function of the fraction of full-load motor input power are listed in Table 16.11.

Table 16.11: Example VFD Efficiency Curve Coefficients

VFD Rated Output Power (hp)	a_{vfd}	b_{vfd}	c_{vfd}
3	0.978856	0.034247	-0.007862
5	0.977485	0.028413	-0.002733
10	0.978715	0.022227	0.001941
20	0.984973	0.017545	-0.000475
30	0.987405	0.015536	-0.005937
50	0.987910	0.018376	-0.001692
60	0.971904	0.014537	0.011849

Table 16.11: Example VFD Efficiency Curve Coefficients

VFD Rated Output Power (hp)	a_{vfd}	b_{vfd}	c_{vfd}
75	0.991874	0.017897	-0.001301
100	0.982384	0.012598	0.001405
≥ 200	0.984476	0.009828	-0.004560

VFD input power (electrical, W) is:

$$H_{VFD} = \frac{H_{motor}}{\eta_{VFD}} \quad (16.244)$$

System Total Efficiency: The combined efficiency of the fan system components (i.e., fan, belt, motor, and VFD) is:

$$\eta_{TOTAL} = \eta_{fan} \cdot \eta_{belt} \cdot \eta_{motor} \cdot \eta_{VFD} \quad \left(= \frac{Q_{fan} \cdot \Delta P_{fan}}{H_{VFD}} \right) \quad (16.245)$$

Heat Loss to Air: To calculate the temperature rise from waste heat entering the air stream from the fan, belt, and motor, it is assumed that the user-specified “motor in air fraction” applies to the belt and motor but not to the VFD. The power “lost” to the air (W) is:

$$\dot{Q}_{toair} = H_{fan} + (H_{motor} - H_{fan}) \cdot f_{motortoair} \quad (16.246)$$

16.4.3 Fan Energy Index

Fan Energy Index (FEI) is an energy-efficiency metric for fans including their motors and drives. This metric provides a standardized and consistent basis for comparing fan energy performance across fan types and sizes at a given fan operating point. Fan specifiers can use it to understand and communicate fan-efficiency design intent, while legislative and regulatory bodies can use it to define energy-efficiency requirements of fans.

ANSI/AMCA Standard 208-18 defines the calculation method for FEI. The standard has been written to support the adoption of energy efficient fans in the energy and construction codes and standards (e.g., ASHRAE Standards 90.1, 189.1, and California Appliances Standards Title 20) and to support utility rebate programs. FEI is a replacement for fan efficiency grade (FEG), a metric currently referenced in model energy codes and standards such as ASHRAE 90.1, ASHRAE 189.1, and IECC and in federal regulations in several Asian countries.

FEI is defined as a ratio of the electrical input power of a reference fan to the electrical input power of the actual fan for which the FEI is calculated, both calculated at the same duty point, i, which is characterized by a value of airflow (Q_i) and pressure ($P_{t,i}$ or $P_{s,i}$). FEI can be calculated for each point on a fan curve.

FEI is reported in the EquipmentSummary table report in the Fans subtable.

$$FEI_{t,i} \text{ or } FEI_{s,i} = \frac{\text{ReferenceFanElectricalInputPower}}{\text{ActualFanElectricalInputPower}} = \frac{FEP_{ref,i}}{FEP_{act,i}} \quad (16.247)$$

where:

Figure 16.23: Motor Normalized Efficiency vs. Motor Load Fraction

Figure 16.24: VFD Efficiency vs. Fraction of Motor Full-Load Input Power (*Source: DOE 2008*)

Figure 16.25: VFD Efficiency vs. Fraction of Full-Load Motor Speed (*Courtesy of Saftronics*)

$FEI_{t,i}$ is the FEI based on fan total pressure

$FEI_{s,i}$ is the FEI based on fan static pressure.

The FEI is reported for *Fan:SystemModel*, *Fan:ConstantVolume*, *Fan:OnOff*, *Fan:VariableVolume*, and *Fan:ZoneExhaust* objects. User defined Fan objects are used to simulate the actual fan electrical input power $FEP_{act,i}$ at the design operating point. The reference fan electrical input power $FEP_{ref,i}$ is calculated using the following method.

Reference fan shaft power ($H_{i,ref}$) is calculated on a fan total pressure basis or a static pressure basis, depending on the category of the reference fan to calculate FEI. For all EnergyPlus fans (except) *Fan:ComponentModel* total pressure is defined. So the FEI is reportable only for limited category of fans that are calculated based on the fan total pressure, namely Centrifugal Housed, Centrifugal Inline, Centrifugal PRV Supply, Axial Inline, Laboratory Exhaust, Jet Fan and Circulating.

The reference fan concept is used to normalize the FEI calculation to a consistent power level independent of fan type, fan drive components or any regulatory requirements. The reference fan electrical input power is a function of airflow and fan pressure. The reference fan is defined as one that requires a certain reference fan shaft power, uses a V-belt drive, has a motor efficiency based on the IE3 level for a four-pole 60 Hz motor and does not have a speed control.

$$FEP_{ref,i} = H_{i,ref} \left(\frac{1}{\eta_{trans,ref}} \right) \left(\frac{1}{\eta_{mtr,ref}} \right) \left(\frac{1}{\eta_{ctrl,ref}} \right) \quad (16.248)$$

where:

$H_{i,ref}$ is the reference fan shaft power (kW)

$\eta_{trans,ref}$ is the reference fan transmission efficiency

$\eta_{mtr,ref}$ is the reference fan motor efficiency

$\eta_{ctrl,ref}$ is the reference fan motor controller efficiency

Reference fan shaft power

Reference fan shaft power ($H_{i,ref}$) is calculated on a fan total pressure basis:

$$H_{i,ref} = \frac{(Q_i + Q_0)(P_{t,i} + P_0 \times \frac{\rho}{\rho_{std}})}{1000 \times \eta_0} \quad (16.249)$$

where:

Q_i is the fan air flow (m^3/s)

$P_{t,i}$ is the fan total pressure (Pa)

ρ is the air density (kg/m^3)

ρ_{std} is the standard air density ($1.2 kg/m^3$)

Q_0 is $0.118 m^3/s$

P_0 is 100 Pa

η_0 is 66%.

Reference fan transmission efficiency

For consistency, the reference fan is defined as one having a V-belt drive transmission, regardless of the drive arrangement of the actual fan for which the FEI is calculated. The reference fan transmission efficiency is calculated using the same equations as found in ANSI/AMCA Standard 207 for V-belt drives:

$$\eta_{trans,ref} = 0.96 \left(\frac{H_{i,ref}}{H_{i,ref} + 1.64} \right)^{.05} \quad (16.250)$$

Reference fan motor efficiency

The reference fan is defined as having a motor efficiency based on the IE3 level for a four-pole 60 Hz motor. In order to simplify the calculation of part load efficiency for this reference fan motor and to avoid sizing and otherwise identifying a specific motor for this reference fan, a curve fit is used through the IE3 motor efficiency requirements. The result is a reference motor efficiency that varies continuously based on the required motor output power.

Reference fan motor output power:

$$H_{t,ref} = \frac{H_{i,ref}}{\eta_{trans,ref}} \quad (16.251)$$

The reference fan motor efficiency is calculated according to Equation 16.252 using the coefficients A–E found in Table 16.12:

$$\eta_{mtr,ref} = A \cdot [\log_{10}(H_{t,ref})]^4 + B \cdot [\log_{10}(H_{t,ref})]^3 + C \cdot [\log_{10}(H_{t,ref})]^2 + D \cdot [\log_{10}(H_{t,ref})] + E \quad (16.252)$$

Table 16.12: Reference Motor Efficiency Coefficients

Type	$H_{t,ref} < 185$ (< 250 BHP)	kW	$H_{t,ref} \geq 185$ (≥ 250 BHP)	kW
A	-0.003812	0		
B	0.025834	0		
C	-0.072577	0		
D	0.125559	0		
E	0.850274	0.962		

Reference fan motor controller efficiency

The reference fan is defined as a constant speed fan. Therefore, the motor controller efficiency is 100%.

$$\eta_{ctrl,ref} = 1 \quad (16.253)$$

16.5 Air System Compound Component Groups

16.5.1 Unitary Systems

16.5.1.1 Overview

The input object `AirLoopHVAC:UnitarySystem` provides a “virtual” component that collects and controls a set of components: fan, heating coil, cooling coil, and/or reheat coil. Reheat coil is modeled for controlling high zone humidity levels or supplementing a heat pump heating coil. The unit may be configured to have either a blow through or draw through fan. In a blow through configuration, fan is generally the first component upstream of heating or cooling coil. In a draw through fan configuration, fan is placed directly after the heating coil and before reheat coil.

16.5.1.2 Model Description

As described previously, the unitary system is a “virtual” component consisting of a fan, heating coil, cooling coil and reheat coil. The sole purpose of the unitary system model is to properly

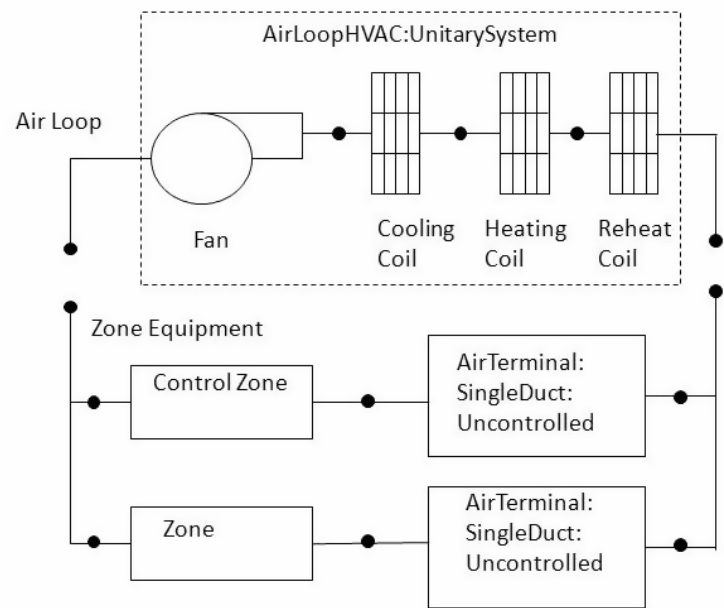

Figure 16.26: Schematic of the EnergyPlus Unitary System (Blow Through Configuration)

coordinate the operation of the various system components. The following sections describe the flow of information within the model, as well as the differences between cycling and continuous supply air fan operation.

16.5.1.3 Controls

There are three types of control types allowed to be specified in the unitary system which are setpoint based, load based or a load based control method according to ASHRAE Standard 90.1. Each control type is described in detail below.

16.5.1.4 Setpoint based control:

The unitary system calculates the current sensible load using the temperature of the inlet node and the System Node Setpoint Temp on the control node. If the control node is not the outlet node, the desired outlet node temperature is adjusted for the current temperature difference between the outlet node and the control node. Likewise, the current latent load is calculated using the humidity ratio of the inlet node and the System Node Humidity Ratio Max on the control node. The controls determine the required coil run-time fraction and dehumidification mode (if applicable) using the steps outlined below.

16.5.1.4.1 Step 1 – Meet Sensible Load Requirement

The controls first attempt to meet the sensible requirement. The specified coil model is called with a part-load ratio (PLR) of 1.0 to determine the full-load output of the coil. This is compared with the desired outlet node temperature and a sensible PLR is calculated. If the PLR is <1.0 , a root solver iteration routine is called to determine the coil run-time fraction which results in the desired outlet node temperature. For a variable-speed DX cooling coil, if the load is smaller than the sensible capacity at the lowest speed, the coil run-time fraction is determined in the same way as a single-speed DX cooling coil. Otherwise, its speed number and speed ratio between two neighboring speeds are selected to match the load.

16.5.1.4.2 Step 2 – Meet Latent Load Requirement (if activated)

If dehumidification controls are active, the leaving humidity ratio resulting from operation to meet the sensible load (Step 1 above) is compared with the desired outlet node humidity ratio. If the humidity requirement is already met, then no further control action is taken. If the humidity requirement has not been met, then the coil is re-simulated depending on the type of humidity control.

16.5.1.4.3 Step 2a – Humidity Control = MultiMode

If the humidity control type is MultiMode, then the coil's enhanced dehumidification mode is activated when the coil type is Coil:Cooling:DX:TwoStageWithHumidityControlMode and Step 1 above is repeated to meet the sensible load using the coil performance resulting from the enhanced dehumidification mode. This is a semi-passive approach to dehumidification which may fall short or may exceed the dehumidification requirement.

16.5.1.4.4 Step 2b – Humidity Control = CoolReheat

If the humidity control type is CoolReheat, the coil is re-simulated to achieve the desired outlet node humidity ratio. This option is valid for all cooling coil types. When the coil type is Coil:Cooling:DX:TwoStageWithHumidityControlMode, only the cooling performance mode is used for this step and enhanced dehumidification mode is not activated.

16.5.1.5 Load based control:

While the unitary system may be configured to serve multiple zones, system operation is controlled by a thermostat located in a single “control” zone. One of the key parameters for the unitary system component is the fraction of the total system air flow that goes through the control zone. This fraction is calculated as the ratio of the maximum air mass flow rate for the air loop’s supply inlet node for the control zone (e.g., AirTerminal:SingleDuct:ConstantVolume:NoReheat, field = Maximum Air Flow Rate, converted to mass flow) to the sum of the maximum air mass flow rates for the air loop’s supply inlet nodes for all zones served by this air loop. The unitary system module scales the calculated load for the control zone upward based on this fraction to determine the total load to be met by the unitary system. The module then proceeds to calculate the required part-load ratio for the system coil and the supply air fan to meet this total load. The heating or cooling capacity delivered by the unitary system is distributed to all of the zones served by this system via the terminal units that supply air to each zone. The supply air fraction that goes through the control zone is calculated as follows:

$$\text{ControlZoneAirFlow Fraction} = \frac{\dot{m}_{TUMax\text{ControlZone}}}{\sum_{j=1}^{NumOfZones} \dot{m}_{TUMax\text{Zone } j}} \quad (16.254)$$

where:

$\dot{m}_{TUMax\text{ControlledZone}}$ is the maximum air mass flow rate for the air loop’s supply inlet node (terminal unit) for the control zone (kg/s)

$\dot{m}_{TUMax\text{Zone } j}$ is the maximum air mass flow rate for the air loop’s supply inlet node for the j th zone (kg/s)

$NumOfZones$ is the number of zones, or number of air loop supply air inlet nodes for all zones served by the air loop.

The unitary system component is able to model supply air fan operation in two modes: cycling fan – cycling coil (i.e., AUTO fan) and continuous fan – cycling coil (i.e., fan ON). Fan:OnOff must be used to model AUTO fan, while Fan:OnOff or Fan:ConstantVolume can be used to model fan ON. The fan operation mode is specified using a supply air fan operating mode schedule where schedule values of 0 denote cycling fan operation and schedule values other than 0 (a 1 is usually used) denote continuous fan operation. Using this schedule, the unitary system fan may be cycled with cooling or heating coil operation or operated continuously based on time of day (e.g., cycling fan operation at night and continuous fan operation during the daytime). If the fan operating mode schedule name field is left blank in the unitary system object, the unitary system assumes cycling or AUTO fan mode operation throughout the simulation.

The unitary system operates based on the user-specified (or autosized) design supply air flow rate(s). The ‘design’ supply air mass flow rate may be different for cooling, heating, and when no cooling or heating is required and the fan operates continuously based on user-specified inputs.

Cooling Operation

If EnergyPlus determines that the unitary system must supply cooling to the control zone to meet the zone air temperature setpoint, then the model computes the total sensible cooling load to be met by the unitary system based on the control zone sensible cooling load and the fraction of the unitary system air flow that goes through the control zone.

$$UnitarySystemCoolingLoad = \frac{ControlZoneCoolingLoad}{ControlZoneAirFlowFraction} \quad (16.255)$$

If the supply air fan operating mode schedule requests cycling fan operation, the model first checks for the presence of an economizer in the outside air system serving the unitary system's air loop (Ref. AirLoopHVAC:OutdoorAirSystem). If an outside air system is not present or if an air-side economizer is not used, the unitary system's compressor is used to meet the unitary system cooling load. If an air-side economizer is used and is active (i.e., economizer controls indicate that conditions are favorable to increase the outside air flow rate), the unitary system will try to meet the cooling load by operating only the supply air fan. If the fan is able to satisfy the unitary system cooling load, the compressor remains off for the entire simulation time step. If the operation of the fan alone is unable to meet the entire cooling load, then the compressor is enabled and additional calculations are performed to determine the compressor's part-load ratio.

The model then calculates the unitary system's sensible cooling energy rate delivered to the zones being served when the system runs at full-load conditions and when the cooling coil is OFF. If the supply air fan cycles with the compressor, then the sensible cooling energy rate is zero when the cooling coil is OFF. However if the fan is configured to run continuously regardless of coil operation, then the sensible cooling energy rate will probably not be zero when the cooling coil is OFF. Calculating the sensible cooling energy rate involves modeling the supply air fan (and associated fan heat), the cooling coil, and the heating and reheat coil (simply to pass the air properties and mass flow rate from its inlet node to its outlet node). For each of these cases (full load and cooling coil OFF), the sensible cooling energy rate delivered by the unitary system is calculated as follows:

$$Full\ Cool\ Output = (Mass\ Flow\ Rate_{full\ load})(h_{out,full\ load} - h_{control\ zone})_{HRmin} - \Delta_{sen,full\ load} \quad (16.256)$$

$$No\ Cool\ Output = (Mass\ Flow\ Rate_{coil\ off})(h_{out,coil\ off} - h_{control\ zone})_{HRmin} - \Delta_{sen,coil\ off} \quad (16.257)$$

where:

$Mass\ Flow\ Rate_{full\ load}$ is the air mass flow rate through unitary system at full-load conditions (kg/s)

$h_{coil,full\ load}$ is the enthalpy of air exiting the unitary system at full-load conditions (J/kg)

$h_{control\ zone}$ is the enthalpy of air in the control zone where the thermostat is located (J/kg)

HR_{min} is the enthalpies evaluated at a constant humidity ratio, the minimum humidity ratio of the unitary system exiting air or the air in the control zone

$Mass\ Flow\ Rate_{coil\ off}$ is the air mass flow rate through the unitary system with the cooling coil OFF (kg/s)

$h_{out,coil\ off}$ is the enthalpy of air exiting the unitary system with the cooling coil OFF (J/kg)

$\Delta_{sen,full\ load}$ is the sensible load difference between the system output node and the zone inlet node at full-load conditions.

$$\begin{aligned} \Delta_{sen,full\ load} &= \frac{MassFlowRate_{Zone\ Inlet}}{Frac} (h_{Out,full\ load} - h_{Zone\ Inlet})_{HRmin} \\ &+ (MassFlowRate_{full\ load} - \frac{MassFlowRate_{Zone\ Inlet}}{Frac}) (h_{Out,full\ load} - h_{Control\ Zone})_{HRmin} \end{aligned} \quad (16.258)$$

where:

$Frac$ is the control zone air fraction with respect to the system mass flow rate

$\Delta_{sen,coil\ off}$ is the sensible load difference between the system output node and the zone inlet node with the heating coil OFF conditions.

$$\begin{aligned} \Delta_{sen,coil\ off} &= \frac{MassFlowRate_{Zone\ Inlet}}{Frac} (h_{Out,coil\ off} - h_{Zone\ Inlet})_{HRmin} \\ &+ (MassFlowRate_{coil\ off} - \frac{MassFlowRate_{Zone\ Inlet}}{Frac}) (h_{Out,coil\ off} - h_{Control\ Zone})_{HRmin} \end{aligned} \quad (16.259)$$

With the calculated sensible cooling energy rates and the total sensible cooling load to be met by the system, the part-load ratio for the unitary system is estimated.

$$PartLoadRatio = MAX \left(0.0, \frac{(UnitarySystemCoolingLoad - NoCoolOutput)}{(FullCoolOutput - NoCoolOutput)} \right) \quad (16.260)$$

Since the part-load performance of the cooling coil is frequently non-linear, and the supply air fan heat varies based on cooling coil operation for the case of cycling fan/cycling coil (AUTO fan), the final part-load ratio for the cooling coil compressor and fan are determined through iterative calculations (successive modeling of the cooling coil and fan) until the unitary system's cooling output matches the cooling load to be met within the convergence tolerance. The convergence tolerance is fixed at 0.001 and is calculated based on the difference between the load to be met and the unitary system's cooling output divided by the load to be met.

$$Tolerance = 0.001 \geq \frac{(UnitarySystemCoolingLoad - Q_{UnitarySystem})}{UnitarySystemCoolingLoad} \quad (16.261)$$

where $Q_{UnitarySystem}$ is the unitary system delivered sensible capacity (W).

If the unitary system has been specified with cycling fan/cycling coil (AUTO fan), then the unitary system's operating supply air mass flow rate is multiplied by $PartLoadRatio$ to determine the average air mass flow rate for the system simulation time step. In this case, the air conditions at nodes downstream of the cooling coil represent the full-load (steady-state) values when the coil is operating.

If the fan operates continuously (i.e., when the supply air fan operating mode schedule values are NOT equal to 0), the operating air mass flow rate through the unitary system is calculated as the average of the user-specified air flow rate when the cooling coil is ON and the user-specified air flow rate when the cooling coil is OFF (user-specified supply air volumetric flow rates converted to dry air mass flow rates).

$$\dot{m}_{UnitarySystem} = PartLoadRatio (\dot{m}_{CoolCoilON}) + (1 - PartLoadRatio) (\dot{m}_{CoilOFF}) \quad (16.262)$$

where:

$\dot{m}_{HeatCoilON}$ is the air mass flow rate through unitary system when the cooling coil is ON (kg/s)

$\dot{m}_{CoilOFF}$ is the air mass flow rate through unitary system when no cooling or heating is needed (kg/s).

In this case, the air conditions at nodes downstream of the cooling coil are calculated as the average conditions over the simulation time step (i.e., the weighted average of full-load conditions when the coil is operating and inlet air conditions when the coil is OFF).

Cooling Operation (multi or variable speed coils)

After the unitary system cooling load is determined as described in Equation 16.255 above, the multi or variable speed cooling coil models calculations are described in this section.

The model calculates the unitary system's sensible cooling energy rate delivered to the zones being served when the system runs at full-load conditions at the highest speed and when the DX cooling coil is OFF. If the supply air fan cycles with the compressor, then the sensible cooling energy rate is zero when the cooling coil is OFF. However if the fan is scheduled to run continuously regardless of coil operation, then the sensible cooling energy rate will not be zero when the cooling coil is OFF. Calculating the sensible cooling energy rate involves modeling the supply air fan (and associated fan heat) and the multi/variable speed DX cooling coil. The multi/variable speed DX heating coil and the supplemental heating coil are also modeled, but only to pass the air properties and mass flow rate from their inlet nodes to their outlet nodes. For each of these cases (full load at highest cooling speed and DX cooling coil OFF), the sensible cooling energy rate delivered by the unitary system is calculated as follows:

$$FullCoolOutput_{Highest\ Speed} = (\dot{m}_{HighestSpeed})(h_{out,full\ load} - h_{control\ zone})_{HRmin} - \Delta_{sen,HighestSpeed} \quad (16.263)$$

$$NoCoolOutput = (\dot{m}_{CoilOff})(h_{out,coil\ off} - h_{control\ zone})_{HRmin} - \Delta_{sen,coil\ off} \quad (16.264)$$

where:

$\dot{m}_{HighestSpeed}$ is the air mass flow rate through unitary system at the highest cooling speed (kg/s)

$h_{out,full\ load}$ is the enthalpy of air exiting the unitary system at full-load conditions [J/kg]

$h_{control\ zone}$ is the enthalpy of air leaving the control zone (where thermostat is located) (J/kg)

HR_{min} is the minimum humidity ratio of the unitary system exiting air or the air leaving the control zone (kg/kg)

$\dot{m}_{CoilOff}$ is the air mass flow rate through the unitary system with the cooling coil OFF (kg/s)

$h_{out,coil\ off}$ is the enthalpy of air exiting the unitary system with the cooling coil OFF (J/kg)

$\Delta_{sen,HighestSpeed}$ is the sensible load difference between the system output node and the zone inlet node at full-load conditions

$\Delta_{sen,coil\ off}$ is the sensible load difference between the system output node and the zone inlet node with the cooling coil OFF conditions.

$$\begin{aligned} \Delta_{sen,HighestSpeed} = & \frac{\dot{m}_{Zone\ Inlet}}{Frac}(h_{Out,full\ load} - h_{Zone\ Inlet})_{HRmin} \\ & + (\dot{m}_{HighestSpeed} - \frac{\dot{m}_{Zone\ Inlet}}{Frac})(h_{Out,full\ load} - h_{Control\ Zone})_{HRmin} \end{aligned} \quad (16.265)$$

$$\begin{aligned} \Delta_{sen,coil\ off} = & \frac{\dot{m}_{Zone\ Inlet}}{Frac}(h_{Out,coil\ off} - h_{Zone\ Inlet})_{HRmin} \\ & + (\dot{m}_{coil\ off} - \frac{\dot{m}_{Zone\ Inlet}}{Frac})(h_{Out,coil\ off} - h_{Control\ Zone})_{HRmin} \end{aligned} \quad (16.266)$$

where $Frac$ is the control zone air fraction with respect to the system mass flow rate.

If the unitary system's sensible cooling rate at the highest speed (full load, no cycling) is insufficient to meet the entire cooling load, the controlled zone conditions will not be met. The reported cycling rate and speed ratio are 1, and the speed number is set to the highest index number. If the total sensible cooling load to be met by the system is less than the sensible cooling rate at the highest speed, then the following steps are performed.

First, calculate the sensible cooling energy rate at Speed 1:

$$FullCoolOutput_{Speed1} = (\dot{m}_{Speed1})(h_{out,fullload} - h_{control\ zone})_{HRmin} - \Delta_{sen,Speed1} \quad (16.267)$$

where:

\dot{m}_{Speed1} is the air mass flow rate through unitary system at Speed 1 (kg/s)

$\Delta_{sen,Speed1}$ is the sensible load difference between the system output node and the zone inlet node at full-load conditions at Speed 1.

$$\begin{aligned} \Delta_{sen,Speed1} = & \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,full\ load} - h_{Zone\ Inlet})_{HRmin} \\ & + \left(\dot{m}_{Speed1} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,full\ load} - h_{Control\ Zone})_{HRmin} \end{aligned} \quad (16.268)$$

If the sensible cooling energy rate delivered by the unitary system at Speed 1 is greater or equal to the sensible load, the cycling ratio (part-load ratio) for the unitary system is estimated.

$$\begin{aligned} CyclingRatio &= \frac{|(CoolingCoilSensibleLoad)|}{FullCoolingCoilCapacity} \\ &= \max \left(0.0, \frac{UnitarySystemCoolingLoad - AddedFanHeat}{FullCoolOutput_{Speed1} - AddedFanHeat_{Speed1}} \right) \end{aligned} \quad (16.269)$$

where:

$AddedFanHeat$ is the generated supply air fan heat, which is a function of part load ratio and as internal component cooling load (W)

$AddedFanHeat_{Speed1}$ is the generated supply air fan heat at Speed 1 for a part load ratio = 1 (W).

Since the part-load performance of the DX cooling coil is frequently non-linear, and the supply air fan heat varies based on cooling coil operation for the case of cycling fan/cycling coil (AUTO fan), the final part-load ratio for the cooling coil compressor and fan are determined through iterative calculations (successive modeling of the cooling coil and fan) until the unitary system's cooling output matches the cooling load to be met within the convergence tolerance. The convergence tolerance is fixed at 0.001 and is calculated based on the difference between the load to be met and the unitary system's cooling output divided by the load to be met.

$$Tolerance = 0.001 \geq \frac{(UnitarySystemOutput_{cycling} - Q_{UnitarySystem})}{UnitarySystemCoolingLoad} \quad (16.270)$$

where the $UnitarySystemOutput_{cycling}$ is the unitary system delivered sensible capacity for Speed 1 operating at a specific cycling ratio (W).

$$UnitarySystemOutput_{cycling} = \dot{m}_{UnitarySystem}(h_{out} - h_{ControlZone})_{HRmin} - \Delta_{cycling} \quad (16.271)$$

where:

$\dot{m}_{UnitarySystem}$ is the average air mass flow rate defined in the next section (kg/s)

h_{out} is the enthalpy of air exiting the unitary system at part load conditions (J/kg)

$\Delta_{cycling}$ is the average sensible load difference between the system output node and the zone inlet node.

$$\Delta_{cycling} = \frac{\dot{m}_{ZoneInlet}}{frac} (h_{ZoneInlet} - h_{ControlZone}) + \left(\dot{m}_{UnitarySystem} - \frac{\dot{m}_{ZoneInlet}}{frac} \right) (h_{Out} - h_{ControlZone}) \quad (16.272)$$

where $\dot{m}_{ZoneInlet}$ is the air mass flow rate in the supply inlet node in the controlled zone (kg/s).

For this case where speed 1 operation was able to meet the required cooling load, the speed ratio is set to zero and speed number is equal to 1.

If the unitary system's cooling output at full load for Speed 1 is insufficient to meet the entire cooling load, the Cycling ratio is set equal to 1.0 (compressor and fan are not cycling). Then the cooling speed is increased and the delivered sensible capacity is calculated. If the full load sensible capacity at Speed n is greater than or equal to the sensible load, the speed ratio for the unitary system is estimated:

$$SpeedRatio = \frac{ABS (UnitarySystemCoolingLoad - AddedFanHeat - FullCoolOutput_{Speedn-1})}{ABS (FullCoolOutput_{Speedn} - FullCoolOutput_{Speedn-1})} \quad (16.273)$$

Although a linear relationship is assumed by applying the speed ratio to obtain the effective capacity and mass flow rate between speed n and n-1, the outlet air node conditions are dependent on the combined outputs and may not be linear. In addition, the supply air fan heat varies with the speed ratio due to different supply mass flow rates between speed n and n-1. Therefore, the final speed ratio for the cooling coil compressor and fan are determined through iterative calculations (successive modeling of the cooling coil and fan) until the unitary system's cooling output matches the cooling load to be met within the convergence tolerance. The convergence tolerance is fixed at 0.001 and is calculated based on the difference between the load to be met and the unitary system's cooling output divided by the load to be met.

$$Tolerance = 0.001 \geq \frac{(UnitarySystemCoolingLoad - UnitarySystemOutput_{SpeedRatio})}{UnitarySystemCoolingLoad} \quad (16.274)$$

where $UnitarySystemOutput_{Speedn}$ is the unitary system delivered sensible capacity between two consecutive speeds at a specific speed ratio (W).

$$\begin{aligned} UnitarySystemOutput_{SpeedRatio} = & (SpeedRatio)FullCoolOutput_{Speedn} \\ & + (1 - SpeedRatio)FullCoolOutput_{Speedn-1} \\ & - AddedFanHeat_{SpeedRatio} \end{aligned} \quad (16.275)$$

where $AddedFanHeat_{SpeedRatio}$ is the generated supply air fan heat at a specific speed ratio (W). In this case, the reported cycling ratio is 1 and speed number is equal to n.

16.5.1.5.1 Air Mass Flow Rate Calculation

Speed 1 operation

If the unitary system has been specified with cycling fan/cycling coil (AUTO fan), then the unitary system's operating supply air mass flow rate is determined by the cycling ratio (PartLoadRatio) for Speed 1. The supply air mass flow rate is multiplied by the cycling ratio to determine the average air mass flow rate for the system simulation time step. The air conditions at nodes downstream of the cooling coils represent the full-load (steady-state) values when the coil is operating.

$$\dot{m}_{UnitarySystem} = (CyclingRatio) \dot{m}_{Speed1} \quad (16.276)$$

If the fan operates continuously (i.e., when the supply air fan operating mode schedule values are NOT equal to 0), the operating air mass flow rate through the unitary system is calculated as the average of the user-specified air flow rate when the unitary system cooling coil is ON at Speed 1 and the user-specified air flow rate when the unitary system cooling coil is OFF (user-specified supply air volumetric flow rates converted to dry air mass flow rates).

$$\dot{m}_{UnitarySystem} = (CyclingRatio) \dot{m}_{Speed1} + (1 - CyclingRatio) \dot{m}_{CoilOff} \quad (16.277)$$

where:

$\dot{m}_{UnitarySystem}$ is the average air mass flow rate through unitary system (kg/s)

\dot{m}_{Speed1} is the air mass flow rate through unitary system when cooling coil is ON at Speed 1 (kg/s)

$\dot{m}_{CoilOff}$ is the air mass flow rate through unitary system when no heating or cooling is needed (kg/s).

In this case, the air conditions at nodes downstream of the cooling coils are calculated as the average conditions over the simulation time step (i.e., the weighted average of full-load conditions when the coil is operating and inlet air conditions when the coil is OFF).

16.5.1.5.2 Higher Speed Operation

When the unitary system operates at higher speeds to meet the required cooling load, the supply air mass flow rate is linearly interpolated between two consecutive speeds:

$$\dot{m}_{UnitarySystem} = (SpeedRatio) \dot{m}_{Speedn} + (1 - SpeedRatio) \dot{m}_{Speedn-1} \quad (16.278)$$

where:

$\dot{m}_{UnitarySystem}$ is the average air mass flow rate through the unitary system for the time step (kg/s)

\dot{m}_{Speedn} is the air mass flow rate through unitary system when cooling coil is ON at Speed n (kg/s)

$\dot{m}_{Speedn-1}$ is the air mass flow rate through unitary system when cooling coil is ON at Speed n-1 (kg/s).

For this case of higher speed operation, the air conditions at nodes downstream of the cooling coils are determined by the delivered cooling capacity and supply air mass flow rates between two consecutive speeds.

Although the above sections present the capacity and air mass flow rate calculation separately, they are dependent and change every iteration until convergence is reached for the time step being simulated.

Heating Operation

Calculations for heating operation are similar to those for cooling operation in most respects. However, due to the inclusion of a supplemental heating coil, additional calculations are necessary to properly meet the total heating load for the zones being served.

If EnergyPlus determines that the unitary system must supply heating to the control zone to meet the zone air temperature setpoint, then the unitary system model computes the total sensible heating load to be delivered to the zones being served based on the control zone sensible heating load and the control zone airflow fraction.

$$UnitarySystemHeatingLoad = \frac{ControlZoneHeatingLoad}{ControlZoneAirFlowFraction} \quad (16.279)$$

The model then calculates the unitary system's sensible heating energy rate delivered to the zones being served when the system runs at full-load conditions and when the heating coil is OFF (without supplemental heater operation in either case). If the supply air fan cycles with the compressor, then the sensible heating energy rate is zero when the compressor is OFF. However if the fan is scheduled to run continuously regardless of coil operation, then the sensible heating energy rate will not be zero when the compressor is OFF. Calculating the sensible heating energy rate involves modeling the supply air fan (and associated fan heat), the cooling coil (simply to pass the air properties and mass flow rate from its inlet node to its outlet node), the heating coil, and the supplemental heating coil (simply to pass the air properties and mass flow rate from its inlet node to its outlet node). For each of these cases (full load and heating coil OFF, without supplemental heater operation in either case), the sensible heating energy rate delivered by the unitary system is calculated as follows:

$$Full\ Heat\ Output = (Mass\ Flow\ Rate_{full\ load})(h_{out,full\ load} - h_{control\ zone})_{HRmin} - \Delta_{sen,full\ load} \quad (16.280)$$

$$No\ Heat\ Output = (Mass\ Flow\ Rate_{coil\ off})(h_{out,coil\ off} - h_{control\ zone})_{HRmin} - \Delta_{sen,coil\ off} \quad (16.281)$$

where:

$Mass\ Flow\ Rate_{full\ load}$ is the air mass flow rate through unitary system at full-load conditions (kg/s)

$h_{out,full\ load}$ is the enthalpy of air exiting the unitary system at full-load conditions (J/kg)

$h_{control\ zone}$ is the enthalpy of air leaving the control zone (where thermostat is located) (J/kg)

HR_{min} are the enthalpies evaluated at a constant humidity ratio, the minimum humidity ratio of the unitary system exiting air or the air leaving the control zone

$Mass\ Flow\ Rate_{coil\ off}$ is the air mass flow rate through the unitary system with the heating coil OFF (kg/s)

$h_{out,coil\ off}$ is the enthalpy of air exiting the unitary system with the heating coil OFF (J/kg)

$\Delta_{sen,full\ load}$ is the sensible load difference between the system output node and the zone inlet node at full-load conditions.

$$\Delta_{sen,full\ load} = \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,full\ load} - h_{Zone\ Inlet})_{HRmin} + \left(\dot{m}_{full\ load} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,full\ load} - h_{Control\ Zone})_{HRmin} \quad (16.282)$$

where:

Frac is the control zone air fraction with respect to the system mass flow rate

$\Delta_{sen,coil\ off}$ is the sensible load difference between the system output node and the zone inlet node with the heating coil OFF conditions.

$$\Delta_{sen,coil\ off} = \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,coil\ off} - h_{Zone\ Inlet})_{HRmin} + \left(\dot{m}_{coil\ off} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,coil\ off} - h_{Control\ Zone})_{HRmin} \quad (16.283)$$

With the calculated sensible heating energy rates and the total sensible heating load to be met by the system, the part-load ratio for the unitary system is estimated.

$$PartLoadRatio = MAX \left(0.0, \frac{(UnitarySystemHeatingLoad - NoHeatOutput)}{(FullHeatOutput - NoHeatOutput)} \right) \quad (16.284)$$

Since the part-load performance of the heating coil is frequently non-linear, and the supply air fan heat varies based on heating coil operation for the case of cycling fan/cycling coil (AUTO fan), the final part-load ratio for the heating coil compressor and fan are determined through iterative calculations (successive modeling of the heating coil and fan) until the unitary system's heating output matches the heating load to be met within the convergence tolerance. The convergence tolerance is fixed at 0.001 and is calculated based on the difference between the load to be met and the unitary system's heating output divided by the load to be met.

$$Tolerance = 0.001 \geq \frac{(UnitarySystemHeatingLoad - Q_{UnitarySystem})}{UnitarySystemHeatingLoad} \quad (16.285)$$

where $Q_{UnitarySystem}$ is the unitary system delivered sensible capacity (W).

If the unitary system's heating coil output at full load is insufficient to meet the entire heating load, PartLoadRatio is set equal to 1.0 (compressor and fan are not cycling) and the remaining heating load is passed to the supplemental heating coil. If the unitary system model determines that the outdoor air temperature is below the minimum outdoor air temperature for compressor operation, the compressor is turned off and the entire heating load is passed to the supplemental gas or electric heating coil. The unitary system exiting air conditions and energy consumption are calculated and reported by the individual component models (fan, heating coil, and supplemental gas or electric heating coil).

If the unitary system has been specified with cycling fan/cycling coil (AUTO fan), then the unitary system's operating supply air mass flow rate is multiplied by PartLoadRatio to determine the average air mass flow rate for the system simulation time step. The air conditions at nodes downstream of the heating coils represent the full-load (steady-state) values when the coils are

operating. If the fan operates continuously (i.e., when the supply air fan operating mode schedule values are NOT equal to 0), the operating air mass flow rate through the unitary system is calculated as the average of the user-specified air flow rate when the unitary system heating coil is ON and the user-specified air flow rate when the unitary system heating coil is OFF (user-specified supply air volumetric flow rates converted to dry air mass flow rates).

$$\dot{m}_{UnitarySystem} = PartLoadRatio(\dot{m}_{HeatCoilON}) + (1 - PartLoadRatio)(\dot{m}_{CoilOFF}) \quad (16.286)$$

where:

$\dot{m}_{HeatCoilON}$ is the air mass flow rate through unitary system when the heating coil is ON (kg/s)

$\dot{m}_{CoilOFF}$ is the air mass flow rate through unitary system when no heating or cooling is needed (kg/s).

In this case, the air conditions at nodes downstream of the heating coils are calculated as the average conditions over the simulation time step (i.e., the weighted average of full-load conditions when the coils are operating and inlet air conditions when the coils are OFF).

16.5.1.6 Heating Operation (multi or variable speed coils)

After the unitary system heating load is determined as described in Equation 16.279 above, the multi or variable speed heating coil models calculation are described in this section.

The model calculates the unitary system's sensible heating energy rate delivered to the zones being served when the system runs at full-load conditions at the highest speed and when the DX heating coil is OFF (without supplemental heater operation in either case). If the supply air fan cycles with the compressor, then the sensible heating energy rate is zero when the compressor is OFF. However if the fan is scheduled to run continuously regardless of coil operation, then the sensible heating energy rate will not be zero when the compressor is OFF. Calculating the sensible heating energy rate involves modeling the supply air fan (and associated fan heat), the DX cooling coil (simply to pass the air properties and mass flow rate from its inlet node to its outlet node), the DX heating coil, and the supplemental heating coil (simply to pass the air properties and mass flow rate from its inlet node to its outlet node). For each of these cases (full load and DX heating coil OFF, without supplemental heater operation in either case), the sensible heating energy rate delivered by the unitary system is calculated as follows:

$$FullHeatOutput_{HighestSpeed} = (\dot{m}_{HighestSpeed})(h_{out,full\ load} - h_{control\ zone})_{HRmin} - \Delta_{sen,HighestSpeed} \quad (16.287)$$

$$NoHeatOutput = (\dot{m}_{CoilOff})(h_{out,coil\ off} - h_{control\ zone})_{HRmin} - \Delta_{sen,coil\ off} \quad (16.288)$$

where:

$\dot{m}_{HighestSpeed}$ is the air mass flow rate through unitary system at the highest heating speed (kg/s)

$h_{out,full\ load}$ is the enthalpy of air exiting the unitary system at full-load conditions (J/kg)

$h_{control\ zone}$ is the enthalpy of air leaving the control zone (where thermostat is located) (J/kg)

HR_{min} are the enthalpies evaluated at a constant humidity ratio, the minimum humidity ratio of the unitary system exiting air or the air leaving the control zone

$\dot{m}_{CoilOff}$ is the air mass flow rate through the unitary system with the heating coil OFF (kg/s)

$h_{out,coil\ off}$ is the enthalpy of air exiting the unitary system with the heating coil OFF (J/kg)

$\Delta_{sen,full\ load}$ is the sensible load difference between the system output node and the zone inlet node at full-load conditions.

$$\begin{aligned} \Delta_{sen,HighestSpeed} = & \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,full\ load} - h_{Zone\ Inlet})_{HRmin} \\ & + \left(\dot{m}_{HighestSpeed} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,coil\ off} - h_{Control\ Zone})_{HRmin} \end{aligned} \quad (16.289)$$

where:

Frac is the control zone air fraction with respect to the system mass flow rate

$\Delta_{sen,coil\ off}$ is the sensible load difference between the system output node and the zone inlet node with the heating coil OFF conditions.

$$\begin{aligned} \Delta_{sen,coil\ off} = & \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,coil\ off} - h_{Zone\ Inlet})_{HRmin} \\ & + \left(\dot{m}_{coil\ off} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,coil\ off} - h_{Control\ Zone})_{HRmin} \end{aligned} \quad (16.290)$$

If the unitary system's DX heating coil output full load at the highest speed is insufficient to meet the entire heating load, the remaining heating load is passed to the supplemental heating coil. If the unitary system model determines that the outdoor air temperature is below the minimum outdoor air temperature for compressor operation (specified by the user), the compressor is turned off and the entire heating load is passed to the supplemental gas or electric heating coil. The unitary system exiting air conditions and energy consumption are calculated and reported by the individual component models (fan, DX heating coil, and supplemental gas or electric heating coil).

If the total heating load to be met by the system is less than the sensible heating rate at the highest speed, then the following steps are performed.

First, calculate the sensible heating energy rate at Speed 1:

$$FullHeatOutput_{Speed1} = (\dot{m}_{Speed1})(h_{out,full\ load} - h_{control\ zone})_{HRmin} - \Delta_{sen,Speed1} \quad (16.291)$$

where:

\dot{m}_{Speed1} is the air mass flow rate through unitary system at Speed 1 (kg/s)

$\Delta_{sen,Speed1}$ is the sensible load difference between the system output node and the zone inlet node at full-load conditions at Speed 1.

$$\begin{aligned} \Delta_{sen,Speed1} = & \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,full\ load} - h_{ZoneInlet})_{HRmin} \\ & + \left(\dot{m}_{Speed1} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,coil\ off} - h_{Control\ Zone})_{HRmin} \end{aligned} \quad (16.292)$$

Second, if the sensible heating energy rate delivered by the unitary system at Speed 1 is greater or equal to the sensible load, the cycling ratio (part-load ratio) for the unitary system is estimated.

$$\begin{aligned}
CyclingRatio &= \frac{|(HeatingCoilSensibleLoad)|}{FullHeatingCoilCapacity} \\
&= \max\left(0.0, \frac{UnitarySystemHeatingLoad - AddedFanHeat}{FullHeatOutput_{Speed1} - AddedFanHeat_{Speed1}}\right)
\end{aligned} \tag{16.293}$$

where:

AddedFanHeat is the generated supply air fan heat, which is a function of part load ratio and as internal component heating load (W)

AddedFanHeat_{Speed1} is the generated supply air fan heat at Speed 1 (part load ratio = 1) (W).

Since the part-load performance of the DX heating coil is frequently non-linear, and the supply air fan heat varies based on heating coil operation for the case of cycling fan/cycling coil (AUTO fan), the final part-load ratio for the heating coil compressor and fan are determined through iterative calculations (successive modeling of the heating coil and fan) until the unitary system's heating output matches the heating load to be met within the convergence tolerance. The convergence tolerance is fixed at 0.001 and is calculated based on the difference between the load to be met and the unitary system's heating output divided by the load to be met.

$$Tolerance = 0.001 \geq \frac{(UnitarySystemHeatingLoad - UnitarySystemOutput_{cycling})}{UnitarySystemHeatingLoad} \tag{16.294}$$

where *UnitarySystemOutput_{cycling}* is the unitary system delivered sensible capacity for Speed 1 operating at a specific cycling ratio (W).

$$UnitarySystemOutput_{cycling} = \dot{m}_{UnitarySystem} (h_{out} - h_{Control\ Zone})_{HRmin} - \Delta_{cycling} \tag{16.295}$$

where

$\dot{m}_{UnitarySystem}$ is the average air mass flow rate defined in the next section (kg/s)

h_{out} is the enthalpy of air exiting the unitary system at part load conditions (J/kg)

$\Delta_{cycling}$ is the average sensible load difference between the system output node and the zone inlet node.

$$\Delta_{cycling} = \frac{\dot{m}_{ZoneInlet}}{frac} (h_{ZoneInlet} - h_{ControlZone}) + \left(\dot{m}_{UnitarySystem} - \frac{\dot{m}_{ZoneInlet}}{frac} \right) (h_{Out} - h_{ControlZone}) \tag{16.296}$$

where *$\dot{m}_{Zone\ Inlet}$* is the air mass flow rate in the supply inlet node in the controlled zone (kg/s).

For this case where Speed 1 operation was able to meet the required heating load, the speed ratio is set to zero and speed number is equal to 1.

Third, if the unitary system's heating output at full load for Speed 1 is insufficient to meet the entire heating load, the Cycling ratio (PartLoadRatio) is set equal to 1.0 (compressor and fan are not cycling). Then the heating speed is increased and the delivered sensible capacity is calculated. If the full load sensible capacity at Speed n is greater than or equal to the sensible load, the speed ratio for the unitary system is estimated:

$$SpeedRatio = \frac{ABS (UnitarySystemHeatingLoad - AddedFanHeat - FullHeatOutput_{Speedn-1})}{ABS (FullHeatOutput_{Speedn} - FullHeatOutput_{Speedn-1})} \tag{16.297}$$

Although a linear relationship is assumed by applying the speed ratio to obtain the effective capacity and air mass flow rate between speed n and $n-1$, the outlet node conditions are dependent on the combined outputs and may not be linear. In addition, the supply air fan heat varies based on heating coil operation for the case of cycling fan/cycling coil (AUTO fan). Therefore, the final speed ratio for the heating coil compressor and fan are determined through iterative calculations (successive modeling of the heating coil and fan) until the unitary system's heating output matches the heating load to be met within the convergence tolerance. The convergence tolerance is fixed at 0.001 and is calculated based on the difference between the load to be met and the unitary system's heating output divided by the load to be met.

$$Tolerance = 0.001 \geq \frac{(UnitarySystemHeatingLoad - UnitarySystemOutput_{SpeedRatio})}{UnitarySystemHeatingLoad} \quad (16.298)$$

where $UnitarySystemOutput_{SpeedRatio}$ is the unitary system delivered sensible capacity between two consecutive speeds at a specific ratio (W).

$$\begin{aligned} UnitarySystemOutput_{SpeedRatio} &= (SpeedRatio) FullHeatOutput_{Speedn} \\ &+ (1 - SpeedRatio) FullHeatOutput_{Speedn-1} \\ &- AddedFanHeat_{SpeedRatio} \end{aligned} \quad (16.299)$$

where $AddedFanHeat_{SpeedRatio}$ is the generated supply air fan heat at a specific speed ratio (W). In this case, the reported cycling ratio is 1 and speed number is equal to n .

16.5.1.6.1 Air Mass Flow Rate Calculation

The air mass flow rate calculations during heating operation are the same as those described above for cooling operation for multi/variable speed.

16.5.1.7 Single Zone VAV load based control:

The unitary system can also be used to simulate a system capable of maintaining a low fan speed through a range of low to moderate loads. This control scheme is similar to single zone variable-air-volume (VAV) control where the fan speed is maintained at a minimum level and the coil is modulated to a point where the system outlet air temperature reaches a user specified limit. As the outlet air temperature limit is reached and loads increase, the fan speed increases to maintain thermostat control. When the fan speed reaches the maximum flow limit, the system outlet air temperature may exceed the user specified limit, if the coil is capable of providing more capacity, to meet increased load. This model is applicable to AirloopHVAC and ZoneHVAC equipment and is active only for constant fan operating mode. Cycling fan operating may be used, however, during time of cycling fan operating mode, the model reverts to control specified above for Load Based control. Additionally, only specific coil types are allowed for the Single Zone VAV load based control method.

Allowed coil types are:

Cooling coils:

- Coil:Cooling:Water

- Coil:Cooling:WaterDetailed
- Coil:Cooling:DX:SingleSpeed

Heating coils:

- Coil:Heating:Water
- Coil:Heating:Fuel
- Coil:Heating:Electric
- Coil:Heating:DX:SingleSpeed

Other coil types may be used when selecting the Single Zone VAV control method, however, these coils will not be modeled using the Single Zone VAV load based control method and instead will be modeled using the Load Based control method described in a previous section.

The example below shows two implementations of the Single Zone VAV model using the Air-loopHVAC:UnitarySystem object as both air loop equipment serving multiple zones and as zone equipment serving a single zone. Chilled and hot water coils are used with autosized limits on supply air temperature. The supply air temperature limits are intended to reflect the model requirement to allow low speed fan operation at zone loads less than or equal to 50% of the design load. The zone cooling and heating loads identified in the figure are actual simulation data taken from the zone sizing information representative of the control zones used for each system. Outdoor air loads were eliminated for this example (i.e., Outdoor Air = 0).

Figure 16.27: Example of the EnergyPlus Unitary System Single Zone VAV Model

Supply air temperature limits are autosizable and calculated with respect to the zone temperatures at the design cooling and heating peak load conditions. Once the temperature limits are reached and the zone load continues to increase, the fan speed is increased while limiting the maximum outlet air temperature up to the maximum fan speed. At this point, the maximum temperature limits are ignored and the coils are allowed to provide excess temperatures when needed to meet increasing loads. When a supplemental heating coil is used, this coil should be active only when maximum fan speed is reached and will supplement any additional heating required to meet the zone load. The supplemental heating coil also has no maximum temperature limit while attempting to meet high heating loads.

16.5.1.8 High Humidity Control

The specific configuration of the unitary system with supplemental heating coil is shown above (see Figure 16.26). This figure shows the fan placement when a blow through fan is specified. If a draw through fan is specified, the fan is located between the heating coil and the supplemental heating coil. The system is controlled to keep the high relative humidity in the control zone from exceeding the setpoint specified in the object ZoneControl:Humidistat. This option is available when the supply air fan operates continuously (i.e., the supply air fan operating mode schedule values are never equal to 0) or the supply air fan cycles with the compressor. In addition, when high humidity control is specified and the compressor operates, the unitary system operates at the cooling air flow rate when a zone heating load is present as determined by the zone thermostat. High humidity control is specified as either None, MultiMode, or CoolReheat in the Dehumidification Control Type input field. MultiMode is specified when a heat exchanger is used to improve the dehumidification performance of the cooling coil. The heat exchanger will be activated when the sensible part-load ratio is insufficient to meet the zone latent load. CoolReheat is specified when a cooling coil is used to over-cool the supply air stream in order to meet the zone latent load. In this case, a supplemental heating coil will ensure the zone temperature does not fall below the zone heating temperature set point. When a heat exchanger is used in conjunction with a cooling coil and CoolReheat is specified as the Dehumidification Control Type, the heat exchanger is “locked on” to meet either the sensible or latent cooling load. If the dehumidification control type is selected as None and a heat exchanger assisted cooling coil is used, the heat exchanger is “locked on” and the air conditioner runs only to meet the sensible cooling load. A supplemental heating coil is required for all dehumidification control types.

The model first calculates the *PartLoadRatio* required to meet the sensible cooling load. The unitary system’s sensible cooling load is determined from the control zone sensible cooling load to the cooling setpoint and the control zone air flow fraction to maintain the dry-bulb temperature setpoint in the control zone.:

$$UnitarySystemCoolingLoad = \frac{ControlZoneCoolingLoad}{ControlZoneAirFlowFraction} \quad (16.300)$$

The unitary system’s sensible cooling load to be met and the full load cooling output are used to calculate the sensible the part-load ratio iteratively based on user specified convergence criterion.

$$PartLoadRatio = MAX \left(0.0, \frac{(UnitarySystemCoolingLoad - NoCoolOutput)}{(FullCoolOutput - NoCoolOutput)} \right) \quad (16.301)$$

When the unitary system’s sensible cooling capacity meets the system sensible cooling load at a given sensible part load ratio, then the Unitary system meets the controlled zone cooling setpoint temperature. If a moisture (latent) load exists because the control zone humidity has exceeded the setpoint, the total moisture load to be met by the unitary systems (*UnitarySystemMoistureLoad*) is calculated based on the control zone moisture load and the control zone air flow fraction.

$$UnitarySystemMoistureLoad = \frac{ControlZoneMoistureLoad}{ControlZoneAirFlowFraction} \quad (16.302)$$

Then the *LatentPartLoadRatio* required to meet the high humidity setpoint is calculated as follows:

$$LatentPartLoadRatio = MIN \left(PLR_{Min}, \frac{(UnitarySystemMoistureLoad - NoLatentOutput)}{(FullLatentOutput - NoLatentOutput)} \right) \quad (16.303)$$

The model uses the greater of the two part-load ratios, *PartLoadRatio* or *LatentPartLoadRatio*, to determine the operating part-load ratio of the Unitary system's DX cooling coil.

$$LatentPartLoadRatio = MAX (PartLoadRatio, LatentPartLoadRatio) \quad (16.304)$$

As previously described, iterations are performed to converge on the solution within the convergence tolerance.

where:

ControlZoneCoolingLoad is the control zone sensible cooling load to the cooling setpoint (W)

ControlZoneMoistureLoad is the control zone moisture load to the dehumidifying relative humidity setpoint (W)

ControlZoneAirFlowFraction is the supply air fraction that goes through the control zone

FullLatentOutput is the unitary system latent cooling energy rate at full-load conditions (W)

NoLatentOutput is the unitary system latent cooling energy rate with cooling coil OFF (W)

PartLoadRatio is the unitary system part-load-ratio required to meet system sensible load

LatentPartLoadRatio is the unitary system part-load-ratio required to meet system moisture load

PLR_{Min} is the minimum part-load ratio, which is usually 0.0. For the case when the latent capacity degradation model is used (Ref: DX Cooling Coil Model), this value is the minimum part-load ratio at which the cooling coil will dehumidify the air.

When the predicted zone air temperature is above the heating setpoint and if there is a dehumidification load, the supplemental heating coil load is required to offset the excess cooling as shown in Figure 16.28. If the model determines that the *LatentPartLoadRatio* is to be used as the operating part-load ratio of the unitary system's cooling coil, the supplemental heating coil is used to offset the excess sensible capacity provided by the unitary system cooling coil. The model first checks the sensible load that exists for the current simulation time step (predicted zone temperature with no HVAC operation compared to the thermostat setpoint temperatures). If a sensible cooling load or no sensible cooling or heating load exists, the model calculates the difference between the sensible heating load required to reach or maintain the heating dry-bulb temperature setpoint and the actual sensible cooling energy rate delivered by the unit (with *LatentPartLoadRatio*). In this case, the supplemental heating coil is used to offset the excess sensible cooling energy provided by the cooling coil (if any) that could have caused an overshoot of the heating dry-bulb temperature setpoint. Note that when a humidistat is used and high humidity control is required, the zone dry-bulb temperature will typically move toward the heating temperature setpoint when a high moisture (latent) load exists.

If a heating load exists (Figure 16.29), the supplemental heating coil is used to meet the heating coil load and at the same time offset the entire sensible cooling energy rate of the cooling coil (to meet the humidistat setpoint). Note that when a heating load exists and high humidity control is required, the unitary system operates at the user-specified cooling air flow rate for the entire simulation time step. As with the fan, and cooling coil, report variables associated with supplemental heating coil performance (e.g., heating coil energy, heating coil rate, heating coil gas or electric energy, heating coil runtime fraction, etc.) are managed in the supplemental (heating) coil object.

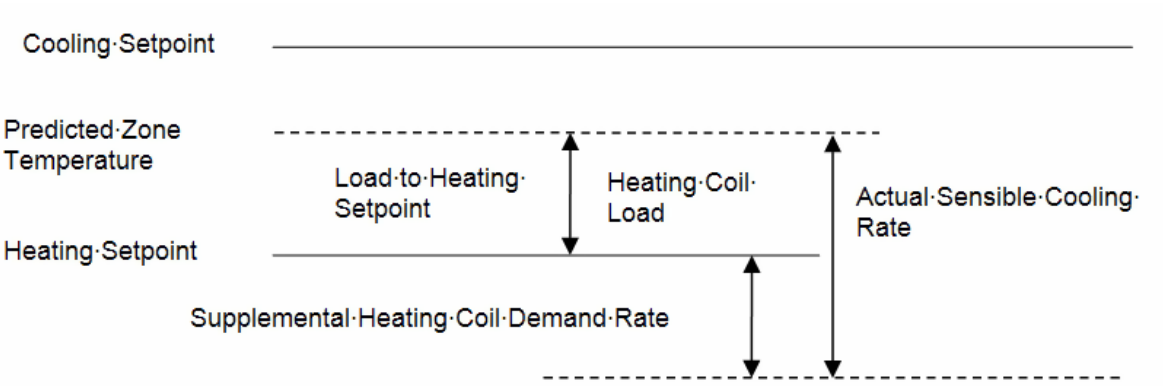

Figure 16.28: Supplemental heating coil load when predicted zone air temperature is above the heating Setpoint

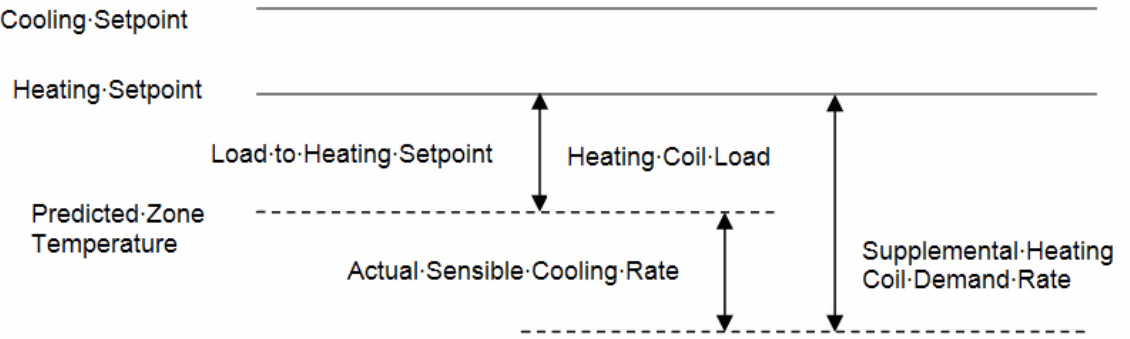

Figure 16.29: Supplemental heating coil load when predicted zone air temperature is below the heating setpoint

16.5.1.9 Waste Heat Calculation

Waste heat calculations are done when the multi speed cooling and heating coils are specified in the unitary system and the heat recovery is active (the value of the Design Heat Recovery Water Flow Rate field is greater than 0), the outlet node temperature of heat recovery is calculated based on the recoverable waste heat generated by the child objects Coil:Cooling:DX:MultiSpeed and Coil:Heating:DX:MultiSpeed:

$$T_{outlet} = T_{inlet} + \frac{Q_{WasteHeat}}{C_p \dot{m}_{hr}} \quad (16.305)$$

where:

T_{outlet} is the outlet node temperature of heat recovery (°C)

T_{inlet} is the inlet node temperature of heat recovery (°C)

$Q_{WasteHeat}$ is the recoverable waste heat generated by its child objects (W)

C_p is the inlet node temperature of heat recovery (°C)

\dot{m}_{hr} is the mass flow rate of heat recovery (kg/s).

If the outlet node temperature is above the value of the Maximum Temp for Heat Recovery field, the outlet node temperature is reset to the value of Maximum Temp for Heat Recovery.

16.5.1.10 Multi-Speed Fan with Water Coils In Unitary System

When modeling multi-speed fan and water coils in unitary system object, the coil's capacity is modulated using speed ratio or part-load ratio. The system load is met by varying the supply air fan speed while operating the coils at maximum water flow. When there is no system load to meet, the water control valve is fully closed. This method of capacity control is called two-position coil control. When the supply fan is cycling between stages, then the speed ratio is calculated, but when the unit cycles between the minimum fan speed and off-position, part-load ratio is calculated. The fan may be off or run at lowest speed continuously to provide ventilation air depending the fan operating schedule. When the fan is operating at the lowest fan speed (Speed = 1), then the water flow rate is reported as the average for the time step by multiplying the maximum water flow by part load ratio. The speed ratio and part-load ratio are calculated iteratively. The set of equations used for the multi-speed fan capacity control in unitary system for water coil AHU modeling are summarized next

16.5.1.10.1 Cycling Between Stages:

When the supply fan is cycling between consecutive speeds, then the speed ratio (SR) and the average mass flow rate are calculated as follows:

$$SR_n = \text{Abs}(\text{SystemLoad} - \text{FullLoadOutput}_{n-1}) / \text{Abs}(\text{FullLoadOutput}_n - \text{FullLoadOutput}_{n-1}) \quad (16.306)$$

$$\dot{m} = \dot{m}_{on,n} SR_n + \dot{m}_{on,n-1} (1 - SR_n) \quad (16.307)$$

$$\dot{m}w = \dot{m}_{w,max} \quad (16.308)$$

16.5.1.10.2 Cycling OnOff at Lowest Stage:

The average supply air flow rate calculation when the fan is running at the lowest fan speed level depends on the fan operating schedule and load. The unitary system part load ratio is given by:

$$PLR = \text{Abs}(\text{SystemLoad} - \text{NoLoadOutput}) / \text{Abs}(\text{FullLoadOutput}_1 - \text{NoLoadOutput}) \quad (16.309)$$

Continuous Fan:

$$\dot{m} = \dot{m}_{on,1} PLR + \dot{m}_{off}(1 - PLR) \quad (16.310)$$

Cycling Fan:

$$\dot{m} = \dot{m}_{on,1} PLR \quad (16.311)$$

$$\dot{m}_w = \dot{m}_{w,max} * PLR \quad (16.312)$$

where:

SR_n is the speed ratio of the water coil unitary system at speed n

PLR is the part load ratio of the unitary system at speed 1

\dot{m} is the average mass flow rate of supply air (kg/s)

$\dot{m}_{on,n-1}$ is the mass flow rate of supply air at fan speed level n-1 (kg/s)

$\dot{m}_{on,n}$ is the mass flow rate of supply air at fan speed level n (kg/s)

\dot{m}_{off} is the mass flow rate of supply air when the coils are off (kg/s)

\dot{m}_w is the average mass flow rate of chilled or hot water (kg/s)

$\dot{m}_{w,max}$ is the maximum or full mass flow rate of chilled or hot water (kg/s)

SystemLoad is the system load to be met by the unitary system (W)

$\text{FullLoadOutput}_{n-1}$ is the fully load system output at fan speed level n-1 (W)

FullLoadOutput_n is the fully load system output at fan speed level n (W).

16.5.2 Forced-Air Furnace and Central Air Conditioning

16.5.2.1 Overview

The input objects AirLoopHVAC:Unitary:Furnace:HeatOnly and AirLoopHVAC:Unitary:Furnace:HeatCool provide a “virtual” component that collect and control a set of components: an on/off or constant volume fan component and a gas or electric heating coil component. If the HeatCool version is selected, then a DX cooling coil is also modeled as part of the system as shown in Figure 16.30 below. For the HeatCool version, an optional reheat coil may also be modeled for controlling high zone humidity levels and the furnace’s configuration when specifying this option is shown in Figure 16.31 below. The unit may be configured to have either a blow through or draw through fan. If a blow through fan configuration is specified, the furnace fan is placed before the heating coil for the HeatOnly version, or before the cooling coil for the HeatCool version as shown in the figure below. If a draw through fan configuration is specified, the fan is placed directly after the heating coil.

Note: the coil order shown here has been revised from previous versions of EnergyPlus to configure the cooling coil upstream of the heating coil. This configuration provides uniformity with all unitary equipment. However, for unitary HeatCool systems that do not use a reheat coil, the heating coil can also be placed upstream of the cooling coil. This optional coil placement is retained to allow compatibility with previous versions of EnergyPlus. For input files developed using previous versions of EnergyPlus, it is recommended that the coil order be revised according to the figure below.

Figure 16.30: Schematic of the EnergyPlus Furnace (Blow Through Configuration)

While the furnace may be configured to serve multiple zones, system operation is controlled by a thermostat located in a single “control” zone. One of the key parameters for the furnace component is the fraction of the total system air flow that goes through the control zone. This fraction is calculated as the ratio of the maximum air mass flow rate for the air loop’s supply inlet node for the control zone (e.g., AirTerminal:SingleDuct:ConstantVolume:NoReheat, field = Maximum Air Flow Rate, converted to mass flow) to the sum of the maximum air mass flow rates for the air loop’s supply inlet nodes for all zones served by this air loop. The furnace module scales the calculated

load for the control zone upward based on this fraction to determine the total load to be met by the furnace. The module then proceeds to calculate the required part-load ratio for the system coil and the supply air fan to meet this total load. The heating or cooling capacity delivered by the furnace is distributed to all of the zones served by this system via the terminal units that supply air to each zone. The supply air fraction that goes through the control zone is calculated as follows:

$$\text{ControlZoneAirFlow Fraction} = \frac{\dot{m}_{TUMax\text{ControlZone}}}{\sum_{j=1}^{NumOfZones} \dot{m}_{TUMax\text{Zone } j}} \quad (16.313)$$

where:

$\dot{m}_{TUMax\text{ControlledZone}}$ is the maximum air mass flow rate for the air loop supply inlet node (terminal unit) for the control zone (kg/s)

$\dot{m}_{TUMax\text{Zone } j}$ is the maximum air mass flow rate for the air loop supply inlet node for the j th zone (kg/s)

$NumOfZones$ is the number of zones, or number of air loop supply air inlet nodes for all zones served by the air loop.

The furnace component is able to model supply air fan operation in two modes: cycling fan – cycling coil (i.e., AUTO fan) and continuous fan – cycling coil (i.e., fan ON). Fan:OnOff must be used to model AUTO fan, while Fan:OnOff or Fan:ConstantVolume can be used to model fan ON. The fan operation mode is specified using a supply air fan operating mode schedule where schedule values of 0 denote cycling fan operation and schedule values other than 0 (a 1 is usually used) denote continuous fan operation. Using this schedule, the furnace fan may be cycled with cooling or heating coil operation or operated continuously based on time of day (e.g., cycling fan operation at night and continuous fan operation during the daytime). If the fan operating mode schedule name field is left blank in the furnace object, the furnace assumes cycling or AUTO fan mode operation throughout the simulation.

The only output variables reported by the furnace object are the fan part-load ratio and the compressor part-load ratio (HeatCool only). The fan part-load ratio is defined as the actual air mass flow rate through the system for the time step divided by the design supply air mass flow rate specified for the furnace ($\dot{m}_{actual}/\dot{m}_{design}$). The furnace operates based on the user-specified (or autosized) design supply air flow rate(s). The ‘design’ supply air mass flow rate may be different for cooling, heating, and when no cooling or heating is required and the fan operates continuously based on user-specified inputs (HeatCool only). For the HeatCool version, If alternate air flow rates are specified for cooling, heating, and when no cooling or heating is required, the design supply air mass flow rate is the maximum of these specified values. Also for the HeatCool version, the compressor part-load ratio is reported as the ratio of the actual cooling load to the full-load sensible capacity (see Equation 16.329). Reporting of other variables of interest for the furnace (heating rate, cooling rate, energy consumption, etc.) is done by the individual system components (fan, heating coil and DX cooling coil).

16.5.2.2 Model Description

As described previously, the furnace is a “virtual” component consisting of a fan, heating coil and, for the HeatCool version, a cooling coil with an optional reheat coil. The sole purpose of the furnace model is to properly coordinate the operation of the various system components. The following sections describe the flow of information within the model for both the HeatOnly and

HeatCool configurations, as well as the differences between cycling and continuous supply air fan operation. The last section describes the optional control of high zone humidity with a reheat coil for the HeatCool configuration.

16.5.2.3 HeatOnly Configuration

The HeatOnly configuration consists of an on/off or constant volume fan and an electric or gas heating coil. When the model is first called during an EnergyPlus simulation, all of the input data specified for each furnace in the input data file are read into data structures for use throughout the remainder of the simulation.

For each simulation time step when the performance of a heat-only furnace is being modeled, the first step is to retrieve the heating load required to meet the thermostat setpoint for the “control” zone (see Figure 16.30. Schematic of the EnergyPlus Furnace). See the section “Summary of Predictor-Corrector Procedure” elsewhere in this document for more details regarding load calculations. Since the furnace may be specified to serve several zones but controlled based on the load calculated for the “control” zone, the total heating load to be met by the furnace is determined from the following equation:

$$\text{Furnace Heating Load} = \frac{\text{Control Zone Heating Load}}{\text{Control Zone Air Flow Fraction}} \quad (16.314)$$

The model then calculates the furnace’s sensible heating energy rate delivered to the zones being served when the system runs at full-load conditions and when the heating coil is OFF. If the supply air fan cycles on and off with the heater, then the sensible heating energy rate is zero when the heating coil is OFF. However if the fan is scheduled to run continuously regardless of coil operation, then the sensible heating energy rate will not be zero when the heating coil is OFF. Calculating the sensible heating energy rate involves modeling the supply air fan (and associated fan heat) and the heating coil. For each of these cases (full load and heating coil OFF), the sensible heating energy rate delivered by the furnace is calculated as follows:

$$\text{Full Heat Output} = (\text{Mass Flow Rate}_{\text{full load}})(h_{\text{out,full load}} - h_{\text{control zone}})_{HR_{\min}} - \Delta_{\text{sen,full load}} \quad (16.315)$$

$$\text{No Heat Output} = (\text{Mass Flow Rate}_{\text{coil off}})(h_{\text{out,coil off}} - h_{\text{control zone}})_{HR_{\min}} - \Delta_{\text{sen,coil off}} \quad (16.316)$$

where:

$\text{Mass Flow Rate}_{\text{full load}}$ is the air mass flow rate through furnace at full-load conditions (kg/s)

$h_{\text{out,full load}}$ is the enthalpy of air exiting the furnace at full-load conditions (J/kg)

$h_{\text{control zone}}$ is the enthalpy of air in the control zone where thermostat is located (J/kg)

HR_{\min} are the enthalpies evaluated at a constant humidity ratio, the minimum humidity ratio of the furnace exiting air or the air in the control zone

$\text{Mass Flow Rate}_{\text{coil off}}$ is the air mass flow rate through the furnace with the heating coil OFF (kg/s)

$h_{\text{out,coil off}}$ is the enthalpy of air exiting the furnace with the heating coil OFF (J/kg)

$\Delta_{\text{sen,full load}}$ is the sensible load difference between the system output node and the zone inlet node at full-load conditions.

$$\begin{aligned}\Delta_{sen,full\ load} &= \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,full\ load} - h_{Zone\ Inlet})_{HRmin} \\ &+ \left(\dot{m}_{full\ load} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,full\ load} - h_{Control\ Zone})_{HRmin}\end{aligned}\quad (16.317)$$

where:

$Frac$ is the control zone air fraction with respect to the system mass flow rate

$\Delta_{sen,coil\ off}$ is the sensible load difference between the system output node and the zone inlet node with the heating coil OFF conditions.

$$\begin{aligned}\Delta_{sen,coil\ off} &= \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,coil\ off} - h_{Zone\ Inlet})_{HRmin} \\ &+ \left(\dot{m}_{coil\ off} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,coil\ off} - h_{Control\ Zone})_{HRmin}\end{aligned}\quad (16.318)$$

With the calculated sensible heating energy rates and the total sensible heating load to be met by the system, the part-load ratio for the furnace is estimated.

$$PartLoadRatio = MAX \left(0.0, MIN \left(1.0, \frac{ABS(FurnaceHeatingLoad - NoHeatOutput)}{ABS(FullHeatOutput - NoHeatOutput)} \right) \right) \quad (16.319)$$

The part-load ratio calculated above is used to determine the required heating coil capacity as $Q_{heating\ coil} = Q_{design} * PartLoadRatio$ where Q_{design} is the nominal heating coil capacity as specified in the heating coil object. If the fan cycles on and off with the heating coil (i.e., when the supply air fan operating mode schedule values are equal to 0), then this part-load ratio is also used to determine the operating mass flow rate of the furnace as

$$\dot{m}_{furnace} = \dot{m}_{design} * PartLoadRatio \quad (16.320)$$

If the fan operates continuously (i.e. fan ON), the operating mass flow rate is specified as \dot{m}_{design} . The furnace's fan and heating coil are then re-simulated to determine the furnace's delivered sensible heating capacity at the above calculated part-load ratio.

$$Q_{furnace} = (\dot{m}_{furnace}) (h_{out,actual} - h_{control\ zone})_{HRmin} - \Delta_{sen,actual} \quad (16.321)$$

where:

$Q_{furnace}$ is the sensible heating capacity delivered by the furnace (W)

$\dot{m}_{furnace}$ is the air mass flow rate through the furnace (kg/s)

$h_{out,actual}$ is the enthalpy of air exiting the furnace (J/kg)

$h_{out,control\ zone}$ is the enthalpy of air in the control zone (J/kg)

HR_{min} are the enthalpies evaluated at a constant humidity ratio, the minimum humidity ratio of the furnace exiting air or the air in the control zone

$\Delta_{sen,actual}$ is the sensible load difference between the system output node and the zone inlet node at the above calculated part-load ratio.

$$\begin{aligned}\Delta_{sen,actual} &= \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,actual} - h_{Zone\ Inlet})_{HRmin} \\ &+ \left(\dot{m}_{furnace} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,actual} - h_{Control\ Zone})_{HRmin}\end{aligned}\quad (16.322)$$

Since the part-load performance of the heating coil can be non-linear, and the supply air fan heat varies based on heating coil operation for the case of cycling fan/cycling coil (AUTO fan),

the final part-load ratio for the heating coil and fan are determined through iterative calculations (successive modeling of the heating coil and fan) until the furnace's heating output matches the heating load to be met within the heating convergence tolerance. The convergence tolerance is fixed at 0.001 and is calculated based on the difference between the load to be met and the furnace's heating output divided by the load to be met.

$$Tolerance \equiv \frac{FurnaceHeatingLoad - Q_{furnace}}{FurnaceHeatingLoad} \leq 0.001 \quad (16.323)$$

If the furnace has been specified with cycling fan/cycling coil (AUTO fan), then the furnace's design air mass flow rate is multiplied by PartLoadRatio to determine the average air mass flow rate for the system simulation time step. The air conditions at nodes downstream of the heating coil represent the full-load (steady-state) values when the coil is operating. If the supply air fan is specified to run continuously (fan ON), then the air mass flow rate remains at the furnace's design air mass flow rate. In this case, the air conditions at nodes downstream of the heating coil are calculated as the average conditions over the simulation time step (i.e., the weighted average of full-load conditions when the coil is operating and inlet air conditions when the coil is OFF).

For the case where the furnace is scheduled to operate with continuous supply air fan operation, but no heating load is required to meet the setpoint temperature in the control zone, the supply air fan model is still called to determine the fan exiting air conditions. The heating coil model is also called, but for the case with no heating load the heating coil model simply passes the inlet air conditions and mass flow rate from its inlet node to its outlet node. The air exiting the heating coil is then sent to the direct air units for distribution to each zone served by the furnace, where the zone heat balance is performed to determine the resulting zone air conditions. The furnace exiting air conditions and energy consumption are calculated and reported by the individual component models (fan and heating coil).

16.5.2.4 HeatCool Configuration

The HeatCool configuration consists of an on/off or constant volume fan, a DX cooling coil, and an electric or gas heating coil. For the cases where a heating load is calculated for the control zone or no heating/cooling load is calculated for the control zone, the model follows nearly identical computational steps as described in the HeatOnly Configuration section above. The only difference is the air mass flow rate during no cooling/heating operation with continuous supply air fan operation can be different from the air mass flow rate during heater operation for the HeatCool configuration. If a cooling load is calculated by EnergyPlus for the control zone, the solution methodology is also virtually identical and is described here for completeness.

If EnergyPlus determines that the furnace must supply cooling to the control zone to meet the zone air temperature setpoint, then the model computes the total sensible cooling load to be met by the furnace based on the control zone sensible cooling load and the fraction of the furnace air flow that goes through the control zone.

$$Furnace\ Cooling\ Load = \frac{Control\ Zone\ Cooling\ Load}{Control\ Zone\ Air\ Flow\ Fraction} \quad (16.324)$$

If the supply air fan operating mode schedule requests cycling fan operation, the model first checks for the presence of an economizer in the outside air system serving the furnace's air loop (Ref. AirLoopHVAC:OutdoorAirSystem). If an outside air system is not present or if an air-side

economizer is not used, the furnace's compressor is used to meet the furnace cooling load. If an air-side economizer is used and is active (i.e., economizer controls indicate that conditions are favorable to increase the outside air flow rate), the furnace will try to meet the cooling load by operating only the supply air fan. If the fan is able to satisfy the furnace cooling load, the compressor remains off for the entire simulation time step. If the operation of the fan alone is unable to meet the entire cooling load, then the compressor is enabled and additional calculations are performed to determine the compressor's part-load ratio.

The model then calculates the furnace's sensible cooling energy rate delivered to the zones being served when the system runs at full-load conditions and when the DX cooling coil is OFF. If the supply air fan cycles with the compressor, then the sensible cooling energy rate is zero when the cooling coil is OFF. However if the fan is configured to run continuously regardless of coil operation, then the sensible cooling energy rate will probably not be zero when the cooling coil is OFF. Calculating the sensible cooling energy rate involves modeling the supply air fan (and associated fan heat), the DX cooling coil, and the heating coil (simply to pass the air properties and mass flow rate from its inlet node to its outlet node). For each of these cases (full load and DX cooling coil OFF), the sensible cooling energy rate delivered by the furnace is calculated as follows:

$$\text{Full Cool Output} = (\text{Mass Flow Rate}_{\text{full load}})(h_{\text{out,full load}} - h_{\text{control zone}})_{HRmin} - \Delta_{\text{sen,full load}} \quad (16.325)$$

$$\text{No Cool Output} = (\text{Mass Flow Rate}_{\text{coil off}})(h_{\text{out,coil off}} - h_{\text{control zone}})_{HRmin} - \Delta_{\text{sen,coil off}} \quad (16.326)$$

where:

$\text{Mass Flow Rate}_{\text{full load}}$ is the air mass flow rate through furnace at full-load conditions (kg/s)

$h_{\text{out,full load}}$ is the enthalpy of air exiting the furnace at full-load conditions (J/kg)

$h_{\text{control zone}}$ is the enthalpy of air in the control zone (where thermostat is located) (J/kg)

HR_{min} are the enthalpies evaluated at a constant humidity ratio, the minimum humidity ratio of the furnace exiting air or the air in the control zone

$\text{Mass Flow Rate}_{\text{coil off}}$ is the air mass flow rate through the furnace with the cooling coil OFF (kg/s)

$h_{\text{out,coil off}}$ is the enthalpy of air exiting the furnace with the cooling coil OFF (J/kg)

$\Delta_{\text{sen,full load}}$ is the sensible load difference between the system output node and the zone inlet node at full-load conditions.

$$\begin{aligned} \Delta_{\text{sen,full load}} &= \frac{\dot{m}_{\text{Zone Inlet}}}{\text{Frac}} (h_{\text{Out,full load}} - h_{\text{Zone Inlet}})_{HRmin} \\ &+ \left(\dot{m}_{\text{full load}} - \frac{\dot{m}_{\text{Zone Inlet}}}{\text{Frac}} \right) (h_{\text{Out,full load}} - h_{\text{Control Zone}})_{HRmin} \end{aligned} \quad (16.327)$$

where:

Frac is the control zone air fraction with respect to the system mass flow rate

$\Delta_{\text{sen,coil off}}$ is the sensible load difference between the system output node and the zone inlet node with the heating coil OFF conditions.

$$\begin{aligned} \Delta_{\text{sen,coil off}} &= \frac{\dot{m}_{\text{Zone Inlet}}}{\text{Frac}} (h_{\text{Out,coil off}} - h_{\text{Zone Inlet}})_{HRmin} \\ &+ \left(\dot{m}_{\text{coil off}} - \frac{\dot{m}_{\text{Zone Inlet}}}{\text{Frac}} \right) (h_{\text{Out,coil off}} - h_{\text{Control Zone}})_{HRmin} \end{aligned} \quad (16.328)$$

With the calculated sensible cooling energy rates and the total sensible cooling load to be met by the system, the part-load ratio for the furnace is estimated.

$$PartLoadRatio = MAX \left(0.0, \frac{ABS(FurnaceCoolingLoad - NoCoolOutput)}{ABS(FullCoolOutput - NoCoolOutput)} \right) \quad (16.329)$$

Since the part-load performance of the DX cooling coil is frequently non-linear (Ref: DX Cooling Coil Model), and the supply air fan heat varies based on cooling coil operation for the case of cycling fan/cycling coil (AUTO fan), the final part-load ratio for the cooling coil compressor and fan are determined through iterative calculations (successive modeling of the cooling coil and fan) until the furnace's cooling output matches the cooling load to be met within the convergence tolerance. The convergence tolerance is fixed at 0.001 and is calculated based on the difference between the load to be met and the furnace's cooling output divided by the load to be met.

$$Tolerance \equiv \frac{FurnaceHeatingLoad - Q_{furnace}}{FurnaceHeatingLoad} \leq 0.001 \quad (16.330)$$

where $Q_{furnace}$ is the furnace delivered sensible capacity (W).

If the furnace has been specified with cycling fan/cycling coil (AUTO fan) and high humidity control *has not* been specified, then the furnace's operating supply air mass flow rate is multiplied by PartLoadRatio to determine the average air mass flow rate for the system simulation time step. The air conditions at nodes downstream of the cooling coil represent the full-load (steady-state) values when the coil is operating. If a cycling fan is used and high humidity control *has* been specified, the calculation of average air mass flow rate is based on the greater of the heating or cooling part-load ratio (see following section on high humidity control). When the heating part-load ratio is greater than the cooling part-load ratio, the air conditions at nodes downstream of the cooling coil represent the weighted average of full-load conditions when the cooling coil is operating and inlet air conditions when the cooling coil is off (i.e., the fan continues to operate due to a heating requirement where the heating PLR is greater than the cooling PLR). If the supply air fan is specified to run continuously (fan ON), then the air mass flow rate continues to operate at the user-specified supply air mass flow rate when no cooling or heating is required. In this case, the air conditions at nodes downstream of the cooling coil are calculated as the average conditions over the simulation time step (i.e., the weighted average of full-load conditions when the coil is operating and inlet air conditions when the coil is OFF). The furnace exiting air conditions and energy consumption are calculated and reported by the individual component models (fan and DX cooling coil).

16.5.2.5 High Humidity Control with HeatCool Configuration

An optional reheat coil can be specified with the HeatCool configuration to allow the furnace to control high zone humidity levels. The specific configuration of the HeatCool Furnace with high humidity control option is shown in Figure 16.31. The figure below shows the fan placement when a blow through fan is specified. If a draw through fan is specified, the fan is located between the heating coil and the reheat coil. The system is controlled to keep the relative humidity in the control zone from exceeding the setpoint specified in the object ZoneControl:Humidistat. This option is available when the supply air fan operates continuously (i.e., the supply air fan operating mode schedule values are never equal to 0) or the supply air fan cycles with the compressor. For

the case of cycling fan mode when the high humidity control is specified as CoolReheat *and* the heating part-load ratio is greater than the compressor part-load ratio, the air conditions at nodes downstream of the cooling coil are calculated as the average conditions during the duration of fan operation (i.e., the weighted average of full load conditions when the coil is operating and inlet air conditions when the coil is off and the fan continues to operate to meet the heating load). For the case where cycling fan mode is used *and* the heating part-load ratio is less than the compressor part-load ratio, the air conditions at the nodes downstream of the cooling coil are simply the full load (steady-state) values when the coil is operating. In addition, when high humidity control is specified and the compressor operates, the furnace operates at the cooling air flow rate when a zone heating load is present as determined by the zone thermostat.

High humidity control is specified as either None, MultiMode, or CoolReheat in the Dehumidification Control Type input field. MultiMode is specified when a heat exchanger is used to improve the dehumidification performance of the cooling coil. The heat exchanger will be activated when the sensible part-load ratio is insufficient to meet the zone latent load. CoolReheat is specified when a DX cooling coil is used to over-cool the supply air stream in order to meet the zone latent load. In this case, a reheat coil will ensure the zone temperature does not fall below the zone heating temperature set point. When a heat exchanger is used in conjunction with a DX cooling coil and CoolReheat is specified as the Dehumidification Control Type, the heat exchanger is “locked on” to meet either the sensible or latent cooling load. If the dehumidification control type is selected as None and a heat exchanger assisted cooling coil is used, the heat exchanger is “locked on” and the air conditioner runs only to meet the sensible cooling load. Although a reheat coil is required when CoolReheat is specified in the Dehumidification Control Type input field, this reheat coil may optionally be present for the other Dehumidification Control Types (e.g., None and Multimode). If the reheat coil is present and the dehumidification control type input is not specified as CoolReheat, the reheat coil will not be active. This allows changing the dehumidification control option without requiring a change in the unit’s coil configuration.

The model first calculates the PartLoadRatio required to meet the sensible cooling load as described above (see Equation 16.329) to maintain the dry-bulb temperature setpoint in the control zone. If a moisture (latent) load exists because the control zone humidity has exceeded the setpoint, the total moisture load to be met by the HeatCool furnace (SystemMoistureLoad) is calculated based on the control zone moisture load and the control zone air flow fraction. The model then calculates the LatentPartLoadRatio required to meet the humidistat setpoint.

$$SystemMoistureLoad = \frac{Control\ Zone\ Moisture\ Load}{Control\ Zone\ Air\ Flow\ Fraction} \quad (16.331)$$

$$LatentPartLoadRatio = MAX \left(MinPLR, \frac{ABS(SystemMoistureLoad - NoLatentOutput)}{ABS(FullLatentOutput - NoLatentOutput)} \right) \quad (16.332)$$

where:

FullLatentOutput is the furnace’s latent cooling energy rate at full-load conditions (W)

NoLatentOutput is the furnace’s latent cooling energy rate with the cooling coil OFF (W)

MinPLR is the minimum part-load ratio, which is usually 0.0. For the case when the latent capacity degradation model is used (Ref: DX Cooling Coil Model), this value is the minimum part-load ratio at which the cooling coil will dehumidify the air.

The model uses the greater of the two part-load ratios, `PartLoadRatio` or `LatentPartLoadRatio`, to determine the operating part-load ratio of the furnace's DX cooling coil. As previously described, iterations are performed to converge on the solution within the convergence tolerance.

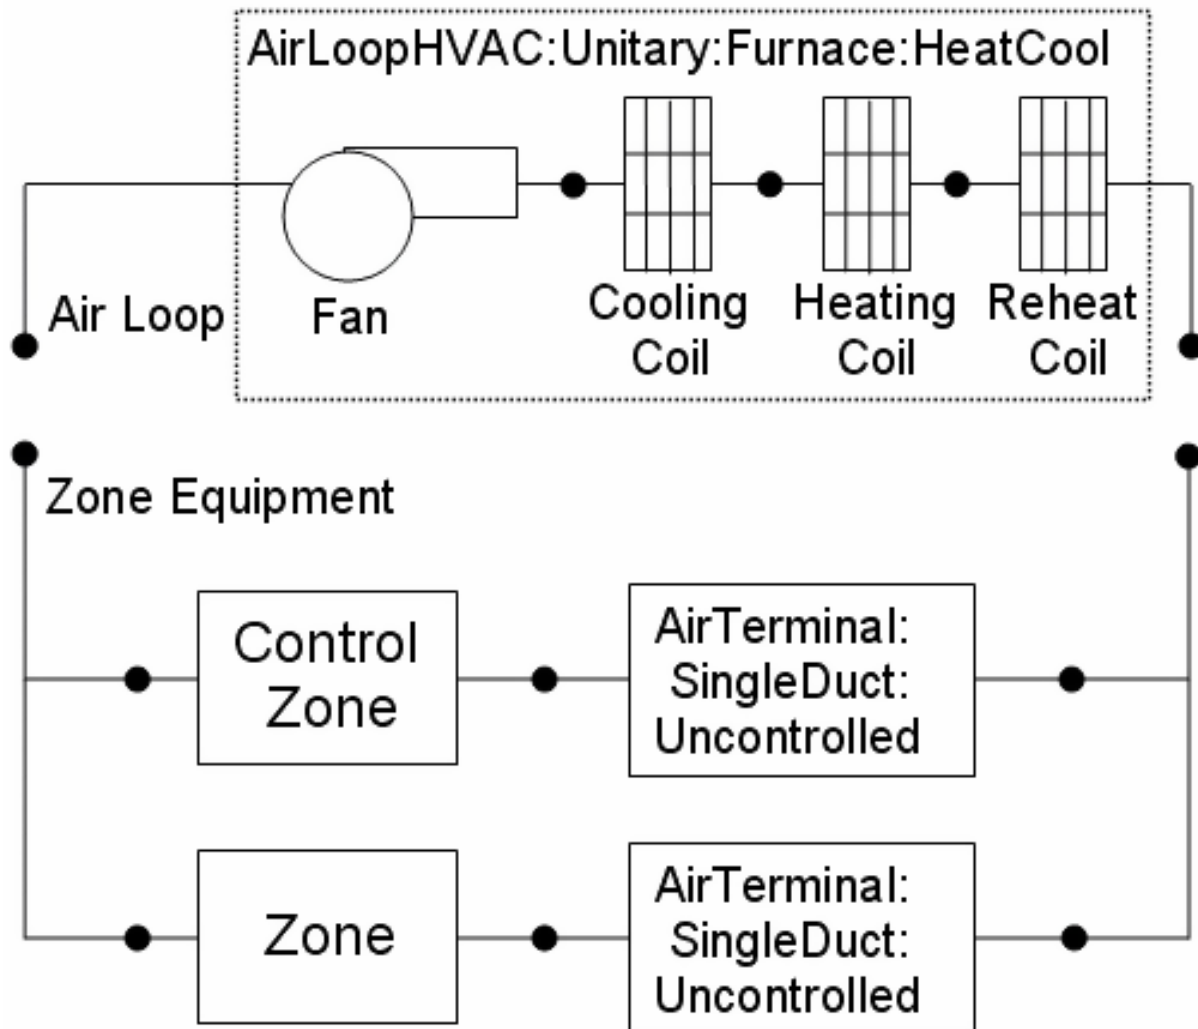

Figure 16.31: Schematic for Blow Through Furnace with High Humidity Control

If the model determines that the `LatentPartLoadRatio` is to be used as the operating part-load ratio of the furnace's cooling coil, the reheat coil is used to offset the excess sensible capacity provided by the unit. The model first checks the sensible load that exists for the current simulation time step (predicted zone temperature with no HVAC operation compared to the thermostat setpoint temperatures). If a sensible cooling load or no sensible cooling or heating load exists (Figure 16.32), the model calculates the difference between the sensible heating load required to reach or maintain the heating dry-bulb temperature setpoint and the actual sensible cooling energy rate delivered by the unit (with `LatentPartLoadRatio`). In this case, the reheat coil is used to offset the excess sensible cooling energy provided by the DX cooling coil (if any) that could have caused an overshoot of the heating dry-bulb temperature setpoint. Note that when a humidistat is used and high humidity control is required, the zone dry-bulb temperature will typically move toward the heating temperature setpoint when a high moisture (latent) load exists. If a heating load exists (Figure 16.33), the

reheat coil is used to offset the entire sensible cooling energy rate of the DX cooling coil (to meet the humidistat setpoint) and the heating coil is used to meet the entire heating load as described in the HeatOnly configuration section above. Note that when a heating load exists and high humidity control is required, the furnace operates at the user-specified cooling air flow rate for the entire simulation time step. As with the fan, DX cooling coil, and heating coil, report variables associated with reheat coil performance (e.g., heating coil energy, heating coil rate, heating coil gas or electric consumption, heating coil runtime fraction, etc.) are managed in the reheat (heating) coil object.

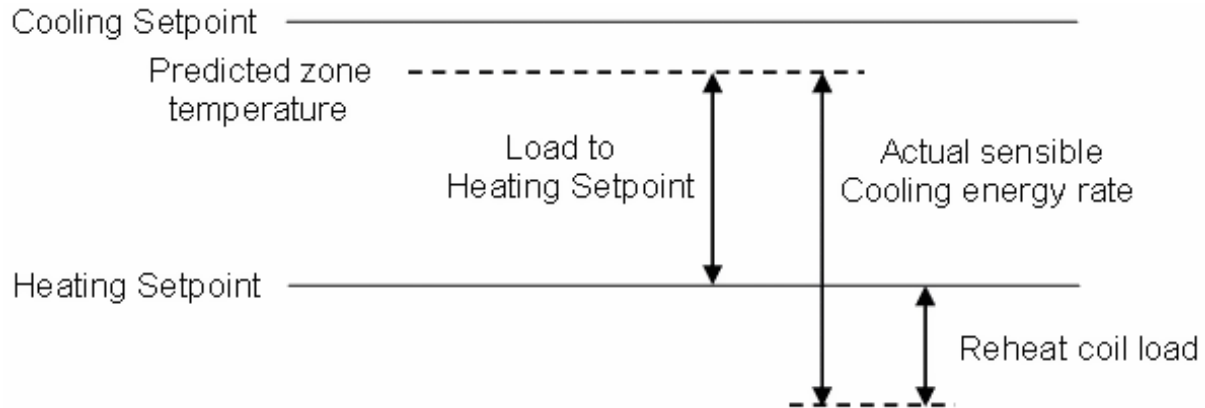

Figure 16.32: Reheat Coil Load when Predicted Zone Temperature is Above Heating Setpoint

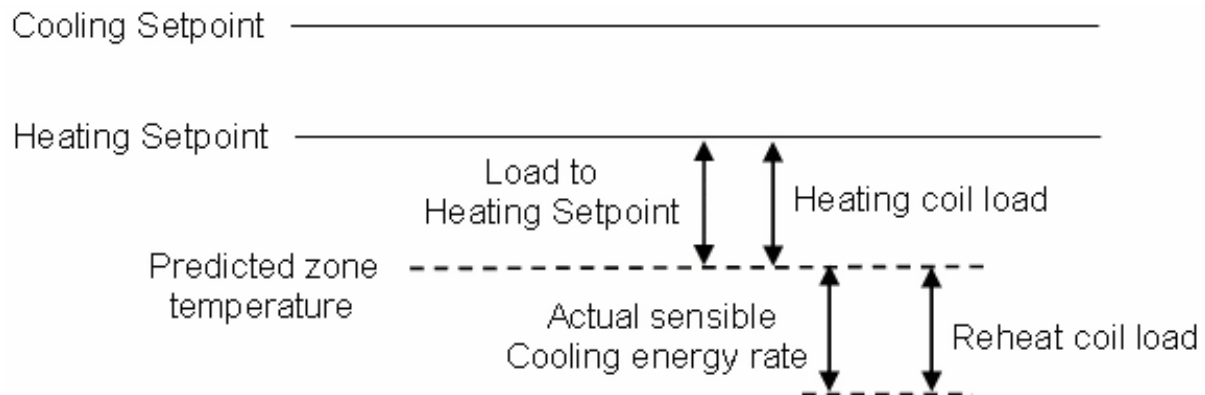

Figure 16.33: Reheat Coil Load when Predicted Zone Temperature is Below Heating Setpoint

16.5.3 Unitary Systems

The input objects AirLoopHVAC:UnitaryHeatCool and AirLoopHVAC:UnitaryHeatOnly provides models that are identical to the Furnace and Central Air models described above. Please reference the previous section for details.

16.5.4 Unitary System with Changeover-Bypass-Variable Air Volume

16.5.4.1 Overview

The input object `AirLoopHVAC:UnitaryHeatCool:VAVChangeoverBypass` provides a model for a changeover-bypass variable air volume (CBVAV) unitary system that is a compound object made up of other components. Each CBVAV system consists of an outside air mixer, direct expansion (DX) cooling coil, heating coil, and a supply air fan as shown in the figures below. Zone thermostats and terminal units are required in each zone served by this system. The terminal units are specific to this system type and are either `AirTerminal:SingleDuct:VAV:HeatAndCool:Reheat` or `AirTerminal:SingleDuct:VAV:HeatAndCool:NoReheat`. A zone humidistat and single zone max humidity setpoint manager may also be specified to help control high humidity levels. These individual components are described elsewhere in this document. The CBVAV unitary system object coordinates the operation of these components and is modeled as a type of air loop equipment (Ref. `AirLoopHVAC`).

Figure 16.34: Schematic of a Changeover Bypass VAV Unitary System with Draw Through Fan

The CBVAV unitary system conditions one or more zones and is controlled by thermostats located in each zone (the use of a single humidistat is also allowed when using multi-mode DX cooling coils). The CBVAV system operates to meet the zone sensible cooling or sensible heating requirements as dictated by the thermostat schedule(s). The priority control input determines the mode of operation and is specified as Cooling Priority, Heating Priority, or Zone Priority. If Cooling Priority is specified, the system operates to meet the cooling load when any zone served by this system (air loop) requires cooling. If Heating Priority is specified, the system operates to meet the heating load when any zone requires heating. If Zone Priority is specified, the system operates based on the maximum number of zones requiring either heating or cooling.

Once the operating mode is determined, the CBVAV model calculates a target supply air temperature required to operate a single terminal unit at its maximum air flow rate. The remaining

Figure 16.35: Schematic of Changeover Bypass VAV Unitary System with Blow Through Fan

terminal units will modulate as required to maintain the dry-bulb temperature in the zone they are serving according to the thermostat schedule for their respective zone. The system air flow rate (through the supply air fan, cooling coil and heat coil) remains constant during cooling operation, heating operation, and no cooling/heating mode as specified by the user. Therefore, as the zone terminal units modulate to reduce zone air flow rates, the excess system air flow is “bypassed” from the bypass duct splitter node back to the bypass duct mixer node of the CBVAV system (see figures above).

The CBVAV system is able to model supply air fan operation in two modes: cycling fan – cycling coil (i.e., AUTO fan) and continuous fan – cycling coil (i.e., fan ON). A Fan:OnOff or Fan:ConstantVolume is used in either case. Since the excess system air flow is bypassed while the zone terminal units modulate, the supply air fan operates the entire simulation time step when heating or cooling is required. For this reason, AUTO fan only allows the supply air fan to turn off when no cooling or heating is required. If fan ON is specified, the supply air fan runs the entire time the system is scheduled to operate (via its availability schedule). The mode of operation for the supply air fan is specified through a fan operating mode schedule where a value of 0 in the schedule indicates cycling fan mode and a value greater than 0 indicates continuous fan mode. If the schedule is not provided, the supply air fan operating mode is considered to be continuous (fan ON).

Output variables reported for the CBVAV system include the supply air fan part-load ratio, the compressor part-load ratio, and the electric consumption of the CBVAV system. Additional output variables report the total heating rate and total cooling rate provided by the CBVAV system. The sensible and latent components for total system cooling and heating are also available as output variables. Reporting of other variables of interest for the CBVAV system (DX coil cooling rate, heating rate, crankcase electric power and energy, supply air fan electric power, etc.) is done by

the individual system components (fan, DX cooling coil, and heating coil).

16.5.4.2 Model Description

As described previously, the CBVAV system conditions one or more zones and is controlled by zone thermostats (Ref. ZoneControl:Thermostat). For each simulation time step, EnergyPlus performs a zone air heat balance to determine if cooling or heating is required to meet the zone thermostat setpoints, excluding any impacts from CBVAV system operation. CBVAV system performance is then modeled with all heating/cooling coils off but with the supply air fan operating according to the user specified supply air fan operating mode schedule. If the zone air heat balance plus the impact of CBVAV system operation with coils off results in no requirement for heating or cooling by the CBVAV coils, or if the CBVAV system is scheduled off (via its availability schedule), then the CBVAV coils do not operate and the compressor part-load ratio output variable is set to 0. If the model determines that cooling or heating is required and the CBVAV system is scheduled to operate, the model calculates a target supply air temperature required to maintain a single terminal unit at its maximum air flow rate, the amount of bypass air returning to the bypass duct mixer node, and the part-load ratio of the cooling or heating coils in order to meet the target supply air temperature.

When high humidity control is desired, a ZoneControl:Humidistat input object and a Setpoint-Manager:SingleZone:Humidity:Maximum, SetpointManager:MultiZone:MaximumHumidity:Average or SetpointManager:MultiZone:Humidity:Maximum object are required. The air outlet node of the CBVAV system is used as the control node for the setpoint manager. For this reason, only a single humidistat should be specified for one of the zones being served by this system. If humidistat/setpoint manager objects are specified for more than one zone served by this system, only the last of the SetpointManager:SingleZone:Humidity:Maximum objects is used (the setpoint manager objects are read in order of occurrence in the input file). Since the outlet node of the CBVAV system is always used as the control node, the setpoints calculated by the previous setpoint managers are overwritten by the last setpoint manager in the input. When a heat exchanger is used to improve the dehumidification performance of the cooling coil (i.e. CoilSystem:Cooling:DX:HeatExchangerAssisted), the heat exchanger is always active and can not be turned on and off based on zone humidity levels.

The remainder of this section describes the calculations performed when cooling or heating coil operation is required. For any HVAC simulation time step, the CBVAV system can only cool or heat the air, not both. Because the CBVAV system bypasses system air flow back to the inlet of the CBVAV unit, the system operates for the entire simulation time step. If the user specifies continuous fan operation, then the supply air fan continues to operate at a user-specified flow rate even during periods when the coils cycle off. If the user specifies AUTO fan operation, then the supply air fan cycles off for the entire simulation time step only when no cooling or heating is required.

16.5.4.2.1 Operating Mode

The first step in modeling a CBVAV system is to obtain the cooling or heating load for each zone as calculated by EnergyPlus based on the zone thermostat setpoint temperature(s). The calculated loads for each zone are used to determine the total cooling and heating requirements for all zones served by this system. In addition to summing the zone cooling and heating loads, the number of zones in cooling and the number of zones in heating are totalized. The priority control mode

specified by the user is then used to determine the operating mode for this simulation time step.

If Cooling Priority is specified and the total cooling requirement in all zones is not equal to zero, then cooling is selected as the operating mode. If the total cooling requirement is equal to zero and the total heating requirement is not equal to zero, then heating is selected as the operating mode. If the total cooling requirement and total heating requirement are equal to zero then the zones are allowed to float (no heating or cooling provided).

If Heating Priority is specified and the total heating requirement in all zones is not equal to zero, then heating is selected as the operating mode. If the total heating requirement is equal to zero and the total cooling requirement is not equal to zero, then cooling is selected as the operating mode. If the total cooling requirement and total heating requirement are equal to zero then the zones are allowed to float (no heating or cooling provided).

If Zone Priority is specified and the total number of zones requiring cooling is greater than the total number of zones requiring heating, then cooling is selected as the operating mode. If the total number of zones requiring heating is greater than the total number of zones requiring cooling, then heating is selected as the operating mode. If the total number of zones requiring cooling is equal to the total number of zones requiring heating, then the magnitude of the total cooling and heating requirements for all zones sets the operating mode. In this case, if the magnitudes of the cooling and heating requirements are zero, then the zones are allowed to float (no heating or cooling provided). If the magnitudes of the cooling and heating requirements are non-zero and identical, then cooling is selected as the operating mode.

16.5.4.2.2 Calculation of Bypass Duct Mixer Node Conditions

The operation of this system is unique in that it uses constant-air-volume equipment to provide variable air volume to the conditioned zones. This is accomplished with the use of a bypass duct (shown in the figures above) which shunts excess system air flow from the bypass duct splitter node at the system's outlet back to the bypass duct mixer node at the system's inlet. The air conditions at the bypass duct mixer node are based on the inlet air to the CBVAV system, the system outlet air conditions required to meet the zone loads, and the fraction of bypassed air. The following calculations are performed each simulation time step.

$$BypassFrac = 1.0 - \left(\frac{\dot{m}_{supply}}{\dot{m}_{system}} \right) \quad (16.333)$$

$$T_{bypassductmixernode} = (1 - BypassFrac) T_{inlet} + (BypassFrac) T_{outlet} \quad (16.334)$$

$$\omega_{bypassductmixernode} = (1 - BypassFrac) \omega_{inlet} + (BypassFrac) \omega_{outlet} \quad (16.335)$$

$$h_{bypassductmixernode} = PsyHFnTdbW (T_{mixerinlet}, \omega_{mixerinlet}) \quad (16.336)$$

where:

$BypassFrac$ is the fraction of system air directed to the bypass duct mixer node

\dot{m}_{supply} is the air mass flow rate at the system's air outlet node (kg/s)

\dot{m}_{system} is the air mass flow rate through the CBVAV system including the coils and supply air fan (kg/s)

$T_{bypassductmixernode}$ is the air temperature at the bypass duct mixer node (°C)

T_{inlet} is the air inlet node temperature (°C)

T_{outlet} is the air outlet node temperature (°C)

$\omega_{bypassductmixernode}$ is the air humidity ratio at the bypass duct mixer node (kg/kg)

ω_{inlet} is the air inlet node humidity ratio (kg/kg)

ω_{outlet} is the air outlet node humidity ratio (kg/kg)

$h_{bypassductmixernode}$ is the air enthalpy at the bypass duct mixer node (J/kg)

$PsyHFnTdbW$ is an EnergyPlus psychrometric function calculating enthalpy given dry-bulb temperature and humidity ratio.

16.5.4.2.3 Cooling Operation

If the model determines that the CBVAV system must supply cooling to the zones, the model first calculates a target outlet air dry-bulb temperature required to operate a single terminal unit at its maximum air flow rate. The minimum target temperature for all zones is used to control the CBVAV system in cooling mode.

$$T_{target}^i = T_{Zone}^i + \frac{Q_{Zone}^i}{\dot{m}_{zone,max}^i C_p}; \quad i = 1, n \quad (16.337)$$

$$T_{target} = MIN(T_{target}^i); \quad i = 1, n \quad (16.338)$$

where:

T_{target}^i is the target supply air temperature for zone i (°C)

T_{zone}^i is the air temperature in zone i (°C)

Q_{zone}^i is the cooling or heating load for zone i where cooling loads are negative values and heating loads are positive values (W)

C_p is the specific heat of supply air with coils off (J/kg-K)

$\dot{m}_{zone,max}^i$ is the maximum terminal unit mass flow rate in zone i (kg/s)

T_{target} is the target supply (outlet) air temperature for the CBVAV system (°C).

The model then calculates the part-load ratio of the DX compressor required to meet the target supply (outlet) air temperature. Since the part-load performance of the DX cooling coil is frequently non-linear (Ref: Coil:Cooling:DX:SingleSpeed model), the actual part-load ratio for the cooling coil compressor is determined through iterative calculations (successive modeling of the DX cooling coil model) until the CBVAV system's outlet air temperature (including on/off cycling effects of the DX coil) matches the target supply (outlet) air temperature within a small temperature convergence tolerance (1E-5°C).

Since the supply air fan operates continuously for each simulation time step (or is OFF for the entire HVAC system time step), the air conditions at nodes downstream of the cooling coil are calculated as the average conditions over the simulation time step (i.e., the weighted average of coil's outlet node conditions when the coil is operating and the coil's inlet node conditions when the coil is OFF).

16.5.4.2.4 Heating Operation

Modeling the CBVAV system's DX heating coil is identical to the calculations described above for cooling operation except that the maximum target supply air temperature for all zones is used to control the CBVAV system in heating mode.

$$T_{target} = MAX(T_{target}^i); \quad i = 1, n \quad (16.339)$$

Iterative calculations (successive modeling of the DX heating coil model) are used to determine the final heating coil part-load ratio to account for the non-linear performance of the DX heating coil at part-load conditions.

When a gas or electric heating coil is used instead of a DX heating coil, the amount of heat required by the coil is calculated based on the target supply (outlet) air temperature and the coil inlet air temperature as follows:

$$Q_{heating} = \dot{m}_{system} C_p (T_{target} - T_{inlet,heatcoil}) \quad (16.340)$$

where:

$Q_{heating}$ is the heating coil load (W)

C_p is the specific heat of heating coil inlet air (J/kg-K)

$T_{inlet,heatcoil}$ is the heating coil inlet air temperature (°C).

16.5.4.2.5 Floating Operation (no cooling or heating)

When the zone thermostats determine that there is no cooling or heating requirement in any zone, the CBVAV coils are OFF and the zone temperatures are allowed to float. However, a special case exists where the user specifies continuous supply air fan operation and no cooling or heating requirements exist in any zone. In this case, the outlet air temperature of the CBVAV system (with fan ON and coils OFF) is compared to the target outlet air temperatures required to maintain the zone's cooling and heating setpoint temperatures. If the outlet air temperature with the supply fan ON and coils OFF is below the target outlet air temperature required to maintain the heating setpoint, then heating mode is enabled to avoid overshooting the zone heating setpoint temperature. Conversely, if the outlet air temperature with the supply fan ON and coils OFF is above the target outlet air temperature required to maintain the cooling setpoint, then cooling mode is enabled to avoid overshooting the zone cooling setpoint temperature. This special case is handled at any time a no load condition is reported by the thermostats and overshooting the zone air temperature setpoint is possible regardless of the priority control mode selected by the user.

16.5.4.2.6 Minimum and Maximum Outlet Air Temperature in Cooling/Heating Operation

The user also specifies a minimum outlet air temperature during cooling operation and a maximum outlet air temperature during heating operation. The target outlet air temperature, as calculated above, is compared to each of these limits during each simulation time step. The resulting target outlet air temperature is used to control the heating and cooling coils.

$$T_{target} = MAX(T_{target}, T_{min,cooling}) \quad (16.341)$$

$$T_{target} = MIN(T_{target}, T_{max,heating}) \quad (16.342)$$

where:

$T_{min,cooling}$ is the minimum outlet air temperature during cooling operation (°C)

$T_{max,heating}$ is the maximum outlet air temperature during heating operation (°C).

16.5.4.2.7 Air Flow Calculations

The changeover-bypass VAV system operates based on user-specified (or autosized) air flow rates. The CBVAV system air flow rate (i.e., air flow through the supply air fan and heating/cooling coils) during cooling operation may be different than the system air flow rate during heating operation. In addition, the system air flow rate when no cooling or heating is required but the supply air fan remains ON can be different than the air flow rates when cooling or heating is required. The outside air flow rates can likewise be different in these various operating modes. The model takes these different air flow rates into account when simulating the performance of the CBVAV system. The system air flow rate for each simulation time step is based on the current operating mode (cooling, heating, or no cooling/heating) and is reported on the inlet/outlet air nodes of the various CBVAV components (e.g. fan, cooling coil, and heating coil). The supply air flow rate delivered to the individual zones is calculated based on the sum of the air flow rates through each terminal unit and is reported at the air inlet and outlet nodes of the CBVAV system each simulation time step. The difference between the system air mass flow rate and the supply air mass flow rate delivered to all zones is equal to the bypass air mass flow rate which is also reported each simulation time step.

The system and outside air flow rates when a system coil is ON (e.g., system air volumetric flow rate during cooling operation, system air volumetric flow rate during heating operation, outside air volumetric air flow rate during cooling operation, and outside air volumetric air flow rate during heating operation) or the system coils are OFF and the fan operates continuously (e.g., system air volumetric flow rate when no cooling or heating is needed and outside air volumetric air flow rate when no cooling or heating is needed) are specified by the user, or can be autosized, and are converted from volumetric flow rate to mass flow rate at standard conditions. If the user has specified cycling fan operation, then the system air and outside air mass flow rates when the system coils are OFF the entire time step are zero. If the user has specified constant fan operation, then the air flow rates when no cooling or heating is needed are used when the system coils are OFF the entire time step.

There is one special case. If the user has specified constant fan operation and they specify that the system air volumetric flow rate when no cooling or heating is needed is zero (or if the field is left blank), then the model assumes that the system air mass flow rate when the system coils are OFF the entire time step is equal to the corresponding air mass flow rate when any system coil was last operating (ON). This model handles the zero (or blank) entry for outside air volumetric flow rate when no cooling or heating is needed in an analogous fashion.

$$\dot{m}_{system} = \rho_{air,std} * \dot{V}_{mode} \quad (16.343)$$

$$\dot{m}_{system,OA} = \rho_{air,std} * \dot{V}_{mode,OA} \quad (16.344)$$

$$\dot{m}_{supply} = \sum_{i=1}^n \dot{m}_{zone} \quad (16.345)$$

$$\dot{m}_{bypass} = \dot{m}_{system} - \dot{m}_{supply} \quad (16.346)$$

where:

$\rho_{air,std}$ is the standard air density (1.204 kg/m³) adjusted for the local barometric pressure (standard barometric pressure corrected for altitude, ASHRAE 1997 HOF pg. 6.1)

\dot{V}_{mode} is the user-specified system volumetric flow rate in cooling, heating, or no cooling or heating mode (m^3/s)

$\dot{m}_{system,OA}$ is the outdoor air mass flow rate introduced through the CBVAV system (kg/s)

$\dot{V}_{mode,OA}$ is the user-specified outdoor air volumetric flow rate in cooling, heating, or no cooling or heating mode (m^3/s).

16.5.4.2.8 Calculation of System Heating and Cooling Rates

At the end of each HVAC simulation time step, this object reports the heating or cooling rate and energy delivered by the system, as well as the electric power and consumption by the system. In terms of thermal energy delivered by the system, the sensible, latent and total energy transfer rates for the system are calculated as follows:

$$\dot{Q}_{total} = (\dot{m}_{supply})(h_{outlet} - h_{inlet}) \quad (16.347)$$

$$\dot{Q}_{sensible} = (\dot{m}_{supply})(h_{outlet} - h_{inlet})_{HRmin} \quad (16.348)$$

$$\dot{Q}_{latent} = \dot{Q}_{total} - \dot{Q}_{sensible} \quad (16.349)$$

where:

\dot{Q}_{total} is the total energy transfer rate by the system (W)

$\dot{Q}_{sensible}$ is the sensible energy transfer rate by the system (W)

\dot{Q}_{latent} is the latent energy transfer rate by the system (W)

h_{inlet} is the enthalpy of the air entering the unit at its inlet node (J/kg)

h_{outlet} is the enthalpy of the air leaving the unit at its outlet node (J/kg)

HR_{min} is the minimum of the inlet air and outlet air humidity ratio (kg/kg).

Since each of these energy transfer rates can be calculated as positive or negative values, individual reporting variables are established for cooling and heating and only positive values are reported. The following calculations are representative of what is done for each of the energy transfer rates:

If $\dot{Q}_{total} < 0$, then:

$$\begin{aligned} \dot{Q}_{total,cooling} &= |\dot{Q}_{total}| \\ \dot{Q}_{total,heating} &= 0 \end{aligned} \quad (16.350)$$

Else:

$$\begin{aligned} \dot{Q}_{total,cooling} &= 0.0 \\ \dot{Q}_{total,heating} &= \dot{Q}_{total} \end{aligned} \quad (16.351)$$

where:

$\dot{Q}_{total,cooling}$ is the output variable ‘Unitary System Total Cooling Rate, W’

$\dot{Q}_{total,heating}$ is the output variable ‘Unitary System Total Heating Rate, W’.

In addition to heating and cooling rates, the heating and cooling energy supplied by the system are also calculated for the time step being reported. The following example for total zone cooling energy is representative of what is done for the sensible and latent energy as well as the heating counterparts.

$$Q_{total,cooling} = \dot{Q}_{total,cooling} * TimeStepSys * 3600 \quad (16.352)$$

where:

$Q_{total,cooling}$ is the output variable ‘Unitary System Total Cooling Energy, J’

$TimeStepSys$ is the HVAC system simulation time step (hr)

3600 is a conversion factor (sec/hr).

16.5.4.3 Changeover-bypass VAV Unitary System Sizing

The changeover-bypass VAV system is modeled as an air loop component and is sized according to the methodology described elsewhere in this document (Ref. System Design Loads and Air Flow Rates). The following volumetric air flow rates may be autosized:

- System air volumetric flow rate during cooling operation
- System air volumetric flow rate during heating operation
- System air volumetric flow rate when no cooling or heating is needed
- Outside air volumetric air flow rate during cooling operation
- Outside air volumetric air flow rate during heating operation
- Outside air volumetric air flow rate when no cooling or heating is needed

16.5.5 Unitary Air-To-Air Heat Pump

16.5.5.1 Overview

The input object `AirLoopHVAC:UnitaryHeatPump:AirToAir` provides a model for an air-to-air heat pump that is a “virtual” component that consists of an on/off or constant volume fan component, a DX cooling coil, a DX heating coil, and a gas or electric supplemental heating coil. The specific configuration of the blow through heat pump is shown in the following figure. For a draw through heat pump, the fan is located between the DX heating coil and the supplemental heating coil.

While the heat pump may be configured to serve multiple zones, system operation is controlled by a thermostat located in a single “control” zone. One of the key parameters for the heat pump component is the fraction of the total system airflow that goes through the control zone. This fraction is calculated as the ratio of the maximum air mass flow rate for the air loop’s supply inlet node for the control zone (e.g., `AirTerminal:SingleDuct:ConstantVolume:NoReheat`, field = Maximum Air Flow Rate, converted to mass flow) to the sum of the maximum air mass flow rates for the air loop’s supply inlet nodes for all zones served by this air loop. The heat pump module scales the calculated load for the control zone upward based on this fraction to determine the total load to be met by the heat pump. The module then proceeds to calculate the required part-load ratio for the system coil and the supply air fan to meet this total load. The heating or cooling capacity delivered by the heat pump is distributed to all of the zones served by this system via the direct air units that supply air to each zone. The supply air fraction that goes through the control zone is calculated as follows:

Figure 16.36: Schematic of a Blow Through Air-to-Air Heat Pump

$$\text{Control Zone Air Flow Fraction} = \frac{\dot{m}_{TUMax \text{ ControlZone}}}{\sum_{j=1}^{NumOfZones} \dot{m}_{TUMax \text{ Zone } j}} \quad (16.353)$$

where:

$\dot{m}_{TUMax \text{ ControlledZone}}$ is the maximum air mass flow rate for the air loop's supply inlet node (terminal unit) for the control zone (kg/s)

$\dot{m}_{TUMax \text{ Zone } j}$ is the maximum air mass flow rate for the air loop's supply inlet node for the jth zone (kg/s)

$NumOfZones$ is the number of zones, or number of air loop supply air inlet nodes for all zones served by the air loop.

The heat pump component is able to model supply air fan operation in two modes: cycling fan – cycling coil (i.e., AUTO fan) and continuous fan – cycling coil (i.e., fan ON). Fan:OnOff must be used to model AUTO fan, while Fan:OnOff or Fan:ConstantVolume can be used to model fan ON. The fan operation mode is specified using a supply air fan operating mode schedule where schedule values of 0 denote cycling fan operation and schedule values other than 0 (a 1 is usually used) denote continuous fan operation. Using this schedule, the furnace fan may be cycled with cooling or heating coil operation or operated continuously based on time of day (e.g. cycling fan operation at night and continuous fan operation during the day). If the fan operating mode schedule name field is left blank in the heat pump object, the heat pump assumes cycling or AUTO fan mode operation throughout the simulation.

The output variables reported by the heat pump object are fan part-load ratio and compressor part-load ratio. Fan part-load ratio is defined as the actual air mass flow rate through the system for the time step divided by the operating supply air mass flow rate specified for the heat pump ($\dot{m}_{actual}/\dot{m}_{ON}$). The operating supply air mass flow rate may be different for cooling, heating, and when no cooling or heating is required and the fan operates continuously. Compressor part-load ratio is the actual load for the time step divided by the full-load sensible capacity (see Equation 16.359 or 16.367). Reporting of other variables of interest for the heat pump (heating rate, cooling rate, energy consumption, etc.) is done by the individual system components (fan, DX cooling coil, DX heating coil, and supplemental heating coil).

16.5.5.2 Model Description

As described previously, the heat pump is a “virtual” component consisting of a fan, DX cooling coil, DX heating coil and a supplemental heating coil. The sole purpose of the heat pump model is to properly coordinate the operation of the various system components. The following sections describe the flow of information within the model, as well as the differences between cycling and continuous supply air fan operation.

16.5.5.3 Cooling Operation

If EnergyPlus determines that the heat pump must supply cooling to the control zone to meet the zone air temperature setpoint, then the heat pump model computes the total sensible cooling load to be delivered to the zones being served based on the control zone sensible cooling load and the fraction of the heat pump air flow that goes through the control zone.

$$\text{Heat Pump Cooling Load} = \frac{\text{Control Zone Cooling Load}}{\text{Control Zone Air Flow Fraction}} \quad (16.354)$$

If the supply air fan operating mode schedule requests cycling fan operation, the model first checks for the presence of an economizer in the outside air system serving the heat pump's air loop (Ref. AirLoopHVAC:OutdoorAirSystem). If an outside air system is not present or if an air-side economizer is not used, the heat pump's compressor is used to meet the heat pump cooling load. If an air-side economizer is used and is active (i.e., economizer controls indicate that conditions are favorable to increase the outside air flow rate), the heat pump will try to meet the cooling load by operating only the supply air fan. If the fan is able to satisfy the heat pump cooling load, the compressor remains off for the entire simulation time step. If the operation of the fan alone is unable to meet the entire cooling load, then the compressor is enabled and additional calculations are performed to determine the compressor's part-load ratio.

The model then calculates the heat pump's sensible cooling energy rate delivered to the zones being served when the system runs at full-load conditions and when the DX cooling coil is OFF. If the supply air fan cycles with the compressor, then the sensible cooling energy rate is zero when the cooling coil is OFF. However if the fan is scheduled to run continuously regardless of coil operation, then the sensible cooling energy rate will not be zero when the cooling coil is OFF. Calculating the sensible cooling energy rate involves modeling the supply air fan (and associated fan heat) and the DX cooling coil. The DX heating coil and the supplemental heating coil are also modeled, but only to pass the air properties and mass flow rate from their inlet nodes to their outlet nodes. For each of these cases (full load and DX cooling coil OFF), the sensible cooling energy rate delivered by the heat pump is calculated as follows:

$$\text{Full Cool Output} = (\text{Mass Flow Rate}_{\text{full load}})(h_{\text{out,full load}} - h_{\text{control zone}})_{HRmin} - \Delta_{\text{sen,full load}} \quad (16.355)$$

$$\text{No Cool Output} = (\text{Mass Flow Rate}_{\text{coil off}})(h_{\text{out,coil off}} - h_{\text{control zone}})_{HRmin} - \Delta_{\text{sen,coil off}} \quad (16.356)$$

where:

$\text{Mass Flow Rate}_{\text{full load}}$ is the air mass flow rate through heat pump at full-load conditions, (kg/s)

$h_{\text{out,full load}}$ is the enthalpy of air exiting the heat pump at full-load conditions (J/kg)

$h_{\text{control zone}}$ is the enthalpy of air leaving the control zone where the thermostat is located (J/kg)

HR_{min} are the enthalpies evaluated at a constant humidity ratio, the minimum humidity ratio of the heat pump exiting air or the air leaving the control zone

$\text{Mass Flow Rate}_{\text{coil off}}$ is the air mass flow rate through the heat pump with the cooling coil OFF (kg/s)

$h_{\text{out,coil off}}$ is the enthalpy of air exiting the heat pump with the cooling coil OFF (J/kg)

$\Delta_{\text{sen,full load}}$ is the sensible load difference between the system output node and the zone inlet node at full-load conditions.

$$\begin{aligned} \Delta_{\text{sen,full load}} &= \frac{\dot{m}_{\text{Zone Inlet}}}{\text{Frac}} (h_{\text{Out,full load}} - h_{\text{Zone Inlet}})_{HRmin} \\ &+ (\dot{m}_{\text{full load}} - \frac{\dot{m}_{\text{Zone Inlet}}}{\text{Frac}}) (h_{\text{Out,full load}} - h_{\text{Control Zone}})_{HRmin} \end{aligned} \quad (16.357)$$

where:

Frac is the control zone air fraction with respect to the system mass flow rate

$\Delta_{sen,coil\ off}$ is the sensible load difference between the system output node and the zone inlet node with the heating coil OFF conditions.

$$\begin{aligned} \Delta_{sen,coil\ off} = & \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,coil\ off} - h_{Zone\ Inlet})_{HRmin} \\ & + \left(\dot{m}_{coil\ off} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,coil\ off} - h_{Control\ Zone})_{HRmin} \end{aligned} \quad (16.358)$$

With the calculated sensible cooling energy rates and the total sensible cooling load to be met by the system, the part-load ratio for the heat pump is estimated.

$$PartLoadRatio = MAX \left(0.0, \frac{ABS(Heat\ Pump\ Cooling\ Load - NoCoolOutput)}{ABS(FullCoolOutput - NoCoolOutput)} \right) \quad (16.359)$$

Since the part-load performance of the DX cooling coil is frequently non-linear, and the supply air fan heat varies based on cooling coil operation for the case of cycling fan/cycling coil (AUTO fan), the final part-load ratio for the cooling coil compressor and fan are determined through iterative calculations (successive modeling of the cooling coil and fan) until the heat pump's cooling output matches the cooling load to be met within the convergence tolerance. The convergence tolerance is fixed at 0.001 and is calculated based on the difference between the load to be met and the heat pump's cooling output divided by the load to be met.

$$Tolerance \equiv \frac{HeatPumpCoolingLoad - Q_{HeatPump}}{HeatPumpCoolingLoad} \leq 0.001 \quad (16.360)$$

where $Q_{HeatPump}$ is the heat pump delivered sensible capacity (W).

If the heat pump has been specified with cycling fan/cycling coil (AUTO fan), then the heat pump's operating supply air mass flow rate is multiplied by PartLoadRatio to determine the average air mass flow rate for the system simulation time step. In this case, the air conditions at nodes downstream of the cooling coil represent the full-load (steady-state) values when the coil is operating.

If the fan operates continuously (i.e., when the supply air fan operating mode schedule values are NOT equal to 0), the operating air mass flow rate through the heat pump is calculated as the average of the user-specified air flow rate when the cooling coil is ON and the user-specified air flow rate when the cooling coil is OFF (user-specified supply air volumetric flow rates converted to dry air mass flow rates).

$$\dot{m}_{furnace} = PartLoadRatio (\dot{m}_{CoolCoilON}) + (1 - PartLoadRatio) (\dot{m}_{CoilOFF}) \quad (16.361)$$

where:

$\dot{m}_{CoolCoilON}$ is the air mass flow rate through heat pump when the cooling coil is ON (kg/s)

$\dot{m}_{CoilOFF}$ is the air mass flow rate through heat pump when no cooling or heating is needed (kg/s).

In this case, the air conditions at nodes downstream of the cooling coil are calculated as the average conditions over the simulation time step (i.e., the weighted average of full-load conditions when the coil is operating and inlet air conditions when the coil is OFF).

Heating Operation

Calculations for heating operation are similar to those for cooling operation in most respects. However, due to the inclusion of a supplemental heating coil, additional calculations are necessary to properly meet the total heating load for the zones being served.

If EnergyPlus determines that the heat pump must supply heating to the control zone to meet the zone air temperature setpoint, then the heat pump model computes the total sensible heating load to be delivered to the zones being served based on the control zone sensible heating load and the control zone airflow fraction.

$$\text{Heat Pump Heating Load} = \frac{\text{Control Zone Heating Load}}{\text{Control Zone Air Flow Fraction}} \quad (16.362)$$

The model then calculates the heat pump's sensible heating energy rate delivered to the zones being served when the system runs at full-load conditions and when the DX heating coil is OFF (without supplemental heater operation in either case). If the supply air fan cycles with the compressor, then the sensible heating energy rate is zero when the compressor is OFF. However if the fan is scheduled to run continuously regardless of coil operation, then the sensible heating energy rate will not be zero when the compressor is OFF. Calculating the sensible heating energy rate involves modeling the supply air fan (and associated fan heat), the DX cooling coil (simply to pass the air properties and mass flow rate from its inlet node to its outlet node), the DX heating coil, and the supplemental heating coil (simply to pass the air properties and mass flow rate from its inlet node to its outlet node). For each of these cases (full load and DX heating coil OFF, without supplemental heater operation in either case), the sensible heating energy rate delivered by the heat pump is calculated as follows:

$$\text{Full Heat Output} = (\dot{m}_{full\ load})(h_{out,full\ load} - h_{control\ zone})_{HRmin} - \Delta_{sen,full\ load} \quad (16.363)$$

$$\text{No Heat Output} = (\dot{m}_{coil\ off})(h_{out,coil\ off} - h_{control\ zone})_{HRmin} - \Delta_{sen,coil\ off} \quad (16.364)$$

where:

$\dot{m}_{full\ load}$ is the air mass flow rate through heat pump at full-load conditions (kg/s)

$h_{out,full\ load}$ is the enthalpy of air exiting the heat pump at full-load conditions (J/kg)

$h_{control\ zone}$ is the enthalpy of air leaving the control zone (where thermostat is located) (J/kg)

HR_{min} are the enthalpies evaluated at a constant humidity ratio, the minimum humidity ratio of the heat pump exiting air or the air leaving the control zone

$\dot{m}_{coil\ off}$ is the air mass flow rate through the heat pump with the heating coil OFF (kg/s)

$h_{out,coil\ off}$ is the enthalpy of air exiting the heat pump with the heating coil OFF (J/kg)

$\Delta_{sen,full\ load}$ is the sensible load difference between the system output node and the zone inlet node at full-load conditions.

$$\begin{aligned} \Delta_{sen,full\ load} &= \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,full\ load} - h_{Zone\ Inlet})_{HRmin} \\ &+ (\dot{m}_{full\ load} - \frac{\dot{m}_{Zone\ Inlet}}{Frac}) (h_{Out,full\ load} - h_{Control\ Zone})_{HRmin} \end{aligned} \quad (16.365)$$

where:

Frac is the control zone air fraction with respect to the system mass flow rate

$\Delta_{sen,coil\ off}$ is the sensible load difference between the system output node and the zone inlet node with the heating coil OFF conditions.

$$\begin{aligned} \Delta_{sen,coil\ off} &= \frac{\dot{m}_{ZoneInlet}}{Frac} (h_{Out,coil\ off} - h_{ZoneInlet})_{HRmin} \\ &+ \left(\dot{m}_{coil\ off} - \frac{\dot{m}_{ZoneInlet}}{Frac} \right) (h_{Out,coil\ off} - h_{ControlZone})_{HRmin} \end{aligned} \quad (16.366)$$

With the calculated sensible heating energy rates and the total sensible heating load to be met by the system, the part-load ratio for the heat pump is estimated.

$$PartLoadRatio = MAX \left(0.0, \frac{ABS(Heat\ Pump\ Heating\ Load - NoHeatOutput)}{ABS(FullHeatOutput - NoHeatOutput)} \right) \quad (16.367)$$

Since the part-load performance of the DX heating coil is frequently non-linear (Ref: Single-Speed Electric Heat Pump DX Air Heating Coil), and the supply air fan heat varies based on heating coil operation for the case of cycling fan/cycling coil (AUTO fan), the final part-load ratio for the heating coil compressor and fan are determined through iterative calculations (successive modeling of the heating coil and fan) until the heat pump's heating output matches the heating load to be met within the convergence tolerance. The convergence tolerance is fixed at 0.001 and is calculated based on the difference between the load to be met and the heat pump's heating output divided by the load to be met.

$$Tolerance \equiv \frac{HeatPumpHeatingLoad - Q_{HeatPump}}{HeatPumpHeatingLoad} \leq 0.001 \quad (16.368)$$

where $Q_{HeatPump}$ is the heat pump delivered sensible capacity (W).

If the heat pump's DX heating coil output at full load is insufficient to meet the entire heating load, PartLoadRatio is set equal to 1.0 (compressor and fan are not cycling) and the remaining heating load is passed to the supplemental heating coil. If the heat pump model determines that the outdoor air temperature is below the minimum outdoor air temperature for compressor operation, the compressor is turned off and the entire heating load is passed to the supplemental gas or electric heating coil. The heat pump exiting air conditions and energy consumption are calculated and reported by the individual component models (fan, DX heating coil, and supplemental gas or electric heating coil).

If the heat pump has been specified with cycling fan/cycling coil (AUTO fan), then the heat pump's operating supply air mass flow rate is multiplied by PartLoadRatio to determine the average air mass flow rate for the system simulation time step. The air conditions at nodes downstream of the heating coils represent the full-load (steady-state) values when the coils are operating. If the fan operates continuously (i.e., when the supply air fan operating mode schedule values are NOT equal to 0), the operating air mass flow rate through the heat pump is calculated as the average of the user-specified air flow rate when the heat pump heating coil is ON and the user-specified air flow rate when the heat pump heating coil is OFF (user-specified supply air volumetric flow rates converted to dry air mass flow rates).

$$\dot{m}_{HeatPump} = PartLoadRatio (\dot{m}_{HeatCoilON}) + (1 - PartLoadRatio) (\dot{m}_{CoilOFF}) \quad (16.369)$$

where:

$\dot{m}_{HeatCoilON}$ is the air mass flow rate through heat pump when the heating coil is ON (kg/s)

$\dot{m}_{CoilOFF}$ is the air mass flow rate through heat pump when no heating or cooling is needed (kg/s).

In this case, the air conditions at nodes downstream of the heating coils are calculated as the average conditions over the simulation time step (i.e., the weighted average of full-load conditions when the coils are operating and inlet air conditions when the coils are OFF).

16.5.5.4 High Humidity Control with AirToAir HeatPump Model

The specific configuration of the AirToAir HeatPump with supplemental heating coil is shown above (see Figure 16.36). This figure shows the fan placement when a blow through fan is specified. If a draw through fan is specified, the fan is located between the heating coil and the supplemental heating coil. The system is controlled to keep the high relative humidity in the control zone from exceeding the setpoint specified in the object ZoneControl:Humidistat. This option is available when the supply air fan operates continuously (i.e., the supply air fan operating mode schedule values are never equal to 0) or the supply air fan cycles with the compressor. In addition, when high humidity control is specified and the compressor operates, the heatpump operates at the cooling air flow rate when a zone heating load is present as determined by the zone thermostat. High humidity control is specified as either None, MultiMode, or CoolReheat in the Dehumidification Control Type input field. MultiMode is specified when a heat exchanger is used to improve the dehumidification performance of the cooling coil. The heat exchanger will be activated when the sensible part-load ratio is insufficient to meet the zone latent load. CoolReheat is specified when a DX cooling coil is used to over-cool the supply air stream in order to meet the zone latent load. In this case, a supplemental heating coil will ensure the zone temperature does not fall below the zone heating temperature set point. When a heat exchanger is used in conjunction with a DX cooling coil and CoolReheat is specified as the Dehumidification Control Type, the heat exchanger is “locked on” to meet either the sensible or latent cooling load. If the dehumidification control type is selected as None and a heat exchanger assisted cooling coil is used, the heat exchanger is “locked on” and the air conditioner runs only to meet the sensible cooling load. A supplemental heating coil is required for all dehumidification control types.

The model first calculates the *PartLoadRatio* required meeting the sensible cooling load. The heatpump’s sensible cooling load is determined from the control zone sensible cooling load to the cooling setpoint and the control zone air flow fraction to maintain the dry-bulb temperature setpoint in the control zone:

$$HeatPumpCoolingLoad = \frac{ControlZoneCoolingLoad}{ControlZoneAirFlowFraction} \quad (16.370)$$

The heatpump’s sensible cooling load to be met and the full load cooling output are used to calculate the sensible the part-load ratio iteratively based on user specified convergence criterion.

$$PartLoadRatio = MAX \left(0.0, \frac{ABS(HeatPumpCoolingLoad - NoCoolOutput)}{ABS(FullCoolOutput - NoCoolOutput)} \right) \quad (16.371)$$

When the heat pump’s sensible cooling capacity meets the system sensible cooling load at a given sensible part load ratio, then the Heat pump meets the controlled zone cooling setpoint temperature. If a moisture (latent) load exists because the control zone humidity has exceeded the setpoint, the total moisture load to be met by the heat pumps (HeatPumpMoistureLoad) is calculated based on the control zone moisture load and the control zone air flow fraction.

$$\text{HeatPumpMoistureLoad} = \frac{\text{ControlZoneMoistureLoad}}{\text{ControlZoneAirFlowFraction}} \quad (16.372)$$

Then, the *LatentPartLoadRatio* required to meet the high humidity setpoint is calculated as follows:

$$\text{LatentPartLoadRatio} = \text{MIN} \left(\text{PLR}_{\text{Min}}, \frac{\text{ABS}(\text{HeatPumpMoistureLoad} - \text{NoLatentOutput})}{\text{ABS}(\text{FullLatentOutput} - \text{NoLatentOutput})} \right) \quad (16.373)$$

The model uses the greater of the two part-load ratios, *PartLoadRatio* or *LatentPartLoadRatio*, to determine the operating part-load ratio of the Heat Pump's DX cooling coil.

$$\text{LatentPartLoadRatio} = \text{MAX}(\text{PartLoadRatio}, \text{LatentPartLoadRatio}) \quad (16.374)$$

As previously described, iterations are performed to converge on the solution within the convergence tolerance.

In the above equations, the following definitions apply:

ControlZoneCoolingLoad is the control zone sensible cooling load to the cooling setpoint (W)

ControlZoneMoistureLoad is the control zone moisture load to the dehumidifying relative humidity setpoint (W)

ControlZoneAirFlowFraction is the supply air fraction that goes through the control zone

FullLatentOutput is the Heat Pump's latent cooling energy rate at full-load conditions (W)

NoLatentOutput is the Heat Pump's latent cooling energy rate with cooling coil OFF (W)

PartLoadRatio is the heat pump's part-load-ratio required to meet system sensible load

LatentPartLoadRatio is the heat pump's part-load-ratio required to meet system moisture load

PLR_{MIN} is the minimum part-load ratio, which is usually 0.0. For the case when the latent capacity degradation model is used (Ref: DX Cooling Coil Model), this value is the minimum part-load ratio at which the cooling coil will dehumidify the air.

When the predicted zone air temperature is above the heating setpoint and if there is a dehumidification load, the supplemental heating coil load is required to offset the excess cooling as shown in Figure 16.37. If the model determines that the *LatentPartLoadRatio* is to be used as the operating part-load ratio of the heatpump's cooling coil, the supplemental heating coil is used to offset the excess sensible capacity provided by the heat pump DX cooling coil. The model first checks the sensible load that exists for the current simulation time step (predicted zone temperature with no HVAC operation compared to the thermostat setpoint temperatures). If a sensible cooling load or no sensible cooling or heating load exists (see Figure 1.2), the model calculates the difference between the sensible heating load required to reach or maintain the heating dry-bulb temperature setpoint and the actual sensible cooling energy rate delivered by the unit (with *LatentPartLoadRatio*). In this case, the supplemental heating coil is used to offset the excess sensible cooling energy provided by the DX cooling coil (if any) that could have caused an overshoot of the heating dry-bulb temperature setpoint. Note that when a humidistat is used and high humidity control is required, the zone dry-bulb temperature will typically move toward the heating temperature setpoint when a high moisture (latent) load exists.

If a heating load exists (Figure 16.38), the supplemental heating coil is used to meet the heating coil load and at the same time offset the entire sensible cooling energy rate of the DX cooling coil (to meet the humidistat setpoint). Note that when a heating load exists and high humidity control is

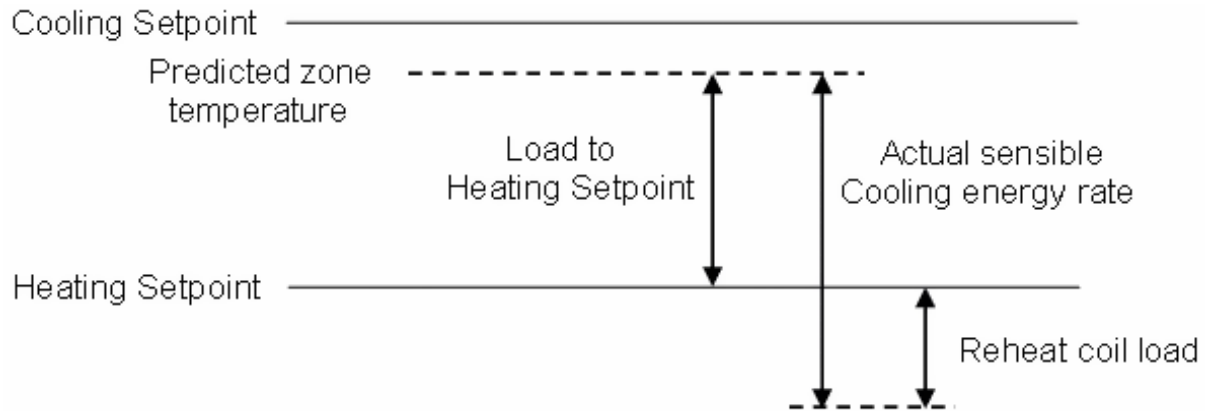

Figure 16.37: Supplemental heating coil load when predicted zone air temperature is above the heating Setpoint

required, the heat pump operates at the user-specified cooling air flow rate for the entire simulation time step. As with the fan, and DX cooling coil, report variables associated with supplemental heating coil performance (e.g., heating coil energy, heating coil rate, heating coil gas or electric energy, heating coil runtime fraction, etc.) are managed in the supplemental (heating) coil object.

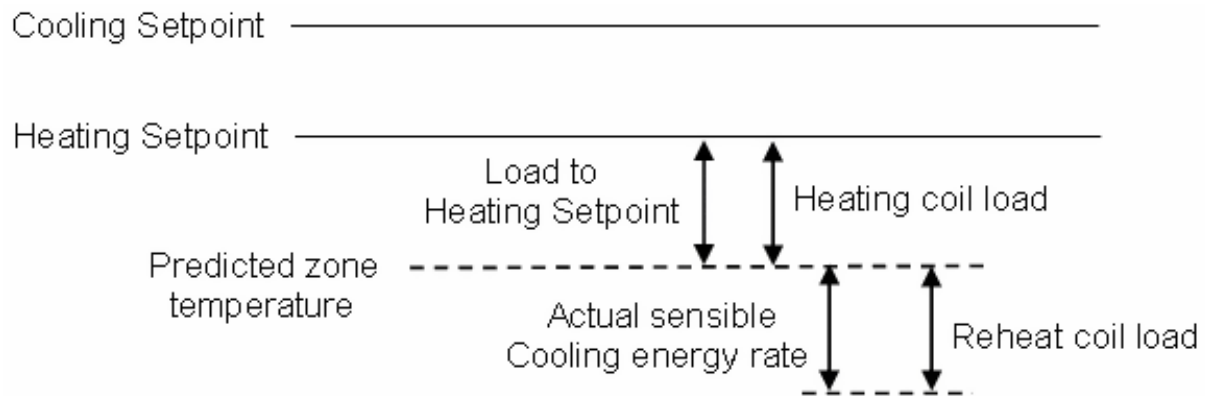

Figure 16.38: Supplemental heating coil load when predicted zone air temperature is below the heating setpoint

16.5.6 Unitary Multi-Speed Air-To-Air Heat Pump

16.5.6.1 Overview

The input object `AirLoopHVAC:UnitaryHeatPump:AirToAir:MultiSpeed` provides a model for a multispeed air-to-air heat pump that is a “virtual” component that consists of an on/off or constant volume fan component, a multispeed DX cooling coil, a multispeed DX heating coil, and a gas or electric supplemental heating coil. The main difference between this heat pump object and other EnergyPlus heat pump objects is that this object allows from two to four discrete compressor speeds for heating and cooling operation (instead of a single speed for each mode). The specific configuration of the blow through heat pump is shown in the following figure. For a draw through heat pump, the fan is located between the DX heating coil and the supplemental heating coil.

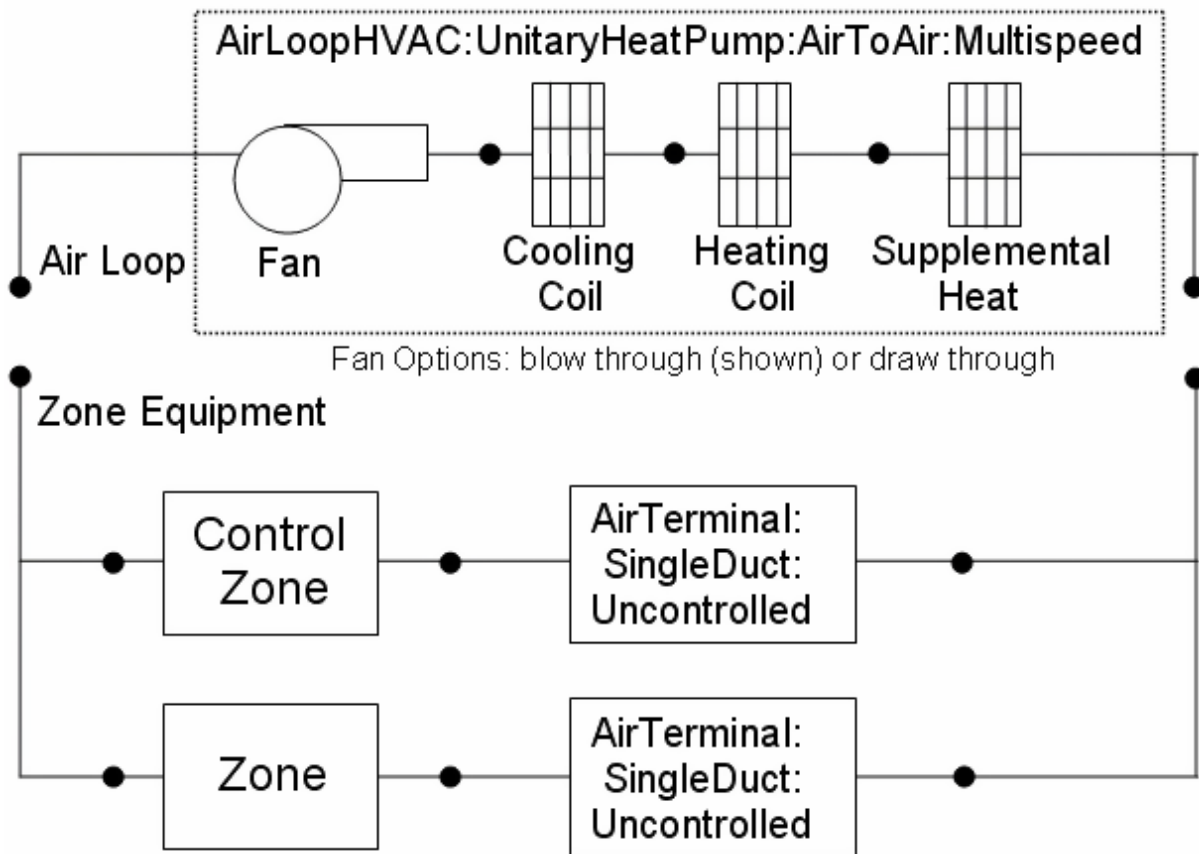

Figure 16.39: Schematic of a Multispeed Air-to-Air Heat Pump (Blow-through Configuration)

While the heat pump may be configured to serve multiple zones, system operation is controlled by a thermostat located in a single “control” zone. One of the key parameters for the heat pump component is the fraction of the total system airflow that goes through the control zone. This fraction is calculated as the ratio of the maximum air mass flow rate for the air loop’s supply inlet node for the control zone (e.g., `AirTerminal:SingleDuct:ConstantVolume:NoReheat`, field = Maximum Air Flow Rate, converted to mass flow) to the sum of the maximum air mass flow rates for the air loop’s supply inlet nodes for all zones served by this air loop. The heat pump module scales the calculated load for the control zone upward based on this fraction to determine the total load to be met by the heat pump. The module then proceeds to calculate the required cycling ratio, speed ratio and speed number for the system coil and determines the supply air mass flow rate to meet this total load based on the speed number. The cycling ratio is the ratio of the sensible load (heating or cooling) to the steady-state capacity of the multispeed heat pump’s DX heating or cooling coil at Speed 1 for the entire system time step. It is equivalent to the part load ratio for a single speed DX coil. The value is between 0.0 and 1.0 when the system operates at its lowest speed (Speed 1) and 1.0 when the multispeed heat pump operates at speeds above 1. The speed ratio is the ratio of time in a system time step that the compressor is at rated speed between two consecutive speed numbers ($[\text{Compressor Speed} - \text{Compressor speed at Speed } i-1] / [\text{Compressor speed at Speed } i - \text{Compressor speed at Speed } i-1]$). The compressor speed ratio is between 0.0 and 1.0 when the speed number is above 1 and is 0.0 during Speed 1 operation. The speed number is the lowest index number whose corresponding full-load sensible capacity at the given air mass flow rate is greater than or equal to the sensible load (heating or cooling) in a system time step. The heating or cooling capacity delivered by the heat pump is distributed to all of the zones served by this system via the direct air units that supply air to each zone.

The heat pump component is able to model supply air fan operation in two modes: cycling fan – cycling coil (i.e., AUTO fan) and continuous fan – cycling coil (i.e., fan ON). `Fan:OnOff` must be used to model AUTO fan, while `Fan:OnOff` or `Fan:ConstantVolume` can be used to model fan ON. The fan operation mode is specified using a supply air fan operating mode schedule where schedule values of 0 denote cycling fan operation and schedule values other than 0 (a 1 is usually used) denote continuous fan operation. Using this schedule, the supply air fan may be cycled with cooling or heating coil operation or operated continuously based on time of day (e.g. cycling fan operation at night and continuous fan operation during the day).

Several output variables are reported by the heat pump object including fan part-load ratio, compressor part-load ratio, cycling ratio, speed ratio and speed number. Fan part-load ratio is defined as the actual air mass flow rate through the system for the time step divided by the operating supply air mass flow rate specified for the heat pump ($\dot{m}_{actual} / \dot{m}_{ON}$) at speed 1. Fan part-load ratio is set to 1.0 when the heat pump operates at speeds above 1. The operating supply air mass flow rate may be different for cooling, heating, and when no cooling or heating is required. Compressor part-load ratio is the actual load for the time step divided by the full-load sensible capacity (see Equation 16.382 or 16.399). If the defrost strategy is reverse cycle for a DX heating coil, the compressor part-load ratio is the sum of the actual load and the defrost load divided by the full-load sensible capacity. Therefore, the compressor part load ratio for the DX heating coil may be greater than the cycling ratio. This heat pump object also reports the sensible, latent and total cooling and heating rate, as well as the electricity consumption for the unit with separate accounting of auxiliary electric consumption. Furthermore, five report variables related to waste heat recovery are available if the user chooses to model this option.

16.5.6.2 Model Description

As described previously, the heat pump is a “virtual” component consisting of a fan, multispeed DX cooling coil, multispeed DX heating coil and supplemental heating coil. The sole purpose of the heat pump model is to properly coordinate the operation of the various system components. The following sections describe the flow of information within the model, as well as the differences between cycling and continuous supply air fan operation.

16.5.6.3 Cooling Operation

The description of heat pump cooling operation is divided in two sections: sensible capacity and average supply air flow rate. Actually, the determinations of capacity and supply air flow rate are related, so these calculations are performed in unison.

16.5.6.3.1 Capacity calculation

If EnergyPlus determines that the heat pump must supply cooling to the control zone to meet the zone air temperature setpoint, then the heat pump model computes the total sensible cooling load (negative) to be delivered to the zones being served based on the control zone sensible cooling load and the fraction of the heat pump air flow that goes through the control zone.

$$\text{Heat Pump Cooling Load} = \frac{\text{Control Zone Cooling Load}}{\text{Control Zone Air Flow Fraction}} \quad (16.375)$$

The model then calculates the heat pump’s sensible cooling energy rate delivered to the zones being served when the system runs at full-load conditions at the highest speed and when the DX cooling coil is OFF. If the supply air fan cycles with the compressor, then the sensible cooling energy rate is zero when the cooling coil is OFF. However if the fan is scheduled to run continuously regardless of coil operation, then the sensible cooling energy rate will not be zero when the cooling coil is OFF. Calculating the sensible cooling energy rate involves modeling the supply air fan (and associated fan heat) and the multispeed DX cooling coil. The multispeed DX heating coil and the supplemental heating coil are also modeled, but only to pass the air properties and mass flow rate from their inlet nodes to their outlet nodes. For each of these cases (full load at highest cooling speed and DX cooling coil OFF), the sensible cooling energy rate delivered by the heat pump is calculated as follows:

$$\text{FullCoolOutput}_{\text{Highest Speed}} = (\dot{m}_{\text{HighestSpeed}}) (h_{\text{out,full load}} - h_{\text{control zone}})_{HR_{\min}} - \Delta_{\text{sen,HighestSpeed}} \quad (16.376)$$

$$\text{NoCoolOutput} = (\dot{m}_{\text{coil off}}) (h_{\text{out,coil off}} - h_{\text{control zone}})_{HR_{\min}} - \Delta_{\text{sen,coil off}} \quad (16.377)$$

where:

$\dot{m}_{\text{HighestSpeed}}$ is the air mass flow rate through heat pump at the highest cooling speed (kg/s)

$h_{\text{out,full load}}$ is the enthalpy of air exiting the heat pump at full-load conditions (J/kg)

$h_{\text{control zone}}$ is the enthalpy of air leaving the control zone (where thermostat is located) (J/kg)

HR_{\min} is the minimum humidity ratio of the heat pump exiting air or the air leaving the control zone (kg/kg)

$\dot{m}_{CoilOff}$ is the air mass flow rate through the heat pump with the cooling coil OFF (kg/s)

$h_{out,coil\ off}$ is the enthalpy of air exiting the heat pump with the cooling coil OFF (J/kg)

$\Delta_{sen,full\ load}$ is the sensible load difference between the system output node and the zone inlet node at full-load conditions.

$$\begin{aligned} \Delta_{sen,HighestSpeed} &= \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,full\ load} - h_{Zone\ Inlet})_{HRmin} \\ &+ \left(\dot{m}_{HighestSpeed} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,full\ load} - h_{Control\ Zone})_{HRmin} \end{aligned} \quad (16.378)$$

where:

Frac is the control zone air fraction with respect to the system mass flow rate

$\Delta_{sen,coil\ off}$ is the sensible load difference between the system output node and the zone inlet node with the cooling coil OFF conditions.

$$\begin{aligned} \Delta_{sen,coil\ off} &= \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,coil\ off} - h_{Zone\ Inlet})_{HRmin} \\ &+ \left(\dot{m}_{coil\ off} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,coil\ off} - h_{Control\ Zone})_{HRmin} \end{aligned} \quad (16.379)$$

If the heat pump's sensible cooling rate at the highest speed (full load, no cycling) is insufficient to meet the entire cooling load, the controlled zone conditions will not be met. The reported cycling rate and speed ratio are 1, and the speed number is set to the highest index number. If the total sensible cooling load to be met by the system is less than the sensible cooling rate at the highest speed, then the following steps are performed.

First, calculate the sensible cooling energy rate at Speed 1:

$$FullCoolOutput_{Speed1} = (\dot{m}_{Speed1}) (h_{out,full\ load} - h_{control\ zone})_{HRmin} - \Delta_{sen,Speed1} \quad (16.380)$$

where:

\dot{m}_{Speed1} is the air mass flow rate through heat pump at Speed 1 (kg/s)

$\Delta_{sen,Speed1}$ is the sensible load difference between the system output node and the zone inlet node at full-load conditions at Speed 1.

$$\begin{aligned} \Delta_{sen,Speed1} &= \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,full\ load} - h_{Zone\ Inlet})_{HRmin} \\ &+ \left(\dot{m}_{Speed1} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,full\ load} - h_{Control\ Zone})_{HRmin} \end{aligned} \quad (16.381)$$

Second, if the sensible cooling energy rate delivered by the heat pump at Speed 1 is greater or equal to the sensible load, the cycling ratio (part-load ratio) for the heat pump is estimated.

$$\begin{aligned} CyclingRatio &= \frac{|(HeatingCoilSensibleLoad)|}{FullHeatingCoilCapacity} \\ &= \max \left(0.0, \frac{|(HeatPumpHeatingLoad - AddedFanHeat)|}{|(FullHeatOutput_{Speed1} - AddedFanHeat_{Speed1})|} \right) \end{aligned} \quad (16.382)$$

where:

AddedFanHeat is the generated supply air fan heat, which is a function of part load ratio and as internal component cooling load (W)

AddedFanHeat_{Speed1} is the generated supply air fan heat at Speed 1 for a part load ratio of 1 (W).

Since the part-load performance of the DX cooling coil is frequently non-linear, and the supply air fan heat varies based on cooling coil operation for the case of cycling fan/cycling coil (AUTO fan), the final part-load ratio for the cooling coil compressor and fan are determined through iterative calculations (successive modeling of the cooling coil and fan) until the heat pump's cooling output matches the cooling load to be met within the convergence tolerance. The convergence tolerance is fixed at 0.001 and is calculated based on the difference between the load to be met and the heat pump's cooling output divided by the load to be met.

$$Tolerance \equiv \frac{HeatPumpCoolingLoad - HeatPumpOutput_{Cycling}}{HeatPumpCoolingLoad} \leq 0.001 \quad (16.383)$$

where HeatPumpOutput_{Cycling} is the heat pump delivered sensible capacity for Speed 1 operating at a specific cycling ratio (W).

$$HeatPumpOutput_{cycling} = \dot{m}_{HeatPump} (h_{out} - h_{Control\ Zone})_{HRmin} - \Delta_{cycling} \quad (16.384)$$

where:

$\dot{m}_{HeatPump}$ is the average air mass flow rate defined in the next section (kg/s)

h_{out} is the enthalpy of air exiting the heat pump at part load conditions (J/kg)

$\Delta_{cycling}$ is the average sensible load difference between the system output node and the zone inlet node.

$$\begin{aligned} \Delta_{cycling} &= \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Zone\ Inlet} - h_{Control\ Zone}) \\ &+ \left(\dot{m}_{HeatPump} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out} - h_{Control\ Zone}) \end{aligned} \quad (16.385)$$

where $\dot{m}_{Zone\ Inlet}$ is the air mass flow rate in the supply inlet node in the controlled zone (kg/s).

For this case where speed 1 operation was able to meet the required cooling load, the speed ratio is set to zero and speed number is equal to 1.

Finally, if the heat pump's cooling output at full load for Speed 1 is insufficient to meet the entire cooling load, the Cycling ratio is set equal to 1.0 (compressor and fan are not cycling). Then the cooling speed is increased and the delivered sensible capacity is calculated. If the full load sensible capacity at Speed n is greater than or equal to the sensible load, the speed ratio for the heat pump is estimated:

$$Speed\ Ratio = \frac{ABS(Heat\ Pump\ Cooling\ Load - AddedFanHeat - Full\ Cool\ Output_{Speedn-1})}{ABS(Full\ Cool\ Output_{Speedn} - Full\ Cool\ Output_{Speedn-1})} \quad (16.386)$$

Although a linear relationship is assumed by applying the speed ratio to obtain the effective capacity and mass flow rate between speed n and n-1, the outlet air node conditions are dependent on the combined outputs and may not be linear. In addition, the supply air fan heat varies with the speed ratio due to different supply mass flow rates between speed n and n-1. Therefore, the final speed ratio for the cooling coil compressor and fan are determined through iterative calculations

(successive modeling of the cooling coil and fan) until the heat pump's cooling output matches the cooling load to be met within the convergence tolerance. The convergence tolerance is fixed at 0.001 and is calculated based on the difference between the load to be met and the heat pump's cooling output divided by the load to be met.

$$Tolerance = 0.001 \geq \frac{Heat\ Pump\ Cooling\ Load - HeatPumpOutput_{SpeedRatio}}{Heat\ Pump\ Cooling\ Load} \quad (16.387)$$

where $HeatPumpOutput_{SpeedRatio}$ is the heat pump delivered sensible capacity between two consecutive speeds at a specific speed ratio (W).

$$\begin{aligned} HeatPumpOutput_{SpeedRatio} &= (SpeedRatio)FullCoolOutput_{Speedn} \\ &= (1 - SpeedRatio)FullCoolOutput_{Speedn-1} - AddedFanHeat_{SpeedRatio} \end{aligned} \quad (16.388)$$

where $AddedFanHeat_{SpeedRatio}$ is the generated supply air fan heat at a specific speed ratio (W). In this case, the reported cycling ratio is 1 and speed number is equal to n.

16.5.6.3.2 Air Mass Flow Rate Calculation

Speed 1 operation

If the heat pump has been specified with cycling fan/cycling coil (AUTO fan), then the heat pump's operating supply air mass flow rate is determined by the cycling ratio (PartLoadRatio) for Speed 1. The supply air mass flow rate is multiplied by the cycling ratio to determine the average air mass flow rate for the system simulation time step. The air conditions at nodes downstream of the cooling coils represent the full-load (steady-state) values when the coil is operating.

$$\dot{m}_{HeatPump} = (CyclingRatio)\dot{m}_{Speed1} \quad (16.389)$$

If the fan operates continuously (i.e., when the supply air fan operating mode schedule values are NOT equal to 0), the operating air mass flow rate through the heat pump is calculated as the average of the user-specified air flow rate when the heat pump cooling coil is ON at Speed 1 and the user-specified air flow rate when the heat pump cooling coil is OFF (user-specified supply air volumetric flow rates converted to dry air mass flow rates).

$$\dot{m}_{HeatPump} = (CyclingRatio)\dot{m}_{Speed1} + (1.0 - CyclingRatio)\dot{m}_{CoilOff} \quad (16.390)$$

where:

$\dot{m}_{HeatPump}$ is the average air mass flow rate through heat pump (kg/s)

\dot{m}_{Speed1} is the air mass flow rate through heat pump when cooling coil is ON at Speed 1 (kg/s)

$\dot{m}_{CoilOff}$ is the air mass flow rate through heat pump when no heating or cooling is needed (kg/s).

In this case, the air conditions at nodes downstream of the cooling coils are calculated as the average conditions over the simulation time step (i.e., the weighted average of full-load conditions when the coil is operating and inlet air conditions when the coil is OFF).

16.5.6.3.3 Higher Speed Operation

When the heat pump operates at higher speeds to meet the required cooling load, the supply air mass flow rate is linearly interpolated between two consecutive speeds:

$$\dot{m}_{HeatPump} = (SpeedRatio)\dot{m}_{Speedn} + (1.0 - SpeedRatio)\dot{m}_{Speedn-1} \quad (16.391)$$

where:

$\dot{m}_{HeatPump}$ is the average air mass flow rate through the heat pump for the time step (kg/s)

\dot{m}_{Speedn} is the air mass flow rate through heat pump when cooling coil is ON at Speed n (kg/s)

$\dot{m}_{Speedn-1}$ is the air mass flow rate through heat pump when cooling coil is ON at Speed n-1 (kg/s).

For this case of higher speed operation, the air conditions at nodes downstream of the cooling coils are determined by the delivered cooling capacity and supply air mass flow rates between two consecutive speeds.

Although the above sections present the capacity and air mass flow rate calculation separately, they are dependent and change every iteration until convergence is reached for the time step being simulated.

16.5.6.4 Heating Operation

The description of heat pump heating operation is divided in two sections: total (sensible) capacity and average supply air flow rate. Actually, the determinations of capacity and supply air flow rate are related, so these calculation are performed in unison.

16.5.6.4.1 Capacity calculation

If EnergyPlus determines that the heat pump must supply heating to the control zone to meet the zone air temperature setpoint, then the heat pump model computes the total sensible heating load (positive) to be delivered to the zones being served based on the control zone sensible heating load and the fraction of the heat pump air flow that goes through the control zone.

$$Heat\ Pump\ Heating\ Load = \frac{Control\ Zone\ Heating\ Load}{Control\ Zone\ Air\ Flow\ Fraction} \quad (16.392)$$

The model then calculates the heat pump's sensible heating energy rate delivered to the zones being served when the system runs at full-load conditions at the highest speed and when the DX heating coil is OFF (without supplemental heater operation in either case). If the supply air fan cycles with the compressor, then the sensible heating energy rate is zero when the compressor is OFF. However if the fan is scheduled to run continuously regardless of coil operation, then the sensible heating energy rate will not be zero when the compressor is OFF. Calculating the sensible heating energy rate involves modeling the supply air fan (and associated fan heat), the DX cooling coil (simply to pass the air properties and mass flow rate from its inlet node to its outlet node), the DX heating coil, and the supplemental heating coil (simply to pass the air properties and mass flow rate from its inlet node to its outlet node). For each of these cases (full load and DX heating coil OFF, without supplemental heater operation in either case), the sensible heating energy rate delivered by the heat pump is calculated as follows:

$$FullHeatOutput_{HighestSpeed} = (\dot{m}_{HighestSpeed}) (h_{out,full\ load} - h_{control\ zone})_{HRmin} - \Delta_{sen,HighestSpeed} \quad (16.393)$$

$$NoHeatOutput = (\dot{m}_{CoilOff}) (h_{out,coil\ off} - h_{control\ zone})_{HRmin} - \Delta_{sen,coil\ off} \quad (16.394)$$

where:

$\dot{m}_{HighestSpeed}$ is the air mass flow rate through heat pump at the highest heating speed (kg/s)

$h_{out,full\ load}$ is the enthalpy of air exiting the heat pump at full-load conditions (J/kg)

$h_{control\ zone}$ is the enthalpy of air leaving the control zone (where thermostat is located) (J/kg)

HR_{min} are the enthalpies evaluated at a constant humidity ratio, the minimum humidity ratio of the heat pump exiting air or the air leaving the control zone

$\dot{m}_{CoilOff}$ is the air mass flow rate through the heat pump with the heating coil OFF (kg/s)

$h_{out,coil\ off}$ is the enthalpy of air exiting the heat pump with the heating coil OFF (J/kg)

$\Delta_{sen,full\ load}$ is the sensible load difference between the system output node and the zone inlet node at full-load conditions.

$$\begin{aligned} \Delta_{sen,HighestSpeed} = & \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,full\ load} - h_{Zone\ Inlet})_{HRmin} \\ & + \left(\dot{m}_{HighestSpeed} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,full\ load} - h_{Control\ Zone})_{HRmin} \end{aligned} \quad (16.395)$$

where:

Frac = Control zone air fraction with respect to the system mass flow rate

$\Delta_{sen,coil\ off}$ = Sensible load difference between the system output node and the zone inlet node with the heating coil OFF conditions

$$\begin{aligned} \Delta_{sen,coil\ off} = & \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,coil\ off} - h_{Zone\ Inlet})_{HRmin} \\ & + \left(\dot{m}_{coil\ off} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,coil\ off} - h_{Control\ Zone})_{HRmin} \end{aligned} \quad (16.396)$$

If the heat pump's DX heating coil output full load at the highest speed is insufficient to meet the entire heating load, the remaining heating load is passed to the supplemental heating coil. If the heat pump model determines that the outdoor air temperature is below the minimum outdoor air temperature for compressor operation (specified by the user), the compressor is turned off and the entire heating load is passed to the supplemental gas or electric heating coil. The heat pump exiting air conditions and energy consumption are calculated and reported by the individual component models (fan, DX heating coil, and supplemental gas or electric heating coil).

If the total heating load to be met by the system is less than the sensible heating rate at the highest speed, then the following steps are performed.

First, calculate the sensible heating energy rate at Speed 1:

$$FullHeatOutput_{Speed1} = (\dot{m}_{Speed1}) (h_{out,full\ load} - h_{control\ zone})_{HRmin} - \Delta_{sen,Speed1} \quad (16.397)$$

where:

\dot{m}_{Speed1} is the air mass flow rate through heat pump at Speed 1 (kg/s)

$\Delta_{sen,Speed1}$ is the sensible load difference between the system output node and the zone inlet node at full-load conditions at Speed 1.

$$\Delta_{sen,Speed1} = \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Out,full\ load} - h_{Zone\ Inlet})_{HRmin} + \left(\dot{m}_{Speed1} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out,full\ load} - h_{Control\ Zone})_{HRmin} \quad (16.398)$$

Second, if the sensible heating energy rate delivered by the heat pump at Speed 1 is greater or equal to the sensible load, the cycling ratio (part-load ratio) for the heat pump is estimated.

$$\begin{aligned} CyclingRatio &= \frac{|(HeatingCoilSensibleLoad)|}{FullHeatingCoilCapacity} \\ &= \max \left(0.0, \frac{|(HeatPumpHeatingLoad - AddedFanHeat)|}{|(FullHeatOutput_{Speed1} - AddedFanHeat_{Speed1})|} \right) \end{aligned} \quad (16.399)$$

where:

AddedFanHeat is the generated supply air fan heat, which is a function of part load ratio and as internal component heating load (W)

AddedFanHeat_{Speed1} is the generated supply air fan heat at Speed 1 for a part load ratio of 1 (W).

Since the part-load performance of the DX heating coil is frequently non-linear (Ref: Single-Speed Electric Heat Pump DX Air Heating Coil), and the supply air fan heat varies based on heating coil operation for the case of cycling fan/cycling coil (AUTO fan), the final part-load ratio for the heating coil compressor and fan are determined through iterative calculations (successive modeling of the heating coil and fan) until the heat pump's heating output matches the heating load to be met within the convergence tolerance. The convergence tolerance is fixed at 0.001 and is calculated based on the difference between the load to be met and the heat pump's heating output divided by the load to be met.

$$Tolerance \equiv \frac{HeatPumpHeatingLoad - HeatPumpOutput_{Cycling}}{HeatPumpHeatingLoad} \leq 0.001 \quad (16.400)$$

where HeatPumpOutput_{Cycling} is the heat pump delivered sensible capacity for Speed 1 operating at a specific cycling ratio (W).

$$HeatPumpOutput_{cycling} = \dot{m}_{HeatPump} (h_{out} - h_{Control\ Zone})_{HRmin} - \Delta_{cycling} \quad (16.401)$$

where:

$\dot{m}_{HeatPump}$ is the average air mass flow rate defined in the next section (kg/s)

h_{out} is the enthalpy of air exiting the heat pump at part load conditions (J/kg)

$\Delta_{cycling}$ is the average sensible load difference between the system output node and the zone inlet node.

$$\begin{aligned} \Delta_{cycling} &= \frac{\dot{m}_{Zone\ Inlet}}{Frac} (h_{Zone\ Inlet} - h_{Control\ Zone}) \\ &+ \left(\dot{m}_{HeatPump} - \frac{\dot{m}_{Zone\ Inlet}}{Frac} \right) (h_{Out} - h_{Control\ Zone}) \end{aligned} \quad (16.402)$$

where $\dot{m}_{Zone\ Inlet}$ is the air mass flow rate in the supply inlet node in the controlled zone (kg/s).

For this case where speed 1 operation was able to meet the required heating load, the speed ratio is set to zero and speed number is equal to 1.

Finally, if the heat pump's heating output at full load for Speed 1 is insufficient to meet the entire heating load, the Cycling ratio (PartLoadRatio) is set equal to 1.0 (compressor and fan are

not cycling). Then the heating speed is increased and the delivered sensible capacity is calculated. If the full load sensible capacity at Speed n is greater than or equal to the sensible load, the speed ratio for the heat pump is estimated:

$$\text{Speed Ratio} = \frac{ABS(\text{Heat Pump Heating Load} - \text{AddedFanHeat} - \text{Full Heat Output}_{\text{Speed}n-1})}{ABS(\text{Full Heat Output}_{\text{Speed}n} - \text{Full Heat Output}_{\text{Speed}n-1})} \quad (16.403)$$

Although a linear relationship is assumed by applying the speed ratio to obtain the effective capacity and air mass flow rate between speed n and $n-1$, the outlet node conditions are dependent on the combined outputs and may not be linear. In addition, the supply air fan heat varies based on heating coil operation for the case of cycling fan/cycling coil (AUTO fan). Therefore, the final speed ratio for the heating coil compressor and fan are determined through iterative calculations (successive modeling of the heating coil and fan) until the heat pump's heating output matches the heating load to be met within the convergence tolerance. The convergence tolerance is fixed at 0.001 and is calculated based on the difference between the load to be met and the heat pump's heating output divided by the load to be met.

$$\text{Tolerance} = 0.001 \geq \frac{\text{Heat Pump Heating Load} - \text{HeatPumpOutput}_{\text{SpeedRatio}}}{\text{Heat Pump Heating Load}} \quad (16.404)$$

where $\text{Heat Pump Output}_{\text{SpeedRatio}}$ is the heat pump delivered sensible capacity between two consecutive speeds at a specific ratio (W).

$$\begin{aligned} \text{HeatPumpOutput}_{\text{SpeedRatio}} &= (\text{SpeedRatio})\text{FullHeatOutput}_{\text{Speed}n} \\ &= (1 - \text{SpeedRatio})\text{FullHeatOutput}_{\text{Speed}n-1} - \text{AddedFanHeat}_{\text{SpeedRatio}} \end{aligned} \quad (16.405)$$

where $\text{AddedFanHeat}_{\text{SpeedRatio}}$ is the generated supply air fan heat at a specific speed ratio (W). In this case, the reported cycling ratio is 1 and speed number is equal to n .

16.5.6.4.2 Air Mass Flow Rate Calculation

The air mass flow rate calculations during heating operation are the same as those described above for cooling operation.

16.5.6.5 Fan Placement

Supply air fan placement impacts the iteration strategy. When the fan placement type is blow through, the air mass flow rate and coil part load factor (PLF) affect the fan outlet conditions. Since the fan is upstream of the coil components with this fan placement, the fan outlet conditions are calculated without knowing the next component's performance at the beginning of each iteration. DX coil performance is strongly dependent on the inlet conditions, so without correct inlet conditions the DX coil components may not be simulated correctly. Therefore, the heat pump components are called twice for each iteration when fan placement is 'blow through'. The correct part load factor for the fan component is obtained after the first call, so that the more realistic fan outlet conditions are used to simulate the coil performance in the second call. This extra call to the heat pump components is not required for the draw through fan since the supply air fan is located downstream of the DX coils with this fan placement.

16.5.6.6 Waste Heat Calculation

When the heat recovery is active (the value of the Design Heat Recovery Water Flow Rate field is greater than 0), the outlet node temperature of heat recovery is calculated based on the recoverable waste heat generated by its child objects (Coil:Cooling:DX:MultiSpeed and Coil:Heating:DX:MultiSpeed):

$$T_{outlet} = T_{inlet} + \frac{Q_{WasteHeat}}{C_p \dot{m}_{hr}} \quad (16.406)$$

where:

T_{outlet} is the outlet node temperature of heat recovery (°C)

T_{inlet} is the inlet node temperature of heat recovery (°C)

$Q_{WasteHeat}$ is the recoverable waste heat generated by its child objects (W)

C_p is the inlet node temperature of heat recovery (°C)

\dot{m}_{hr} is the mass flow rate of heat recovery (kg/s).

If the outlet node temperature is above the value of the Maximum Temp for Heat Recovery field, the outlet node temperature is reset to the value of Maximum Temp for Heat Recovery.

16.5.7 DX Cooling Package

16.5.7.1 Overview

The DX cooling package subsystem model provides a “virtual” component that consists of a DX air cooling coil component as shown in the figure below. The CoilSystem:Cooling:DX input object provides a container component that controls the associated DX cooling coil which is specified in a separate object. This coil can be specified anywhere in the air loop simulation and is controlled by the setpoint(s) on the control node. Optional dehumidification controls may also be specified. CoilSystem:Cooling:DX assumes continuous fan operation for any given time step, because it is not able to control cycling fan operation in the way that other AirLoopHVAC:Unitary* systems can.

This system does not need any plant specification and will provide the electric consumption necessary to operate the compressor and the condenser fan.

16.5.7.2 Controls

The system calculates the current sensible load using the temperature of the inlet node and the System Node Setpoint Temp on the control node. If the control node is not the outlet node, the desired outlet node temperature is adjusted for the current temperature difference between the outlet node and the control node. Likewise, the current latent load is calculated using the humidity ratio of the inlet node and the System Node Humidity Ratio Max on the control node. The controls determine the required coil run-time fraction and dehumidification mode (if applicable) using the steps outlined below.

16.5.7.2.1 Step 1 – Meet Sensible Load Requirement

The controls first attempt to meet the sensible requirement. The specified DX coil model is called with a part-load ratio (PLR) of 1.0 to determine the full-load output of the coil. This is compared with the desired outlet node temperature and a sensible PLR is calculated. If the PLR is <1.0, a root solver iteration routine is called to determine the coil run-time fraction which results

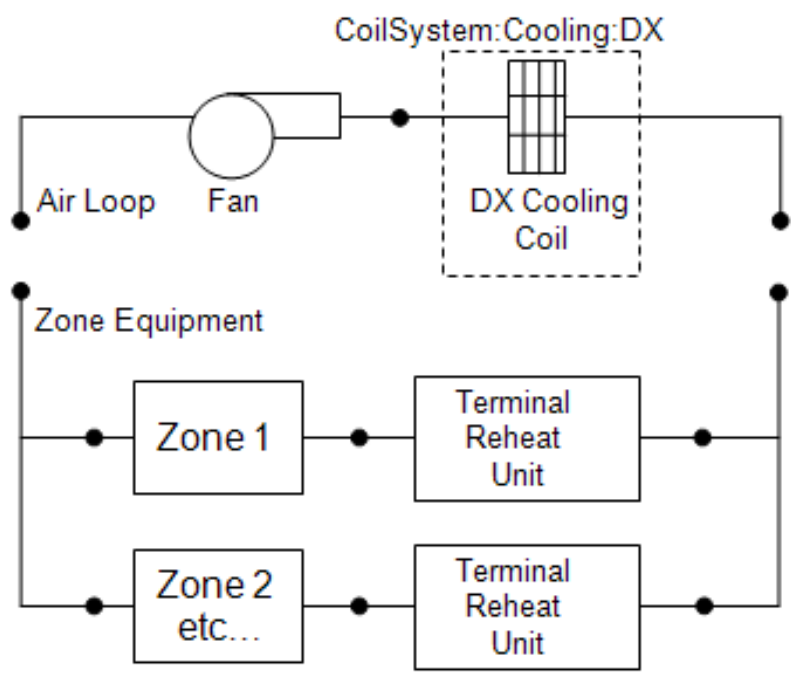

Figure 16.40: Schematic of Packaged DX Cooling Subsystem in Air Loop for a Blow-Thru Application

in the desired outlet node temperature. For a variable-speed DX cooling coil, if the load is smaller than the sensible capacity at the lowest speed, the coil run-time fraction is determined in the same way as a single-speed DX cooling coil. Otherwise, its speed level and speed ratio between two neighboring speeds are selected to match the load.

If the cooling coil type is specified as `CoilSystem:Cooling:DX:CoolingHeatExchangerAssisted` and the dehumidification control type is specified as `CoolReheat`, the heat exchanger is active during this attempt to meet the sensible requirement.

16.5.7.2.2 Step 2 – Meet Latent Load Requirement (if activated)

If dehumidification controls are active, the leaving humidity ratio resulting from operation to meet the sensible load (Step 1 above) is compared with the desired outlet node humidity ratio. If the humidity requirement is already met, then no further control action is taken. If the humidity requirement has not been met, then the coil is re-simulated depending on the type of humidity control.

16.5.7.2.3 Step 2a – Humidity Control = MultiMode

If the humidity control type is `MultiMode`, then the coil's enhanced dehumidification mode is activated when the coil type is `Coil:Cooling:DX:TwoStageWithHumidityControlMode` or the heat exchanger is activated when the coil type is

`CoilSystem:Cooling:DX:CoolingHeatExchangerAssisted` and Step 1 above is repeated to meet the sensible load using the coil performance resulting from the enhanced dehumidification mode. This is a semi-passive approach to dehumidification which may fall short or may exceed the dehumidification requirement. If the user has specified `Run on Latent Load = Yes` in the `CoilSystem:Cooling:DX` object, and there is no sensible load to be met, then the system will try to meet the entire dehumidification load. If dehumidification mode should not be active when there is no sensible load, then choose `Run on Latent Load = No`.

16.5.7.2.4 Step 2b – Humidity Control = CoolReheat

If the humidity control type is `CoolReheat`, the coil is re-simulated to achieve the desired outlet node humidity ratio. This option is valid for all cooling coil types. When the coil type is `Coil:Cooling:DX:TwoStageWithHumidityControlMode`, only the cooling performance mode is used for this step and enhanced dehumidification mode is not activated.

16.5.8 DX Heating Package

16.5.8.1 Overview

The DX heating package subsystem model provides a “virtual” component that consists of a DX air-to-air heating coil component and associated controls. The `CoilSystem:Heating:DX` input object provides a container component that controls the associated DX heating coil which is specified in a separate object. See the entry called `Single-Speed and Variable-Speed Electric Heat Pump DX Air Heating Coil` for details of the coil model itself. This coil can be specified anywhere in the air loop simulation and is controlled by the setpoint on the heating coil's outlet node. This model is analogous to the model for `CoilSystem:Cooling:DX` which is similar but for cooling. The model assumes continuous fan operation for any given time step, because it is not able to control cycling fan operation in the way that other `AirLoopHVAC:Unitary*` systems can.

This system does not need any plant specification and will provide the electric consumption necessary to operate the compressor and the condenser fan.

16.5.8.2 Controls

The DX heating package system calculates how the coil should operate to meet current sensible load using the temperature of the inlet node and the System Node Setpoint Temp on the outlet node. The controls determine the required coil run-time fraction to meet the sensible requirement. The Single-Speed Electric Heat Pump DX Air Heating Coil model is called with a part-load ratio (PLR) of 1.0 to determine the full-load output of the coil. If the PLR is <1.0 , a root solver iteration routine is called to determine the coil run-time fraction which results in the desired outlet node temperature. For a variable-speed DX heating coil, if the load is smaller than the heating capacity at the lowest speed, the coil run-time fraction is determined in the same way as a single-speed DX heating coil. Otherwise, its speed level and speed ratio between two neighboring speeds are selected to match the load.

16.5.9 Desiccant Dehumidifier Package

16.5.9.1 Overview

The input object `Dehumidifier:Desiccant:System` provides a model that packages components for a desiccant-based subsystem that dehumidifies an air stream, normally called the process air stream. A second heated air stream, called the regeneration air stream, is used to remove the collected moisture from the desiccant heat exchanger and this moisture-laden air is then usually exhausted from the building. This `Dehumidifier:Desiccant:System` object is similar to the `Dehumidifier:Desiccant:NoFans` object but has some additional modeling capabilities.

The `Dehumidifier:Desiccant:System` desiccant dehumidifier object in EnergyPlus is a compound object that can be placed anywhere in an air loop. Common locations for this object are in an `AirLoopHVAC:OutdoorAirSystem` or in the main air loop downstream of a cooling coil (postcooling desiccant dehumidifier). This compound object coordinates the operation of several ‘children’ objects: a desiccant heat exchanger, a regeneration air fan, and an optional regeneration air heater. If this dehumidifier is placed in the main air loop immediately downstream of a direct expansion (DX) cooling coil, then the dehumidifier’s operation can be coordinated with the operation of the companion DX coil and it is also possible to specify that the DX system’s condenser waste heat can be used to help regenerate the desiccant heat exchanger. For the case of condenser waste heat regeneration, an optional exhaust fan can also be modeled by this desiccant dehumidifier compound object to help maintain a setpoint temperature for air entering the regeneration side of the desiccant heat exchanger. Refer to the EnergyPlus Input Output Reference for the specific input syntax for this desiccant dehumidifier object.

16.5.9.2 Control Logic

The model first decides if the dehumidifier can operate for the simulation time step, based on its availability schedule and if there is air flow detected on the process air inlet node. If available to operate, then the target humidity ratio for the process outlet air is determined based on the maximum humidity ratio setpoint on the control node (System Node Setpoint Humidity Ratio Max). If the control node is not the process air outlet node, the target humidity ratio is adjusted

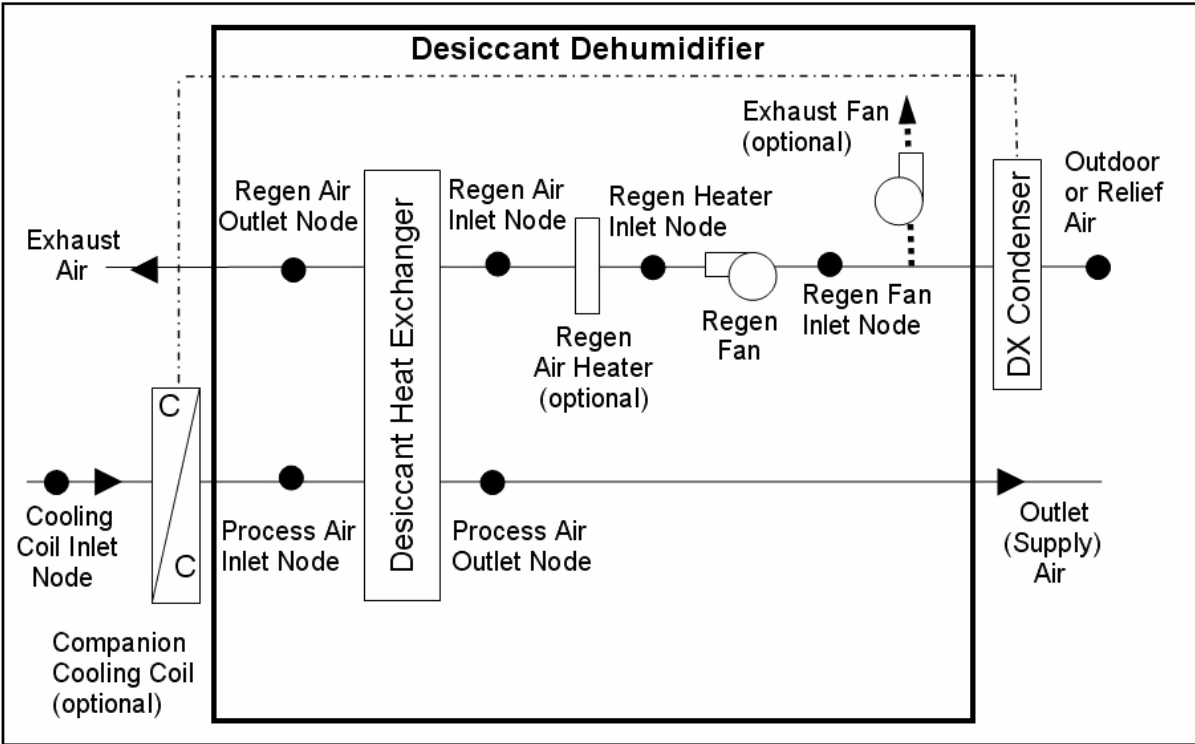

Figure 16.41: Schematic of a Desiccant Dehumidifier with Draw Through Regeneration Fan Placement

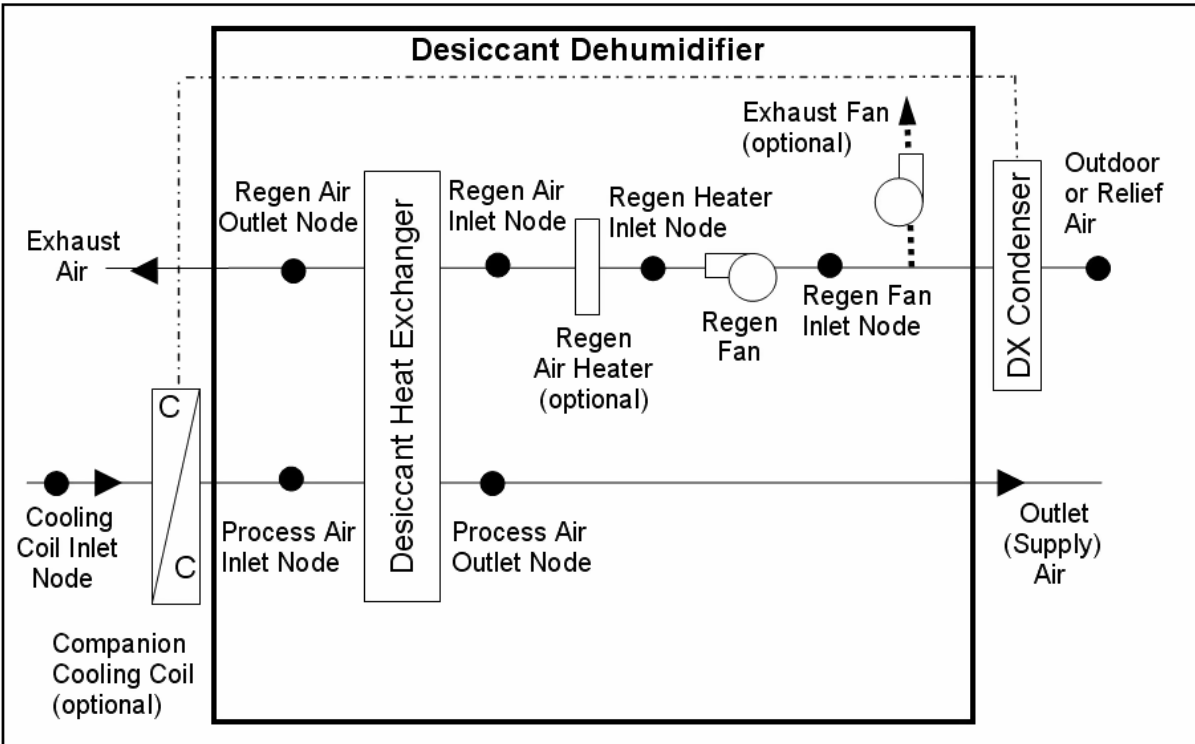

Figure 16.42: Schematic of a Desiccant Dehumidifier in Blow Through Regeneration Fan Placement

for the current humidity ratio difference between the process air outlet node and the control node. If the humidity ratio of the process inlet air is greater than the target humidity ratio for the process outlet air, then the dehumidifier operates to meet the target to the extent possible.

Once it is determined that the dehumidifier should operate, the components upstream of the desiccant heat exchanger's regeneration inlet are modeled. The actual components that are modeled depend on the configuration specified by the user.

If the waste heat from the companion cooling coil is being used to heat the regeneration air, then this model determines the temperature of the air leaving the cooling coil condenser. The user may also specify a setpoint temperature for the regeneration air entering the desiccant heat exchanger and an optional exhaust fan, which can impact the condenser leaving air temperature. For this case, the exhaust fan is used to control the condenser leaving air temperature by boosting the air flow rate through the condenser to meet the setpoint temperature (minus regeneration fan heat if blow through fan placement).

Note: If the desiccant dehumidifier is OFF for a simulation time step but its companion cooling coil is operating and is specified to provide regeneration air heating, then the exhaust fan operates at the maximum air flow rate (i.e., this fan serves as the condenser fan for the companion cooling coil system when regeneration air heating is specified, so the inputs for the companion cooling coil object should not include the condenser fan energy since the condenser fan energy is modeled by the Dehumidifier:Desiccant:SystemDesiccant Dehumidifier object).

The exhaust fan power is determined as follows:

If dehumidifier is operating:

$$\begin{aligned} PLR_{exhaust} &= \frac{\dot{m}_{exhaust}}{\rho_{Std} \dot{V}_{exhaust,max}} \\ P_{exhaust} &= P_{exhaust,max} \cdot ExhFanModFac \end{aligned} \quad (16.407)$$

If dehumidifier is not operating, but companion coil is operating:

$$P_{exhaust} = P_{exhaust,max} \cdot PLR_{companion\ coil} \quad (16.408)$$

where:

$PLR_{exhaust}$ is the part load ratio of the exhaust fan

$\dot{V}_{exhaust,max}$ is the exhaust fan maximum volumetric flow rate, user input (m³/s)

ρ_{Std} is the density of air at standard temperature and pressure [dry air at 20°C] (m³/kg)

$P_{exhaust,max}$ is the exhaust fan maximum power, user input (W)

$ExhFanModFac$ is the exhaust fan power modifier curve evaluated at $PLR_{exhaust}$. If modifier curve not provided by the user, then this factor is assumed to be 1.0.

$PLR_{companion\ coil}$ is the part load ratio of the companion cooling coil

$P_{exhaust}$ is the output variable 'Dehumidifier Exhaust Fan Electric Power, W'.

The exhaust fan electric consumption is then calculated as:

$$E_{exhaust} = P_{exhaust} * TimeStepSys * 3600 \quad (16.409)$$

where:

$E_{exhaust}$ is the output variable 'Dehumidifier Exhaust Fan Electric Energy, J'

$TimeStepSys$ is the HVAC system simulation time step (hr).

Once the outlet conditions from the companion coil condenser are determined (if present), then the regeneration air fan (if blow through configuration) and regeneration air heater (if present) are

simulated. To the extent possible (e.g., if the heater is available to operate based on its availability schedule and it has sufficient heating capacity), the regeneration air heater operates to raise its outlet air temperature to the specified regeneration inlet air setpoint temperature.

With the inlet air conditions to the regeneration and process sides of the desiccant heat exchanger now known, the performance of the desiccant heat exchanger is modeled. If the desiccant dehumidifier is specified with a companion cooling coil upstream of the heat exchanger's process inlet, then the model assumes that the dehumidifier operates at the same time as the companion coil (same part-load ratio). If not, then the desiccant dehumidifier model calculates the fraction of time it must operate to meet the process outlet air maximum humidity target (setpoint) using the following equation:

$$\begin{aligned} DDPartLoadRatio &= \frac{w_{Proc,in} - w_{max,setpoint}}{w_{Proc,in} - w_{Proc,out,HXon}} \\ DDPartLoadRatio &= \max(0.0, DDPartLoadRatio) \\ DDPartLoadRatio &= \min(1.0, DDPartLoadRatio) \end{aligned} \quad (16.410)$$

where:

$DDPartLoadRatio$ is the output variable 'Dehumidifier Part Load Ratio'

$w_{Proc,in}$ is the process inlet air humidity ratio (kg/kg)

$w_{max,setpoint}$ is the target humidity ratio (setpoint) for the process outlet air (kg/kg)

$w_{Proc,out,HXon}$ is the process outlet air humidity ratio when the desiccant heat exchanger operates (kg/kg).

After all of the desiccant dehumidifier components are modeled at the appropriate part load ratio, the water removal rate and water removed are calculated.

$$\begin{aligned} \dot{m}_{water\ removed,Proc} &= \dot{m}_{Proc,in} (w_{Proc,in} - w_{Proc,out}) \\ m_{water\ removed,Proc} &= \dot{m}_{water\ removed,Proc} \cdot TimeStepSys \cdot 3600 \end{aligned} \quad (16.411)$$

where:

$\dot{m}_{water\ removed,Proc}$ is the output variable 'Dehumidifier Removed Water Mass Flow Rate, kg/s'

$\dot{m}_{Proc,in}$ is the air mass flow rate at the process air inlet node (kg/s)

$w_{Proc,out}$ is the process outlet air humidity ratio (kg/kg)

$m_{water\ removed,Proc}$ is the output variable 'Dehumidifier Removed Water Mass, kg'.

16.5.10 Unitary Water-To-Air Heat Pump

16.5.10.1 Overview

The input object `AirLoopHVAC:UnitaryHeatPump:WaterToAir` provides a model for a water-to-Air heat pump that is a “virtual” component that consists of an on/off fan component, a water-to-air heat pump cooling coil, a water-to-air heat pump heating coil, and a gas or electric supplemental heating coil. The specific configuration of the blowthru heat pump is shown in the following figure. For a drawthru heat pump, the fan is located between the water-to-air heat pump heating coil and the supplemental heating coil. The configuration of the water-to-air heat pump in the air loop is similar to an air-to-air heat pump. In addition, a water-to-air heat pump has a water loop connection on its source side. The water loop can be served by a condenser loop (like GHE for Ground source systems), or by a cooling tower/ boiler plant loop (for water loop systems).

There are two different models for water-to-air heat pump cooling and heating coils. Cooling and heating coils are modeled using a Single Speed or Variable Speed Equation Fit model or a Parameter Estimation model. The parameter estimation procedure is quite detailed and the equation fit model is designed to simplify the user inputs. Each model is discussed in short in the following sections. The Variable-Speed Equation Fit model is described in a separate section, as `Coil:Cooling:WaterToAirHeatPump:VariableSpeedEquationFit` and `Coil:Heating:WaterToAirHeatPump:VariableSpeedEquationFit`.

16.5.10.2 Single Speed Equation-Fit Model:

This section describes the equation-fit model for Water-to-Air heat pump (Object names: **Coil:Cooling:WaterToAirHeatPump:EquationFit** and **Coil:Heating:WaterToAirHeatPump:EquationFit**). This documentation is derived from the M.S. dissertation of Tang (2005) which is available on the Oklahoma State University web site . The model uses five non-dimensional equations or curves to predict the heat pump performance in cooling and heating mode. The methodology involved using the generalized least square method to generate a set of performance coefficients from the catalog data at indicated reference conditions. Then the respective coefficients and indicated reference conditions are used in the model to simulate the heat pump performance. The variables or inlet conditions that influenced the water-to-air heat pump performance are load side inlet water temperature, source side inlet temperature, source side water flow rate and load side water flow rate. The governing equations for the cooling and heating mode are as following:

Cooling Mode:

$$\frac{Q_{total}}{Q_{total,ref}} = A1 + A2 \left[\frac{T_{wb}}{T_{ref}} \right] + A3 \left[\frac{T_{w,in}}{T_{ref}} \right] + A4 \left[\frac{\dot{V}_{air}}{\dot{V}_{air,ref}} \right] + A5 \left[\frac{\dot{V}_w}{\dot{V}_{w,ref}} \right] \quad (16.412)$$

$$\frac{Q_{sens}}{Q_{sens,ref}} = B1 + B2 \left[\frac{T_{db}}{T_{ref}} \right] + B3 \left[\frac{T_{wb}}{T_{ref}} \right] + B4 \left[\frac{T_{w,in}}{T_{ref}} \right] + B5 \left[\frac{\dot{V}_{air}}{\dot{V}_{air,ref}} \right] + B6 \left[\frac{\dot{V}_w}{\dot{V}_{w,ref}} \right] \quad (16.413)$$

$$\frac{Power_c}{Power_{c,ref}} = C1 + C2 \left[\frac{T_{wb}}{T_{ref}} \right] + C3 \left[\frac{T_{w,in}}{T_{ref}} \right] + C4 \left[\frac{\dot{V}_{air}}{\dot{V}_{air,ref}} \right] + C5 \left[\frac{\dot{V}_w}{\dot{V}_{w,ref}} \right] \quad (16.414)$$

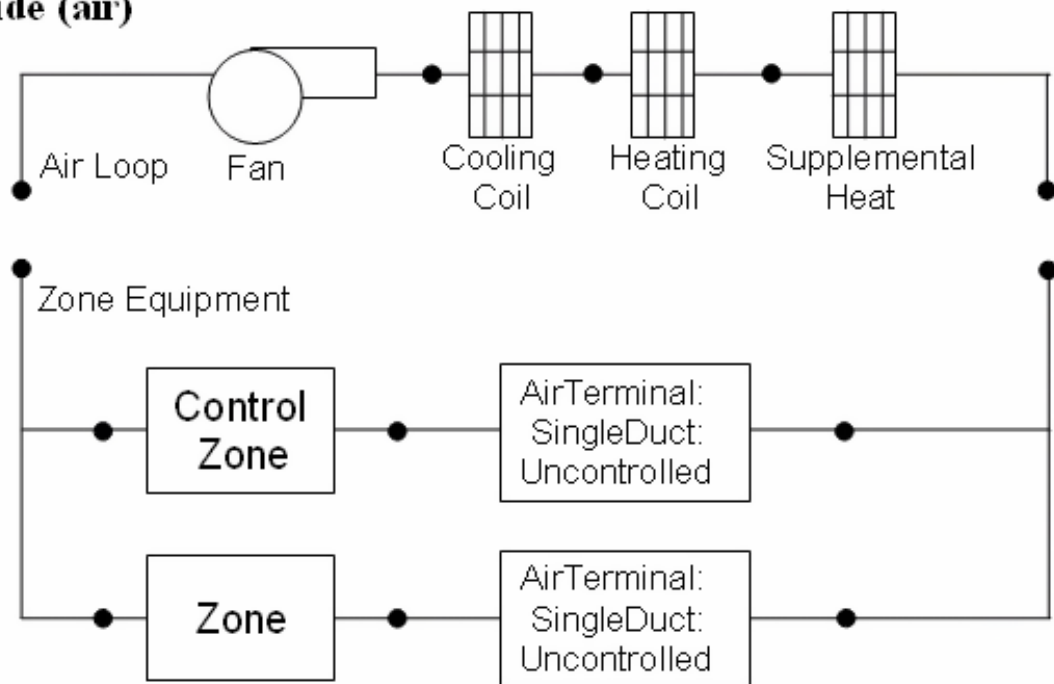

Source Side (water)**Load Side (air)**

Figure 16.43: Source Side and Load Side Configuration of a BlowThru Water-To-Air Heat Pump

Heating Mode:

$$\frac{Q_h}{Q_{h,ref}} = E1 + E2 \left[\frac{T_{db}}{T_{ref}} \right] + E3 \left[\frac{T_{w,in}}{T_{ref}} \right] + E4 \left[\frac{\dot{V}_{air}}{\dot{V}_{air,ref}} \right] + E5 \left[\frac{\dot{V}_w}{\dot{V}_{w,ref}} \right] \quad (16.415)$$

$$\frac{Power_h}{Power_{h,ref}} = F1 + F2 \left[\frac{T_{db}}{T_{ref}} \right] + F3 \left[\frac{T_{w,in}}{T_{ref}} \right] + F4 \left[\frac{\dot{V}_{air}}{\dot{V}_{air,ref}} \right] + F5 \left[\frac{\dot{V}_w}{\dot{V}_{w,ref}} \right] \quad (16.416)$$

Assuming no losses, the source side heat transfer rate for cooling and heating mode is calculated as following:

$$Q_{source,c} = Q_{total} + Power_c \quad (16.417)$$

$$Q_{source,h} = Q_h - Power_h \quad (16.418)$$

where:

$A1 - F5$ are the equation fit coefficients for the cooling and heating mode

T_{ref} is 283K

$T_{w,in}$ is the entering water temperature (K)

T_{db} is the entering air dry-bulb temperature (K)

T_{wb} is the entering air wet-bulb temperature (K)

\dot{V}_{air} is the load side air volumetric flow rate (m³/s)

\dot{V}_w is the source side water volumetric flow rate (m³/s)

Q_{total} is the total cooling capacity (W)

Q_{sens} is the sensible cooling capacity (W)

$Power_c$ is the power consumption in cooling mode (W)

$Q_{source,c}$ is the source side heat transfer rate in cooling mode (W)

Q_h is the total heating capacity (W)

$Power_h$ is the power consumption in heating mode (W)

$Q_{source,h}$ is the source side heat transfer rate in heating mode (W).

The inlet conditions or variables are divided by the reference conditions. This formulation allows the coefficients to fall into smaller range of values. Moreover, the value of the coefficient indirectly represents the sensitivity of the output to that particular inlet variable. The reference conditions used when generating the performance coefficients must be the same as the reference conditions used later in the model. The reference temperature T_{ref} is fixed at 283K. Temperature unit of Kelvin is used instead of Celsius to keep the ratio of the water inlet temperature and reference temperature positive value should the water inlet temperature drop below the freezing point.

For cooling mode, the reference conditions; reference load side air volumetric flow rate ($\dot{V}_{air,ref}$), reference source side water volumetric flow rate ($\dot{V}_{w,ref}$), reference sensible capacity ($Q_{sens,ref}$) and reference power input ($Power_{c,ref}$) are the conditions when the heat pump is operating at the highest cooling capacity or reference cooling capacity ($Q_{total,ref}$) indicated in the manufacturer's catalog. Note that the reference conditions for heating mode might differ from the reference conditions specified for the cooling mode.

16.5.10.3 Coefficient estimation procedure:

The generalized least square method is used to generate the coefficients. This method utilizes an optimization method which calculates the coefficients that will give the least amount of differences between the model outputs and the catalog data. A set of coefficients for the cooling mode is generated which includes A1-A5 for total cooling capacity, B1-B6 for sensible cooling capacity, and C1-C5 for power consumption. The same procedure is repeated for the heating mode to generate the coefficients E1-E5 and F1-F5. An information flow chart showing the inputs, reference conditions, performance coefficients and outputs are shown in the Figure 16.44.

16.5.10.4 High Humidity Control with WaterToAir HeatPump Equation Fit model

The specific configuration of the WaterToAir HeatPump with supplemental heating coil is shown above (see Figure 16.43). This figure shows the fan placement when a blow through fan is specified. If a draw through fan is specified, the fan is located between the heating coil and the reheat coil. The system is controlled to keep the high relative humidity in the control zone from exceeding the setpoint specified in the object ZoneControl:Humidistat. When high humidity control is specified and the compressor operates, the heatpump always operates at the cooling air flow rate when a zone heating load is present as determined by the zone thermostat. High humidity control is specified as either None, or CoolReheat in the Dehumidification Control Type input field. CoolReheat is specified when a DX cooling coil is used to over-cool the supply air stream in order to meet the zone latent load. In this case, a supplemental heating coil will ensure the zone temperature does not fall below the zone heating temperature set point. If the dehumidification control type is selected as None, the WaterToAir HeatPump uns only to meet the sensible cooling load. A supplemental heating coil is required for all dehumidification control types.

The model first calculates the *PartLoadRatio* required meeting the sensible cooling load. The heatpump's sensible cooling load is determined from the control zone sensible cooling load to the cooling setpoint and the control zone air flow fraction to maintain the dry-bulb temperature setpoint in the control zone:

$$HeatPumpCoolingLoad = \frac{ControlZoneCoolingLoad}{ControlZoneAirFlowFraction} \quad (16.419)$$

The heatpump's sensible cooling load to be met and the full load cooling output are used to calculate the sensible the part-load ratio iteratively based on user specified convergence criterion.

$$PartLoadRatio = MAX \left(0.0, \frac{ABS(HeatPumpCoolingLoad - NoCoolOutput)}{ABS(FullCoolOutput - NoCoolOutput)} \right) \quad (16.420)$$

When the heat pumps sensible cooling capacity meets the system sensible cooling load at a given sensible part load ratio, then the Heat pump meets the controlled zone cooling setpoint temperature. If a moisture (latent) load exists because the control zone humidity has exceeded the setpoint, the total moisture load to be met by the heat pumps (*HeatPumpMoistureLoad*) is calculated based on the control zone moisture load and the control zone air flow fraction.

$$HeatPumpMoistureLoad = \frac{ControlZoneMoitureLoad}{ControlZoneAirFlowFraction} \quad (16.421)$$

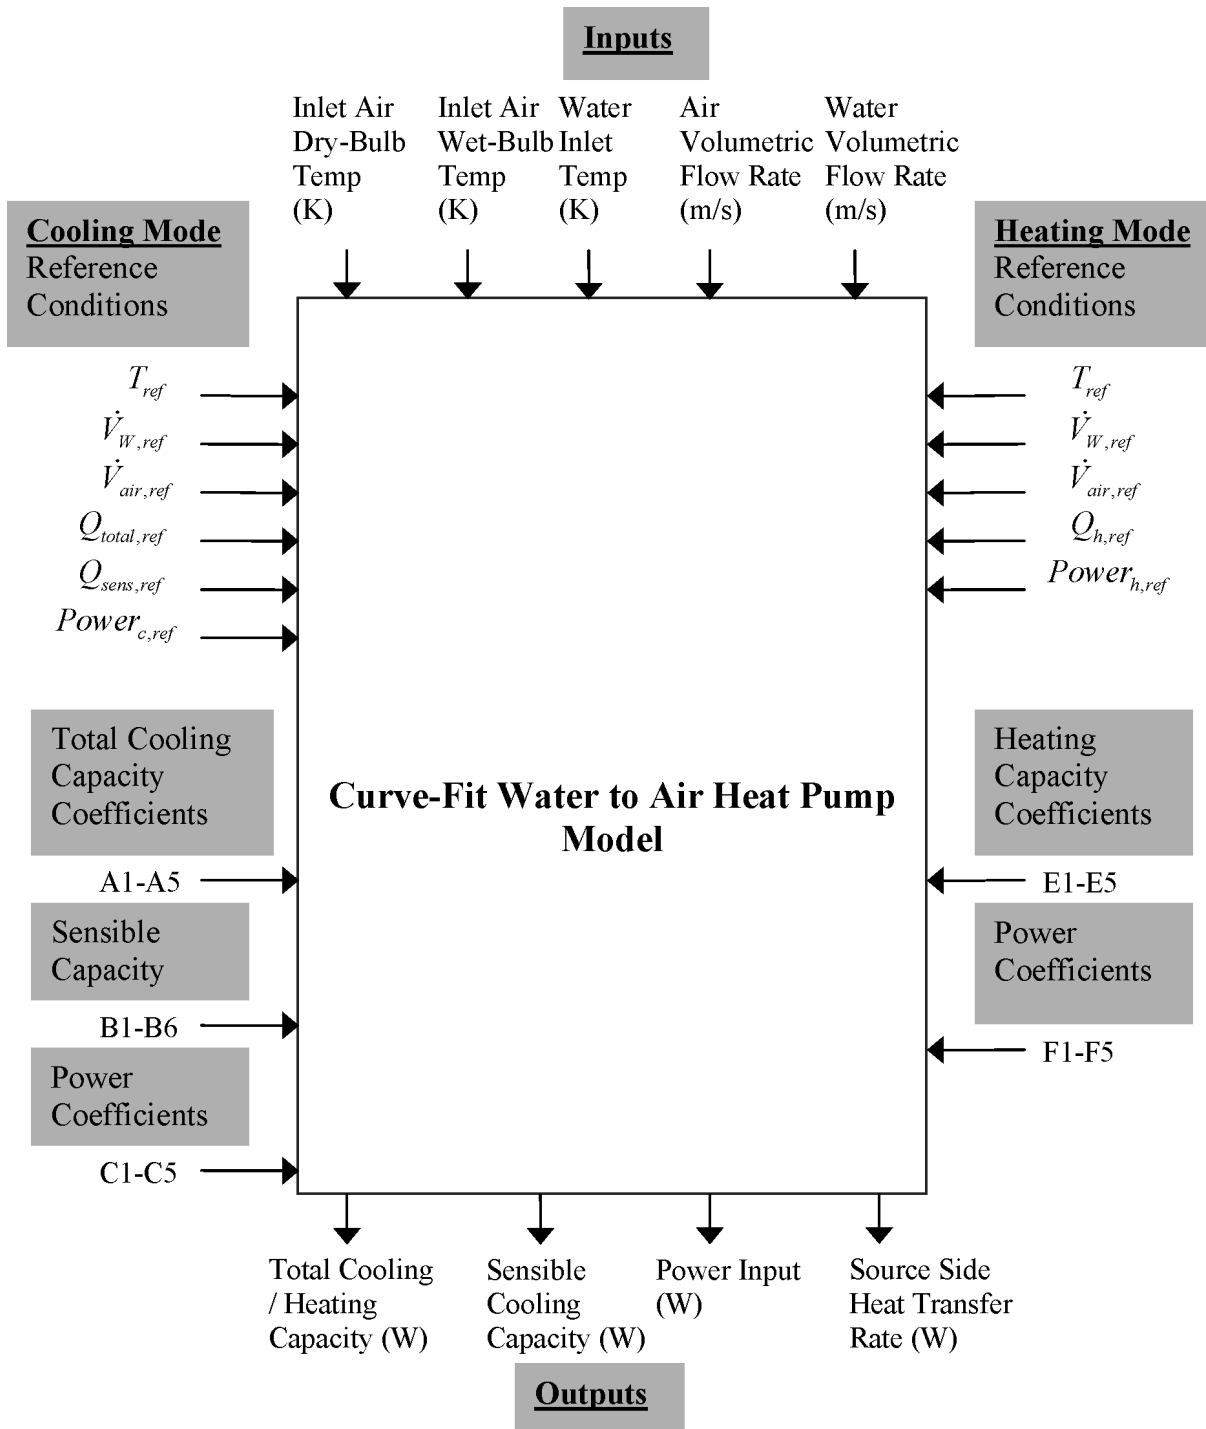

Figure 16.44: Information Flow Chart for Water-to-Air Heat Pump Equation Fit Model (Tang 2005)

Then the *LatentPartLoadRatio* required to meet the high humidity setpoint is calculated as follows:

$$LatentPartLoadRatio = MIN \left(PLR_{Min}, \frac{ABS(HeatPumpMoistureLoad - NoLatentOutput)}{ABS(FullLatentOutput - NoLatentOutput)} \right) \quad (16.422)$$

The model uses the greater of the two part-load ratios, *PartLoadRatio* or *LatentPartLoadRatio*, to determine the operating part-load ratio of the Heat Pump's DX cooling coil.

$$LatentPartLoadRatio = MAX(PartLoadRatio, LatentPartLoadRatio) \quad (16.423)$$

As previously described, iterations are performed to converge on the solution within the convergence tolerance.

where:

ControlZoneCoolingLoad is the control zone sensible cooling load to the cooling setpoint (W)

ControlZoneMoistureLoad is the control zone moisture load to the dehumidifying relative humidity setpoint (W)

ControlZoneAirFlowFraction = is the supply air fraction that goes through the control zone

FullLatentOutput is the Heat Pump's latent cooling energy rate at full-load conditions (W)

NoLatentOutput is the Heat Pump's latent cooling energy rate with cooling coil OFF (W)

PartLoadRatio is the heat pump's part-load-ratio required to meet system sensible load

LatentPartLoadRatio is the heat pump's part-load-ratio required to meet system moisture load

PLR_{MIN} is the minimum part-load ratio, which is usually 0.0. For the case when the latent capacity degradation model is used (Ref: DX Cooling Coil Model), this value is the minimum part-load ratio at which the cooling coil will dehumidify the air.

When the predicted zone air temperature is above the heating setpoint and if there is a dehumidification load, the supplemental heating coil load is required to offset the excess cooling as shown in Figure 16.45. If the model determines that the *LatentPartLoadRatio* is to be used as the operating part-load ratio of the heatpump's cooling coil, the supplemental coil is used to offset the excess sensible capacity provided by the unit. The model first checks the sensible load that exists for the current simulation time step (predicted zone temperature with no HVAC operation compared to the thermostat setpoint temperatures). If a sensible cooling load or no sensible cooling or heating load exists (see Figure 16.45), the model calculates the difference between the sensible heating load required to reach or maintain the heating dry-bulb temperature setpoint and the actual sensible cooling energy rate delivered by the heat pump (with *LatentPartLoadRatio*). In this case, the supplemental heating coil is used to offset the excess sensible cooling energy provided by the DX cooling coil (if any) that could have caused an overshoot of the heating dry-bulb temperature setpoint. Note that when a humidistat is used and high humidity control is required, the zone dry-bulb temperature will typically move toward the heating temperature setpoint when a high moisture (latent) load exists.

If a heating load exists (Figure 16.46), the supplemental heating coil is used to meet the heating coil load and at the same time offset the entire sensible cooling energy rate of the DX cooling coil (to meet the humidistat setpoint). Note that when a heating load exists and high humidity control is required, the heat pump operates at the user-specified cooling air flow rate for the entire simulation time step. As with the fan, and DX cooling coil, report variables associated with supplemental

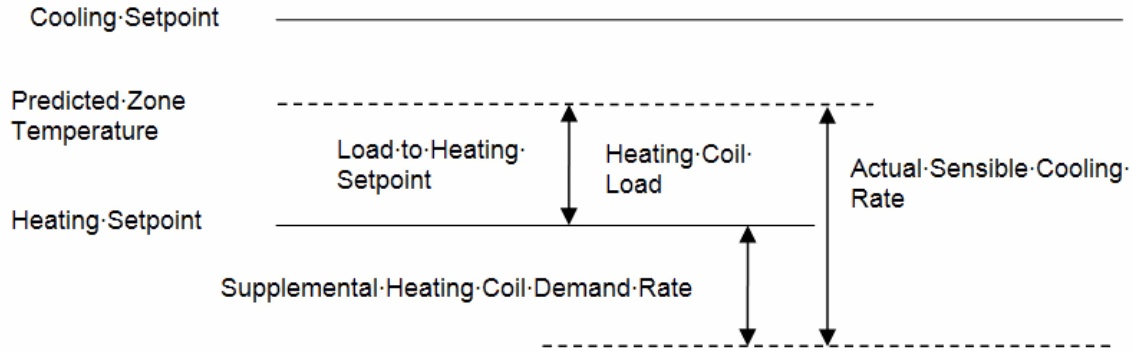

Figure 16.45: Supplemental heating coil load when predicted zone air temperature is above the heating Setpoint

heating coil performance (e.g., heating coil energy, heating coil rate, heating coil gas or electric energy, heating coil runtime fraction, etc.) are managed in the supplemental (heating) coil object.

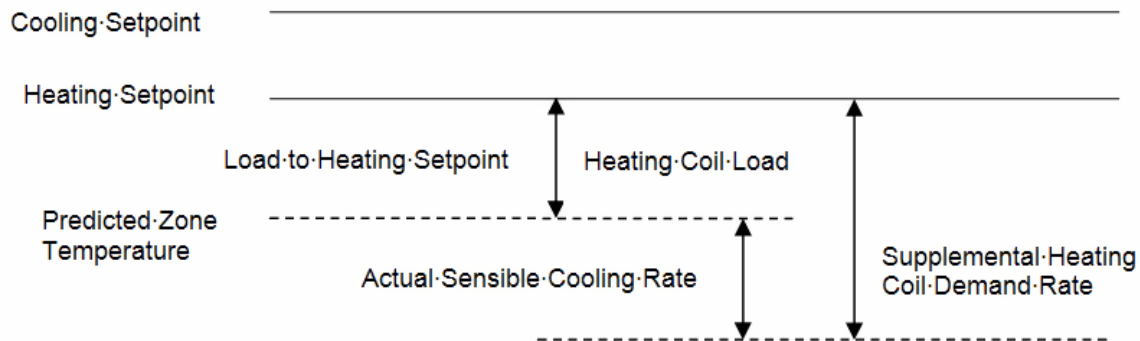

Figure 16.46: Supplemental heating coil load when predicted zone air temperature is below the heating setpoint

16.5.10.5 Parameter Estimation Model

The steady state simulation model (Object: AirLoopHVAC:UnitaryHeatPump:WaterToAir) for a water-to-air vapor compression heat pump is described in this section. The model is implemented under the air-loop manager similar to the algorithm discussed under AirLoopHVAC:UnitaryHeatPump. The heat pump ‘coil’ objects (Coil:Cooling:WaterToAirHeatPump:ParameterEstimation and Coil:Heating:WaterToAirHeatPump:ParameterEstimation) actually consist of a steady state simulation of the unitary heat pump in cooling or heating mode respectively. This documentation is derived from the Ph.D. dissertation of Hui Jin which is available on the Oklahoma State University web site . The model parameters, solution technique and solution algorithm are all identical to that of the water to water heat pump. The only difference between the two models is in the modeling of the water to air heat exchanger.

The effectiveness of this heat exchanger is given by:

$$\varepsilon = 1 - e^{-NTU} \quad (16.424)$$

where NTU is defined by:

$$NTU = \frac{UA}{(\dot{m}C_p)_{water/air}} \quad (16.425)$$

UA for the source side and the load side are two of the parameters estimated in the parameter estimation procedure.

Additional model details and a discussion of the parameters and parameter estimation technique are described in the following section on Water to Water Heat Pumps.

16.6 Water To Water Heat Pumps

There are three water-water heat pump models available in EnergyPlus:

- Parameter estimation based
- Equation fit
- EIR-formulated

Detailed descriptions of the former two models are available in the references Tang and Jin. The EIR formulation was added with EnergyPlus 9.1, based on the popular EIR formulation used in the chiller model. This section describes the important details of the three models.

16.6.1 Equation Fit Water To Water Heat Pump Model

This section describes the equation-fit model for water-to-water heat pump. (Object names: HeatPump:WaterToWater:EquationFit:Cooling & HeatPump:WaterToWater:EquationFit:Heating). This documentation is derived from the M.S. dissertation of Tang (2005) which is available on the Oklahoma State University web site . The model uses four non-dimensional equations or curves to predict the heat pump performance in cooling and heating mode. The methodology involved using the generalized least square method to generate a set of performance coefficients from the catalog data at indicated reference conditions. Then the respective coefficients and indicated reference conditions are used in the model to simulate the heat pump performance. The variables that influenced the water-to-water heat pump performance are load side inlet water temperature, source side inlet temperature, source side water flow rate and load side water flow rate. The governing equations for the cooling and heating mode are as following:

Cooling Mode:

$$\frac{Q_c}{Q_{c,ref}} = A1 + A2 \left[\frac{T_{L,in}}{T_{ref}} \right] + A3 \left[\frac{T_{S,in}}{T_{ref}} \right] + A4 \left[\frac{\dot{V}_L}{\dot{V}_{L,ref}} \right] + A5 \left[\frac{\dot{V}_S}{\dot{V}_{S,ref}} \right] \quad (16.426)$$

$$\frac{Power_c}{Power_{c,ref}} = B1 + B2 \left[\frac{T_{L,in}}{T_{ref}} \right] + B3 \left[\frac{T_{S,in}}{T_{ref}} \right] + B4 \left[\frac{\dot{V}_L}{\dot{V}_{L,ref}} \right] + B5 \left[\frac{\dot{V}_S}{\dot{V}_{S,ref}} \right] \quad (16.427)$$

Heating Mode:

$$\frac{Q_h}{Q_{h,ref}} = C1 + C2 \left[\frac{T_{L,in}}{T_{ref}} \right] + C3 \left[\frac{T_{S,in}}{T_{ref}} \right] + C4 \left[\frac{\dot{V}_L}{\dot{V}_{L,ref}} \right] + C5 \left[\frac{\dot{V}_S}{\dot{V}_{S,ref}} \right] \quad (16.428)$$

$$\frac{Power_h}{Power_{h,ref}} = D1 + D2 \left[\frac{T_{L,in}}{T_{ref}} \right] + D3 \left[\frac{T_{S,in}}{T_{ref}} \right] + D4 \left[\frac{\dot{V}_L}{\dot{V}_{L,ref}} \right] + D5 \left[\frac{\dot{V}_S}{\dot{V}_{S,ref}} \right] \quad (16.429)$$

Assuming no losses, the source side heat transfer rate for cooling and heating mode is calculated as following;

$$Q_{source,c} = Q_c + Power_c \quad (16.430)$$

$$Q_{source,h} = Q_h - Power_h \quad (16.431)$$

where:

$A1 - D5$ are the equation fit coefficients for the cooling and heating mode

T_{ref} is 283.15K

$T_{L,in}$ is the entering load side water temperature (K)

$T_{S,in}$ is the entering source side water temperature (K)

\dot{V}_L is the load side volumetric flow rate (m³/s)

\dot{V}_S is the source side volumetric flow rate (m³/s)

Q_c is the load side heat transfer rate in cooling mode (W)

$Power_c$ is the power consumption in cooling mode (W)

$Q_{source,c}$ is the source side heat transfer rate in cooling mode (W)

Q_h is the load side heat transfer rate in heating mode (W)

$Power_h$ is the power consumption in heating mode (W)

$Q_{source,h}$ is the source side heat transfer rate in heating mode (W).

If the load side heat transfer rate (Q_c or Q_h) or power consumption ($Power_c$ or $Power_h$) are less than or equal to zero, then the heat pump is turned off for that simulation time step, a warning is issued, and the simulation continues.

The inlet conditions or variables are divided by the reference conditions. This formulation allows the coefficients to fall into smaller range of values. Moreover, the value of the coefficient indirectly represents the sensitivity of the output to that particular inlet variable. The reference conditions used when generating the performance coefficients must be the same as the reference conditions used later in the model. The reference temperature T_{ref} is fixed at 283K. Temperature unit of Kelvin is used instead of Celsius to keep the ratio of the water inlet temperature and reference temperature positive value should the water inlet temperature drop below the freezing point.

For cooling mode, the reference conditions; reference load side volumetric flow rate, $\dot{V}_{L,ref}$, reference source side volumetric flow rate, $\dot{V}_{S,ref}$, $Power_{c,ref}$ and reference source side heat transfer rate, $Q_{source,c,ref}$ are the conditions when the heat pump is operating at the highest cooling capacity or reference cooling capacity, $Q_{c,ref}$ indicated in the manufacturer's catalog. Note that the reference conditions for heating mode might differ from the reference conditions specified for the cooling mode.

16.6.1.1 Coefficient estimation procedure

The generalized least square method is used to generate the coefficients. This method utilizes an optimization method which calculates for the coefficients that will give the least amount of differences between the model outputs and the catalog data. A set of coefficients for the cooling mode is generated which includes A1-A5 for load side heat transfer. The same procedure is repeated B, C, and D coefficients. An information flow chart showing the inputs, reference conditions, performance coefficients and outputs are shown in the figure below:

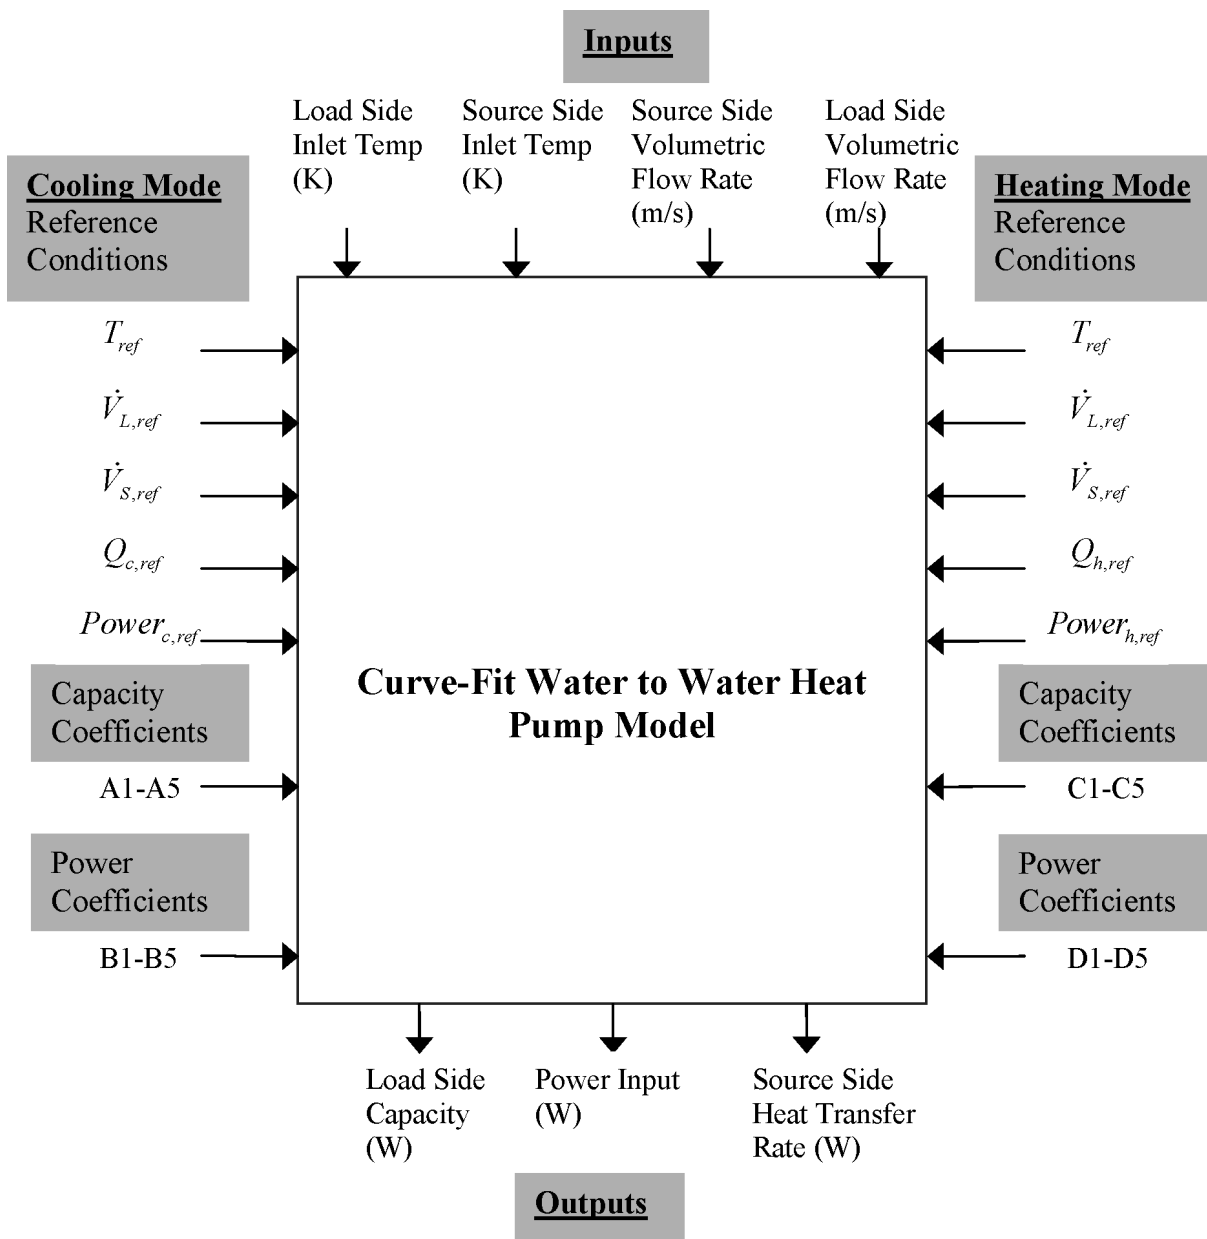

Figure 16.47: Information Flow Chart for Water-To-Water Heat Pump Equation Fit (Tang 2005)

16.6.2 Parameter Estimation Water-To-Water Heat Pump Model

A steady state simulation model for a water-to-water reciprocating vapor compression heat pump (Object names: HeatPump:WaterToWater:ParameterEstimation:Cooling & HeatPump:WaterToWater:ParameterEstimation:Heating) is described in this section. This documentation is derived from the Ph.D. dissertation of Hui Jin which is available on the Oklahoma State University web site . The model incorporates a multivariable unconstrained optimization algorithm to estimate several unspecific parameters. The aim of the model is to describe the detailed physical geometry and operation of each component and replicate the performance of the actual unit in operation. Assuming the thermodynamic process in the expansion device and the pressure drop at the suction and discharge valves to be isenthalpic the heat balance equation is given by

$$\dot{Q}_s = \dot{W} + \dot{Q}_L \quad (16.432)$$

where:

\dot{Q}_s is the source side heat transfer rate (W)

\dot{Q}_L is the load side heat transfer rate (W)

\dot{W} is the compressor power input (W).

The compressor model is based on an isentropic process shown in Figure 16.48 governed by:

$$PV^\gamma = Constant \quad (16.433)$$

where P is pressure and V is specific volume.

Since the refrigerant vapor in the clearance volume as shown in the previous figure goes through a re-expansion procedure, the mass flow rate of the compressor refrigerant is a decreasing function of the pressure ratio.

$$\dot{m} = \frac{PD}{\nu_{suc}} \left(1 + C - C \left(\frac{P_{dis}}{P_{suc}} \right)^{\frac{1}{\gamma}} \right) \quad (16.434)$$

where:

\dot{m} is the refrigerant mass flow rate

PD is the piston displacement

C is the clearance factor

P_{dis} is the discharge pressure

P_{suc} is the suction pressure

γ is the isentropic exponent.

16.6.2.1 Parameter estimation procedure

A set of parameters for the cooling mode is defined on the basis of the equations used in the model. An information flowchart indicating the parameters, inputs to the model and the resulting outputs acquired are shown in Figure 16.49. The estimation of parameters is conducted using the catalog data.

The parameter definition include:

- Piston displacement, PD

Figure 16.48: Schematic indicator diagram for a reciprocating Compressor(Jin 2002)

- Clearance factor, C
- Pressure drop across the suction and discharge valves, P
- Loss factor used to define the electromechanical losses supposed to be proportional to the theoretical power, η
- Superheat in $^{\circ}\text{C}$ or F , T_{sh}
- Constant part of the electromechanical losses, W_{loss}
- Source side heat transfer coefficient, $(UA)_S$
- Load side heat transfer coefficient, $(UA)_L$

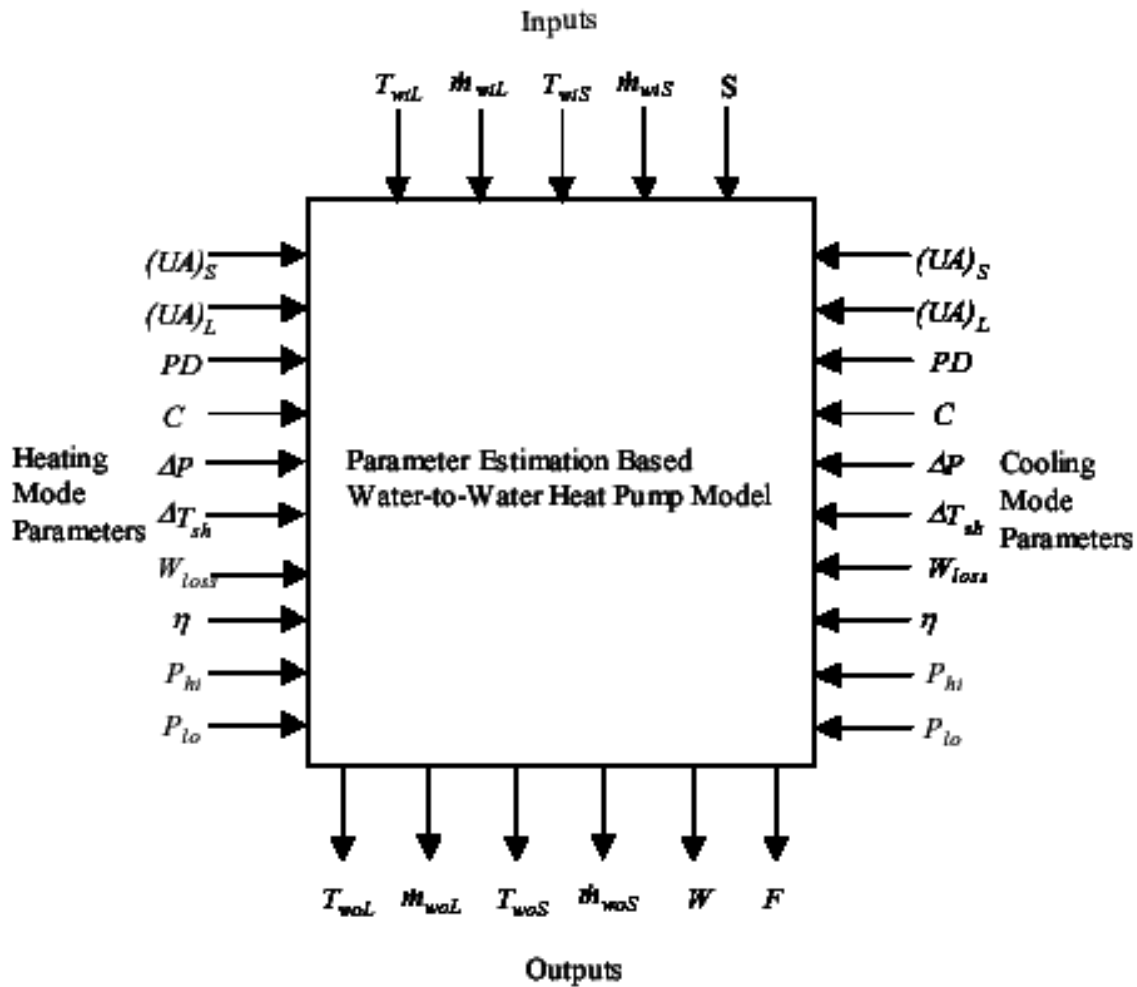

Figure 16.49: Information Flowchart for Water-To-Water Heat Pump Parameter Estimation Mmodel implementation (Jin 2002)

where:

TWiL is the entering water Load side temperature

TW_{iS} is the entering water Source side temperature

\dot{m}_{WiL} is the entering water Load side mass flow rate

\dot{m}_{WiS} is the entering water Source side mass flow rate

S is the Thermostatic Signal.

The parameter estimation procedure incorporates an objective function that computes the difference between the model outputs and the catalog outputs. The objective function is then minimized by using a multi variable unconstrained multi modal Nelder Mead optimization algorithm. As the objective function value lowers after each iteration, the model outputs approach the catalog outputs consequently leading to convergence and the correct parameters are estimated for the respective model. The inputs to the model include the entering water temperatures and mass flow rates on the load side and the source side. The calculation of the objective function is shown in the form of a formula flowchart in Figure 16.50. The square of the sum of the errors (SSQE) for a given set of parameter values that will be minimized is given by:

$$SSQE = \sum_{i=1} \left(\frac{(W_{cat}) - (W)_i}{(W_{cat})} \right)^2 + \left(\frac{(QL_{cat}) - (QL)_i}{(QL_{cat})} \right)^2 \quad (16.435)$$

Where

W_{cat} is the catalog power consumption

W is the model power consumption

QL_{cat} is the catalog load side heat transfer

QL is the model load side heat transfer.

Extrapolation beyond the catalog data grants the parameter estimation model an upper hand in comparison with the equation fit and deterministic models. However, the detailed model is computationally more intensive. Moreover, when the model is implemented within a transient system simulation program, it may come across figures that are random and unplanned by the manufacturer such as low water flow rates or extreme temperatures. This oddity may result in unrealistic set of results.

16.6.2.2 Control Strategy

Both water-to-water heat pump models; parameter estimation based model and curve-fit model use the “cycle time control logic” developed by Murugappan (2002).

This strategy keeps the heat pump from short-cycling whereby the heat pump will stay on or off for the specified cycle time after switching states. The control logic is identical to the operation of a physical heat pump whereby the heat pump does not switch between on and off instantly. Refer to Muraggapan (2002) for the further details on the control strategy.

16.6.3 EIR Formulated Plant Loop Heat Pump Model

This section describes the EIR formulated model for plant loop heat pumps, which can be configured as either a water-source or air-source object. (Object names: HeatPump:PlantLoop:EIR:Cooling & HeatPump:PlantLoop:EIR:Heating). In general, these heat pump objects are treated the same as the other heat pump models by the plant loop. Even though a heat pump is generally a single load coil and a single source coil with a reversing valve, in EnergyPlus, the paradigm is to split the operation into two separate coils, a heating and a cooling. It is certainly possible to connect the load side of both of these to a single plant loop if the controls are established properly. For water-source operation the source side of the coils are often placed on a single loop with some form of condensing supply, either a ground loop heat exchanger or a cooling tower (or a combination of the two). For air-source operation, the outdoor air node is used on the source-side inlet node.

Note that this component is currently a constant flow device (it will always request its full design flow from the plant), with a future addition planned to make it respond to outlet setpoint in order to vary the flow request.

The bookkeeping part of the heat pump code with regards to flow requests and nodal conditions is identical to other water-to-water heat pump components, so this section will only briefly discuss the mathematical formulation of the model.

Once load and source flow rates have been established for the component using the SetComponentFlowRate interface to the plant, and inlet temperatures for each side have been read, a function calculates the response of the unit to these conditions. The process to evaluate the outlet state is as follows:

1. Retrieve load side outlet temperature setpoint
2. Take the reference power usage as $P_{reference}$
3. Evaluate the capacity modifier function using the source inlet temperature and the load side setpoint temperature as the projected outlet temperature ($f_{cap} = f(T_{out,load,set}, T_{in,src})$)
4. Calculate available load side capacity using the reference value and the modifier ($\dot{q}_{load,avail} = \dot{q}_{reference} \cdot f_{cap}$)
5. Calculate the part load ratio using the current plant-dispatched load (constrained between zero and one) ($PLR = \frac{\dot{q}_{plant}}{\dot{q}_{avail}}$)
6. Calculate the actual operating load side heat transfer and the load side outlet temperature ($\dot{q}_{load} = \dot{q}_{avail} PLR$, $T_{out,load} = T_{in,load} \pm \frac{\dot{q}_{load}}{\dot{m}_{load} C_{p,load}}$) – note the plus/minus refers to how the value will be added in heating mode and subtracted in cooling mode. This is required because the sign convention is not consistent and a positive value for calculated heat rate will be obtained for both units under normal conditions.

7. Evaluate power usage by evaluating the EIR curves using the source inlet temperature, actual load side outlet temperature, and the current part load ratio ($f_{eir,t} = f(T_{out,load,set}, T_{in,src})$, $f_{eir,plr} = f(PLR)$, $P = P_{reference} f_{eir,t} f_{eir,plr}$)
8. Perform an energy balance on the unit to determine the source side heat transfer rate and the source side outlet temperature ($q_{src} = q_{load} \pm P$, $T_{out,src} = T_{in,src} \pm \frac{\dot{q}_{src}}{\dot{m}_{src} C_{p,src}}$) – again the plus/minus refers to the different behavior between cooling and heating mode.

16.7 Variable Refrigerant Flow Heat Pumps

A Variable Refrigerant Flow (VRF, or Variable Refrigerant Volume) system is an air-conditioning system that varies the refrigerant flow rate using variable speed compressor(s) in the outdoor unit, and the electronic expansion valves (EEVs) located in each indoor unit. The system meets the space cooling or heating load requirements by maintaining the zone air temperature at the setpoint. The ability to control the refrigerant mass flow rate according to the cooling and/or heating load enables the use of as many as 60 or more indoor units with differing capacities in conjunction with one single outdoor unit. This unlocks the possibility of having individualized comfort control, simultaneous heating and cooling in different zones, and heat recovery from one zone to another. It may also lead to more efficient operations during part-load conditions. VRF can be divided into two common types:

- Heat Pump (HP) type: the most general type that can be used for either cooling or heating, but not simultaneously.
- Heat Recovery (HR) type: can deliver simultaneous heating and cooling to different zones by transferring heat between the cooling and heating indoor units. This generally occurs in the winter season in medium-sized to large-sized commercial buildings with a substantial core such as computer rooms.

There are two alternative VRF models available in EnergyPlus to simulate the energy performance of VRF:

1. **System Curve based Model (VRF-SysCurve).** In this model, a number of system level curves are used to describe the VRF system performance. It uses the *AirConditioner:VariableRefrigerantFlow* object to describe both the HP and HR systems.
2. **Physics based Model (VRF-FluidTCtrl).** This model is able to consider the dynamics of more operational parameters and is applicable for fluid temperature control. It uses the *AirConditioner:VariableRefrigerantFlow:FluidTemperatureControl:HP* object for the HP system and *emphAirConditioner:VariableRefrigerantFlow:FluidTemperatureControl:HR* for the HR system.

16.7.1 System Curve based VRF Model (VRF-SysCurve)

16.7.1.1 Overview

This section describes the System Curve based VRF Model (VRF-SysCurve), which can address both the heat pump and heat recovery operating modes and support air-, evaporatively-, or water-

cooled condenser equipment (throughout this section, the term “condenser” refers to the outdoor unit where the compressor is located.)

The figure below schematically depicts the AirConditioner:VariableRefrigerantFlow (VRF AC) system. The outdoor unit is connected directly to the zone terminal units using a zone terminal unit list (ref: ZoneTerminalUnitList). The VRF AC system conditions multiple zones and is controlled by thermostats located in each zone. Zone terminal units operate to meet the zone sensible cooling or sensible heating requirements as determined by the zone thermostat schedule.

When the heat pump does *not* operate to reclaim waste heat, the VRF AC system can only operate in either cooling *or* heating mode. Based on the master thermostat priority control selection, the operating mode is determined by polling the appropriate zone(s) served by the VRF HP system. When the system is operating in cooling mode, the cooling coils will be enabled only in the terminal units where zone cooling is required. When the system is operating in heating mode, the heating coils will be enabled only in the terminal units where zone heating is required. Supply air fans will continue to operate if the zone terminal unit’s fan operating mode is set to continuous fan.

When the heat pump *does* operate to reclaim waste heat, the VRF AC system can simultaneously cool and heat multiple zones. The heat pump will select an operating mode according to the dominant load as reported by the zone thermostat(s). The calculation of the dominant load is based on the master thermostat priority control selection and may either be based on individual zone loads, the number of zones requiring cooling or heating, the master thermostat zone load, or an operating mode schedule. The heat pump will operate in cooling mode, and provide waste heat to zones with a heating load, when the dominant load among all zone terminal units is cooling. The heat pump will operate in heating mode, and absorb heat from zones with a cooling load, when the dominant load among all zone terminal units is heating.

The figure below shows the VRF AC terminal units with draw through fan placement. Blow through fan placement can also be modeled by connecting the supply air fan inlet node to the outside air mixer’s mixed air node if an outdoor air mixer is used or to the zone terminal unit inlet node if an outdoor air mixer is not used. The variable refrigerant flow heat pump coordinates the operation of these components and is modeled as a type of zone equipment where the *zone terminal units* are specified in a zone equipment list (Ref. ZoneHVAC: EquipmentList and ZoneHVAC:EquipmentConnections). The AirConditioner: VariableRefrigerantFlow object *is not* specified in an air primary loop or a zone equipment list object.

The terminal unit is able to model supply air fan operation in two modes: cycling fan – cycling coil (i.e., AUTO fan) and continuous fan – cycling coil (i.e., fan ON). Fan:OnOff must be used to model AUTO fan, while Fan:OnOff or Fan:ConstantVolume can be used to model fan ON.

Output variables reported by the VRF AC object include the heat pump’s operating capacity (cooling or heating), electric consumption, operating COP, defrost electric consumption, part-load ratio (ratio of actual capacity to available capacity), runtime fraction (when cycling), cycling ratio (actual compressor cycling rate), crankcase heater power, and other report variables associated with an evaporative condenser. Report variables are also available to indicate the maximum available terminal unit cooling or heating capacity (i.e., when the condensers available capacity is insufficient to supply the capacity requested by all terminal units). Reporting of other variables of interest for the VRF AC (fan electric power, DX coil cooling rate, DX coil heating rate, terminal unit total cooling rate, etc.) is done by the individual system components (e.g., fan, DX cooling coil, DX heating coil, and zone terminal unit). For convenience, the total cooling and heating coil capacities (i.e., the coil loads) is also reported.

Figure 16.51: Variable Refrigerant Flow Heat Pump (draw through fan placement)

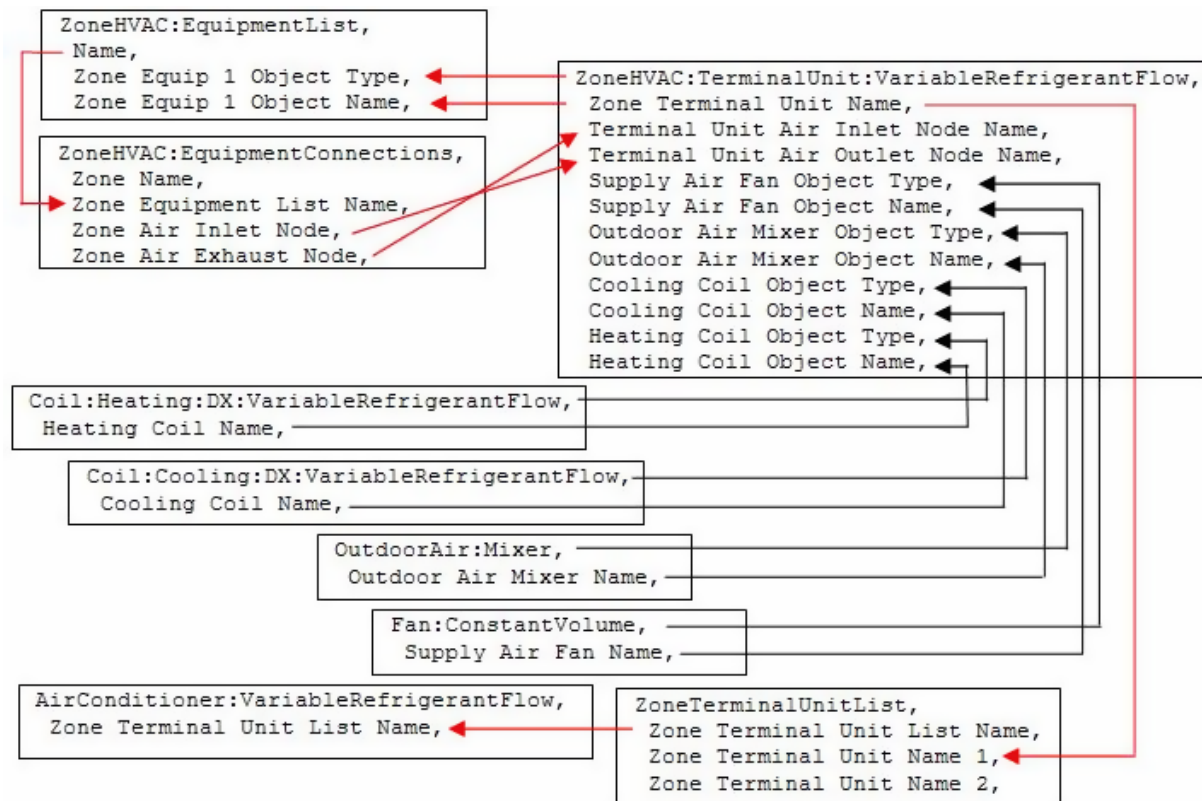

Figure 16.52: Energyplus object connections for VRF-SysCurve model

16.7.1.2 Model Description

As described previously, the VRF AC system conditions multiple zones and is controlled by one or more zone thermostats (ZoneControl:Thermostatic). Each simulation time step, EnergyPlus performs a zone air heat balance to determine if cooling or heating is required to meet each zone's thermostat set point. When heat pump mode is selected (i.e., heat recovery is not selected), an operating mode is chosen based on the master thermostat priority control and all terminal units are operated in that specific mode. When heat recovery mode is selected, the dominant load is determined based on the master thermostat priority control and the outdoor unit operates in this mode. The indoor terminal units operate in either cooling or heating mode based on the individual coil loads. The heat pump condenser is then modeled to determine any impact the condensing unit might have on the zone terminal units (i.e., capacity limitations due to over-sized terminal units, operating limitations due to allowable operating temperature range, impacts of defrost operation, changes in performance when heat recovery mode is active, etc.). The following sections describe the performance calculations for cooling and heating.

16.7.1.3 Cooling Operation

The operating capacity of the heat pump is calculated based on the user defined input for the heat pump's rated cooling capacity, the ratio of indoor terminal unit capacity to outdoor unit capacity (combination ratio), the actual operating conditions, and whether or not the system's heat recovery mode is active. Performance correction factors are used to correct for off-design performance as follows:

16.7.1.4 Cooling Combination Ratio Correction Factor

The cooling combination ratio correction factor is defined as the total terminal unit rated cooling capacity divided by the heat pump's rated cooling capacity. The combination ratio is important when multiple terminal units (or DX coils) are attached to a single variable-speed condensing unit. If the combination ratio is less than 1, the condenser's rated capacity is assumed to be able to meet the indoor terminal unit's demand request. However, if the combination ratio is determined to be greater than 1, the maximum cooling capacity available from the heat pump's condenser may be higher than the user specified rated cooling capacity. The combination ratio capacity correction factor is based on a linear, quadratic or cubic curve and provides a multiplier > 1 to correct for combination ratio's greater than 1. For example, a combination ratio of 1.3 (130%) may result in a combination ratio capacity correction factor of 1.06 (outdoor condenser can actually provide 106% of rated capacity) . The cooling combination ratio correction factor is applied to cooling performance calculations. If the cooling combination ratio correction curve name is not specified by the user, the cooling combination ratio correction factor ($CR_{cooling,correction}$) in the following equation is assumed to be equal to 1.

$$CR_{cooling,rated} = \frac{\sum_1^n \dot{Q}_{coil(i),cooling,rated}}{\dot{Q}_{cooling,total,rated}} \quad (16.436)$$

$$CR_{cooling,correction} = a + b(CR_{cooling,rated}) + c(CR_{cooling,rated})^2 + d(CR_{cooling,rated})^3 \quad (16.437)$$

$$CR_{cooling,correction} = MAX(1.0, CR_{cooling,correction}) \quad (16.438)$$

where:

$\dot{Q}_{coil(i),cooling,rated}$ is the rated total (sensible + latent) cooling capacity in zone i (W)

$\dot{Q}_{cooling,total,rated}$ is the rated total cooling capacity of heat pump (W)

$CR_{cooling,correction}$ is the Cooling Combination Ratio capacity correction factor at rated conditions (this value is reported in the eio file)

$a - d$ are the equation coefficients for cooling combination ratio correction factor

$CR_{cooling,rated}$ is the cooling combination ratio defined as the total indoor terminal unit's rated total cooling capacity divided by the rated total cooling capacity of the heat pump condenser.

The sum of the individual zone total cooling requirements is used to calculate the performance of the outdoor condensing unit. The operating capacities of the indoor cooling coils are calculated based on the indoor cooling coil's rated cooling capacity and the actual operating conditions. The operating capacity of the heat pump condenser is calculated in a similar fashion using a load-weighted average indoor wet-bulb temperature of all operating cooling coils.

16.7.1.5 Cooling Capacity Ratio Modifier Function of Low Temperature

The heat pump's cooling capacity correction factor (function of temperature) is determined by averaging the zone cooling coil inlet air wet-bulb temperature for all operating cooling coils. A load-weighted average inlet air wet-bulb temperature is used in the calculations. The weighted average cooling coil inlet air wet-bulb temperature and the outdoor condenser entering air dry-bulb temperature are then used to calculate the temperature correction factor in cooling mode for the

heat pump condenser. If the *Condenser Type* is WaterCooled, then the cooling capacity curve will be function of weighted average cooling coil inlet air wet-bulb temperature and outdoor condenser entering water temperature. The actual zone air wet-bulb temperature is used to calculate the operating capacity of the individual zone cooling coils.

$$\dot{Q}_{zone,total} = \sum_1^i \dot{Q}_{zone(i)} \quad (16.439)$$

$$T_{wb,avg} = \sum_1^i (T_{wb,i}) \left(\frac{\dot{Q}_{zone(i)}}{\dot{Q}_{zone,total}} \right) \quad (16.440)$$

The operating capacity of the heat pump is calculated using a bi-quadratic equation using a load-weighted average indoor wet-bulb temperature and outdoor dry-bulb temperature as the independent variables.

$$CAPFT_{HP,cooling} = a + b(T_{wb,avg}) + c(T_{wb,avg})^2 + d(T_c) + e(T_c)^2 + f(T_{wb,avg})(T_c) \quad (16.441)$$

The operating capacity of the terminal unit's DX cooling coil is calculated using either a linear, quadratic, or cubic curve. If more information is available to more accurately model the DX cooling coil, a bi-quadratic curve may be used (i.e., if the performance of the DX cooling coil is also a function of outdoor dry-bulb temperature).

$$CAPFT_{coil,cooling} = a + b(T_{wb,i}) + c(T_{wb,i})^2 + d(T_{wb,i})^3 \quad (16.442)$$

or

$$CAPFT_{coil,cooling} = a + b(T_{wb,i}) + c(T_{wb,i})^2 + d(T_c) + e(T_c)^2 + f(T_{wb,i})(T_c) \quad (16.443)$$

where:

$T_{wb,i}$ is the wet-bulb temperature of the air entering the cooling coil in zone i (°C)

$T_{wb,avg}$ is the load-weighted average wet-bulb temperature of the air entering all operating cooling coils (°C)

$\dot{Q}_{zone(i)}$ is the total (sensible + latent) cooling load in zone i (W)

$\dot{Q}_{zone,total}$ is the total (sensible + latent) cooling load in all zones (W)

$CAPFT_{HP,cooling}$ is the heat pump Cooling Capacity Ratio Modifier (function of temperature)

$CAPFT_{coil,cooling}$ is the zone coil Cooling Capacity Ratio Modifier (function of temperature)

$a - f$ are the equation coefficients for Cooling Capacity Ratio Modifier

T_c is the temperature of the air entering an air-cooled or evaporatively-cooled condenser (°C).

16.7.1.6 Using multiple curves to define Cooling Capacity Ratio Modifier

The cooling capacity ratio modifier determines the change in total (sensible + latent) capacity with respect to the heat pump rated cooling capacity. This modifier corrects for off-design performance and provides the operating total (sensible + latent) cooling capacity for the heat pump condenser. The performance data for VRF AC systems may be specified using a single curve object, however, if the performance data does not reflect a smooth change in performance as outdoor conditions

vary, the overall performance of the system may be described using two cooling capacity ratio modifier curves (i.e., a separate curve at low and high outdoor temperatures) and a boundary curve (i.e., the curve defining the separation at specific outdoor temperatures). If the *Condenser Type* is WaterCooled, the cooling capacity and EIR modifier curves may be represented using the low temperature curve input field only.

16.7.1.7 Application of Dual Performance Curves

Two additional inputs are available to more accurately model the cooling performance of a VRF AC system. The first additional input is a boundary curve which is used to distinguish differences in performance at “low” and “high” outdoor temperature regions and the second input is a cooling capacity performance curve for the “high” outdoor temperature region. The boundary curve is a linear, quadratic or cubic curve defining the outdoor temperature as a function of average indoor wet-bulb temperature. The cooling capacity ratio function of high temperature curve is a biquadratic curve using average indoor wet-bulb temperature and outdoor dry-bulb temperature as the two independent variables. These additional curves are used to define the performance over two separate performance regions as shown in Figure 16.54. The red circles in the figure identify the points at which the performance changes abruptly (i.e., slopes or shapes are significantly different) and are used to create the boundary curve. The performance on either side of the boundary curve can be a smooth curve changing with outdoor condition or a flat plateau where system controls maintain a constant operating condition. This type of performance cannot be accurately simulated using a single performance curve object. For this reason, dual capacity performance curves may be used.

Note: If the cooling performance can be described using a single performance curve object, the boundary and high temperature performance curve objects are not required.

Manufacturers may also provide this information in a tabular format. In this case the data should first be graphically displayed to identify any non-linearities and to also identify where an abrupt change in performance occurs so that a boundary curve can be created.

The cooling capacity ratio boundary curve object is used to differentiate between dual cooling capacity ratio performance curves. This curve defines the outdoor temperature below which the cooling capacity ratio function of low temperature curve object is used, otherwise, the cooling capacity ratio function of high temperature curve object is used.

$$T_{OA,DB} = a + b(T_{I,WB}) + c(T_{I,WB})^2 + d(T_{I,WB})^3 \quad (16.444)$$

where:

$T_{OA,DB}$ is the outside air dry-bulb temperature (°C)

a-d are the coefficients for cooling capacity ratio boundary curve object

$T_{I,WB}$ is the weighted average indoor wet-bulb temperature (°C).

For the performance data shown below in Figure 16.53, the boundary curve would be created by identifying the outdoor dry-bulb temperature at which the performance changed abruptly for each of the indoor wet-bulb temperature curves shown in the figure. The following example shows the data interpreted from the figure used to regress the cooling capacity ratio boundary curve coefficients. For this example, the regression coefficients were found to be: A1 = 29.87396, B1 = -0.6928, C1 = 0.01928, D1 = -0.000532.

Although the capacity and energy performance curves each have an independent boundary curve input, in this example the same boundary curve may be used for both the capacity and energy input ratio curves. When the “low” and “high” predicted performance data do not line up at the boundary

Separation Curve		OAT = A1 + B1*IWB + C1*IWB^2 + D1*IWB^3				
OAT	IWB	IWB^2	IWB^3	Predicted		
17	24	576	13824	17.00148		
18.3	22	484	10648	18.30193		
19.5	20	400	8000	19.47593		
20.5	18	324	5832	20.54898		
21.6	16	256	4096	21.54659		
22	15	225	3375	22.02509		

Figure 16.53: Performance Data for Variable Refrigerant Flow Air Conditioner Model

curve points, the boundary curve may have to be modified slightly to allow a smooth transition in performance from the “low” to “high” temperature region. In this case, the boundary curves for capacity and energy may be different.

A regression is then performed on the data to the left of the boundary curve to calculate the low temperature cooling performance curve coefficients. A regression is also performed on the data to the right of the boundary curve to create the high temperature cooling performance curve coefficients. The model then uses the boundary curve to determine which performance curve (low or high) to use during the simulation. For example, given a particular average indoor wet-bulb temperature, if the boundary curve object calculates an outdoor dry-bulb temperature that is above the actual outdoor dry-bulb temperature then the cooling capacity ratio function of low temperature performance curve is used to determine AC system performance for that specific simulation time step. When creating the boundary curve, be careful to make sure the low and high performance curves meet, as closely as possible, at the boundary curve points (i.e., that discontinuities do not exist or are minimized to the extent possible). Tabular data may also be used to specify performance and will usually eliminate the need for dual performance curves.

16.7.1.8 Determining Cooling Coil Sensible Capacity

The zone terminal unit’s cooling coil is controlled by a zone thermostat and must meet a zone “sensible” load. The cooling coil’s sensible capacity is defined as the cooling coil’s total capacity multiplied by the coil’s sensible heat ratio (SHR) at the current operation conditions. Since the SHR of the variable refrigerant flow cooling coil changes as the inlet air wet-bulb temperature and the operating part-load ratio change, an iterative solution technique must be used to determine the coil’s sensible capacity. The target solution is found when the sensible capacity of the zone cooling coil equals the zone sensible cooling load (if sufficient capacity is available). The iterative solution converges when the difference (error) between the zone sensible cooling load and the terminal unit sensible cooling capacity is within tolerance (0.001) or the terminal unit has insufficient capacity to meet the zone sensible cooling load. Refer to the description of the VRF cooling coil model for further details (ref: Variable Refrigerant Flow Cooling Coil).

$$\dot{Q}_{coil(i),cooling,total} = \dot{Q}_{coil(i),cooling,rated} (CAPFT_{coil,cooling}) \quad (16.445)$$

$$PLR_i = 1 \quad (16.446)$$

Figure 16.54: Non-Linear Performance of VRF Heat Pump in Cooling Mode

Iteration Loop (PLR_i)

$$SHR_{PLR} = f(T_{wb,i}, PLR_i, \dot{m}_i)$$

$$\dot{Q}_{coil(i),cooling,sensible} = \dot{Q}_{coil(i),cooling,total} (SHR_{PLR}) (PLR_i) \quad (16.447)$$

$$Error = (\dot{Q}_{zone(i)} - \dot{Q}_{coil(i),cooling,sensible}) / \dot{Q}_{zone(i)}$$

End Iteration Loop

where:

$\dot{Q}_{coil(i),cooling,total}$ is the zone terminal unit total (sensible + latent) cooling capacity (W), report variable “Zone VRF Air Terminal Total Cooling Rate”

$\dot{Q}_{coil(i),cooling,sensible}$ is the zone terminal unit sensible cooling capacity (W), report variable “Zone VRF Air Terminal Sensible Cooling Rate”

PLR_i is the cooling coil sensible part-load ratio in zone i

SHR_{PLR} is the cooling coil sensible heat ratio (function of PLR, inlet air wet-bulb temperature, and cooling coil inlet air mass flow rate)

\dot{m}_i is the cooling coil inlet air mass flow rate (m³/s).

The terminal unit total cooling (sensible + latent) capacity is then summed to provide the total terminal unit cooling requirement. The cooling coils capacity includes the impacts of fan heat and any outdoor air provided to the zone.

$$\dot{Q}_{cooling,TerminalUnits} = \sum_1^i (\dot{Q}_{coil(i),cooling,total}) (PLR(i)) \quad (16.448)$$

where $\dot{Q}_{cooling,TerminalUnits}$ is the total terminal unit cooling requirement (sensible + latent) in all zones (W).

The piping correction factor is then used to adjust the total zone cooling requirement to account for piping losses in the air conditioner’s refrigeration piping system.

16.7.1.9 Cooling Piping Correction Factor in cooling mode

The cooling piping correction factor is calculated using either one or two independent variables. Both the equivalent piping length and the combination ratio are used together to determine piping losses, or the equivalent piping length itself is used. The vertical height specified by the user is also added to the result calculated by either. If a single independent variable is used, a linear, quadratic, or cubic equation is used to determine the equivalent length correction factor. If two independent variables are used, a biquadratic equation is used to determine the equivalent length correction factor. The program will automatically use the correct equation based on the performance curve type. In either case, a single coefficient adjusts the piping correction factor based on the difference in height from the highest to lowest terminal unit. Coefficients a-d (e) in the following equation(s) are inputs in the piping correction factor for length in cooling mode performance curve object. Coefficient f is a direct input to the VRF model as the piping correction factor for height in cooling mode coefficient. The equivalent piping length in cooling mode ($P_{EQ,cooling}$) is also a direct input in the VRF model. The cooling combination ratio ($CR_{cooling}$) is automatically calculated by the program. The vertical height, the difference between the highest and lowest terminal unit (e.g., 12 m higher than condenser – 3 m lower than condenser = 9 m height), is a common input for both cooling and heating. When all terminal units are above or below the outdoor unit, an average

positive or negative value is used. The limits on the calculated cooling piping correction factor are $0.5 < P_{correction,cooling} < 1$.

$$CR_{cooling} = \frac{\sum_{i=1}^n \dot{Q}_{coil(i),cooling,rated}}{\dot{Q}_{cooling,total,rated}} \quad (16.449)$$

$$P_{correction,cooling} = a + b(P_{EQ,cooling}) + c(P_{EQ,cooling})^2 + d(P_{EQ,cooling})^3 + f(P_H) \quad (16.450)$$

or

$$P_{correction,cooling} = a + b(P_{EQ,cooling}) + c(P_{EQ,cooling})^2 + d(CR_{cooling}) + e(CR_{cooling})^2 + f(P_{EQ,cooling})(CR_{cooling}) + g(P_H) \quad (16.451)$$

where:

$P_{correction,cooling}$ is the Piping Correction Factor in Cooling Mode

$a - f$ are equation coefficients for piping correction factor in cooling mode

g is the user specified piping correction factor for height in cooling mode coefficient

$P_{EQ,cooling}$ is the user specified equivalent piping length in cooling mode (m)

$CR_{cooling}$ is the combination ratio in cooling mode (total rated indoor terminal unit capacity divided by the rated condenser cooling capacity) (reported to eio file)

P_H is the user specified vertical height used for piping correction factor calculation (m).

An example piping correction factor chart is shown in the following figure. The height selected for use in the equation above is selected to minimize the piping correction factor and serves to identify the worst case piping losses.

Figure 16.55: Typical Piping Factor Correction Chart

The total demand on the heat pump condenser is then calculated as the quotient of the total terminal unit cooling capacity and the cooling piping correction factor. The piping losses are fixed throughout the simulation (i.e., these losses are not based on which terminal units are requesting refrigerant).

$$\dot{Q}_{cooling,total} = \frac{\dot{Q}_{cooling,TerminalUnits}}{P_{correction,cooling}} \quad (16.452)$$

The heat pump's total available cooling capacity is then calculated as:

$$\dot{Q}_{HP,cooling,total} = \dot{Q}_{cooling,total,rated} (CAPFT_{HP,cooling}) (CR_{cooling,correction}) \quad (16.453)$$

where:

$\dot{Q}_{cooling,total}$ is the total heat pump condenser cooling load (W)

$\dot{Q}_{HP,cooling,total}$ is the heat pump total available cooling capacity (W).

16.7.1.10 Heat-Recovery-Cooling-Capacity-Modifier

When operating in heat recovery mode, the heat pump's available cooling capacity is typically different than the available capacity when operating in cooling only mode. This modifier is used to adjust the available cooling capacity using a fraction when heat recovery is active. This fraction is based on a bi-quadratic equation with weighted average indoor temperature (i.e., the indoor terminal units weighted average inlet temperatures) and outdoor temperatures used as the independent terms.

$$HRCapMod_{HP,cooling} = a + b(T_{ent}) + c(T_{ent})^2 + d(T_{cond}) + e(T_{cond})^2 + f(T_{ent})(T_{cond}) \quad (16.454)$$

This equation can be used to provide a constant fractional difference for available cooling capacity in heat recovery mode (i.e., only a is non-zero) or a fractional term that varies with indoor and outdoor conditions. With very limited performance data available at this time, it is recommended that only the constant (a) term be used at this time. When the VRF system is not operating in heat recovery mode, this fraction is set to 1. The available cooling capacity in heat recovery mode is then:

$$\dot{Q}_{HR,cooling,total} = \dot{Q}_{HP,cooling,total} (HRCapMod_{HP,cooling}) \quad (16.455)$$

where $\dot{Q}_{HR,cooling,total}$ = heat recovery total available cooling capacity (W).

The figure below shows VRF system laboratory data for cooling only mode (solid characters) and heat recovery mode (dotted characters). Using the limited laboratory data, the available cooling capacity fraction used to model heat recovery mode is approximately 0.91 and the cooling energy fraction is approximately 1.14. This is the only data available at this time to estimate the impact of heat recovery mode on performance. In the bi-quadratic equation, only coefficient a should be used until more complete data sets exist. Laboratory testing will eventually provide more data and better estimates of performance in heat recovery mode.

16.7.1.11 Transition from Cooling Only mode to Heat Recovery mode

When the VRF system transitions from cooling only operation to heat recovery operation, this transition takes some finite amount of time. During the transition period the available cooling capacity can change significantly. The following figure illustrates the transition between cooling only mode and heat recovery mode. For this test, the VRF system was turned on and allowed to reach steady-state operation. Three of the four indoor terminal units were operating in cooling mode. When the fourth terminal unit was enabled in heating mode, the transition from cooling only mode to heat recovery mode took approximately 45 minutes. During this time, the available cooling is significantly reduced and recovers over time. When the system again reaches steady-state

Figure 16.56: Comparison of cooling only and heat recovery mode operation

operation, the available cooling capacity and power consumption are markedly different. Although computer models do not typically simulate this type of transitional performance, efforts to model this aspect of performance were included in the VRF AC heat recovery model. The initial heat recovery cooling capacity fraction and heat recovery cooling capacity time constant are used to model this transition period. The initial heat recovery cooling capacity fraction identifies the fraction of available heat recovery mode cooling capacity at the start of the transition period, the heat recovery cooling capacity time constant identifies the time needed to recover to 99% of the steady-state value. This exponential model used for simulating the transition period can be turned off by setting the initial heat recovery cooling capacity fraction to 1.

16.7.1.12 Heat Recovery Cooling Capacity Fraction and Time Constant

When the heat pump changes operating modes (i.e., from cooling only to heat recovery mode), the transition does not happen immediately. There is a time delay, and a period of time where the available cooling capacity is well below the steady-state capacity available after the system has had time to adjust. When this type of transition is modeled, an exponential decay curve is used. At the start of the transition period, only a fraction (k_{cool}) of the steady-state capacity in heat recovery mode is available. The remaining capacity is recovered over a period of 5 time constants (t_c) and is modeled with the following equation. This equation was used to replicate both the cooling capacity and condenser power curves in the previous figure.

$$\dot{Q}_{HR,avail,cooling} = k_{cool} \left(\dot{Q}_{HR,cooling,total} \right) + (1 - k_{cool}) \left(\dot{Q}_{HR,cooling,total} \right) (1 - e^{(-t/\tau_c)}) \quad (16.456)$$

Figure 16.57: Laboratory test identifies performance changes during transition period

where:

k_{cool} is the fraction of steady-state capacity at beginning of heat recovery mode

t_c is the time constant to reach steady-state operation, 5 time constants equals 99% of steady-state capacity (hr)

$\dot{Q}_{HR,avail,cooling}$ is the available cooling capacity in heat recovery mode (W)

$\left(1 - e^{(-t/t_{c,cool})}\right)$ is the multiplier used during the transition period from cooling mode to heat recovery mode. This multiplier can be viewed using the report variable “VRF Heat Pump Heat Recovery Status Change Multiplier” (ref: object Output:Variable).

The operating part-load ratio of the VRF system can then be calculated:

$$PLR = \frac{\dot{Q}_{cooling,total}}{\dot{Q}_{HR,avail,cooling}} \quad (16.457)$$

where PLR is the heat pump part-load ratio, report variable “VRF Heat Pump Part Load Ratio”.

Note: for calculation purposes $\dot{Q}_{HR,avail,cooling}$ is equivalent to $\dot{Q}_{HR,cooling,total}$ when heat recovery mode is not active.

The heat pump total available cooling capacity must be greater than or equal to the total cooling capacity requested by the zone terminal units. When the total operating capacity of all terminal unit's will be greater than the available operating capacity of the heat pump condenser, one or more of the terminal unit's operating capacity must be reduced to the point where the sum of the indoor terminal unit demand request plus piping losses is equal to the total available cooling capacity of the outdoor condenser. At this point, the part-load ratio of the heat pump condenser will be equal to 1.

A maximum terminal unit cooling capacity limit is used to restrict the cooling capacity of each indoor terminal unit. The capacity limit is equivalent to a maximum allowed operating capacity for all zone terminal units. This limit is used to conserve energy between multiple indoor terminal units and a single outdoor condensing unit. Assuming no terminal unit can provide more capacity than can be delivered by the outdoor condenser, the terminal unit total cooling capacity calculation previously discussed is revised as follows:

$$\dot{Q}_{coil(i),cooling} = \sum_1^i MIN \left(\left(\dot{Q}_{coil(i),cooling,total} \right) (PLR(i)), CoolingCapacityLimit \right) \quad (16.458)$$

where $CoolingCapacityLimit(CL_{cooling})$ is the report variable (ref: Output:Variable) describing the “VRF Heat Pump Maximum Capacity Cooling Rate” (W).

When multiple terminal units are operating, the terminal units near their maximum capacity are more likely to be capacity limited than those terminal units operating well below their available capacity. The assumption here is that terminal units that are not capacity limited can provide more refrigerant to meet the same load. When the model finds that there is no terminal unit capacity limit, this variable will report 1E+20 indicating that no limit exists. The figure below demonstrates the application of the capacity limit factor for the case where all indoor terminal units are operating at different capacities. A solution is reached when the sum of the indoor terminal unit’s cooling capacities (accounting for piping losses) is equal to the heat pump condenser’s available cooling capacity.

When the heat pump’s part-load ratio is less than 1 (i.e., the total capacity of all terminal unit’s is less than the actual operating capacity of the heat pump condenser), the heat pump’s part-load ratio is compared to the minimum heat pump part-load ratio. If the heat pump’s part-load ratio is less than the minimum heat pump part-load ratio, the heat pump will cycle on and off to meet the cooling load. A correction factor is used to account for startup losses of the compression system.

Cooling Part-Load Fraction Correlation (function of cycling ratio)

The cooling part-load fraction correlation (function of heat pump cycling ratio) is a linear, quadratic or cubic curve with the independent variable being cycling ratio (part-load ratio / minimum part-load ratio). The output of this curve is used in combination with the rated EIR and EIR modifier curves to give the “effective” EIR for a given simulation time step.

$$CyclingRatioFrac = a + b (CyclingRatio) + c (CyclingRatio)^2 + d (CyclingRatio)^3 \quad (16.459)$$

where:

$$CyclingRatio = \frac{PLR}{PLR_{min}} \quad (16.460)$$

a-c (d) are the coefficients for the quadratic (cubic) cycling ratio correlation curve equation.

The cycling ratio can be viewed using the report variable “VRF Heat Pump Cycling Ratio” (ref: Output:Variable).

The cooling part-load ratio correlation should be normalized to a value of 1.0 when the cycling ratio equals 1.0 (i.e., no efficiency losses when the heat pump runs continuously [$PLR \geq PLR_{min}$] for the simulation time step). For cycling ratio values between 0 and 1 ($0 \leq CyclingRatio < 1$), the following rules apply:

Figure 16.58: Example of Cooling Capacity Limit

$CyclingRatioFrac \geq 0.7$ and $CyclingRatioFrac \geq CyclingRatio$

If $CyclingRatioFrac < 0.7$ a warning message is issued, the program resets the $CyclingRatioFrac$ value to 0.7, and the simulation proceeds. The runtime fraction of the heat pump is defined as $CyclingRatio/CyclingRatioFrac$. If $CyclingRatioFrac < CyclingRatio$, the runtime fraction will exceed 1. In this case a warning message is issued and the runtime fraction of the heat pump is limited to 1.0.

$$Heat\ Pump\ Runtime\ Fraction\ (HPRTF) = \frac{CyclingRatio}{CyclingRatioFrac} \quad (16.461)$$

The heat pump runtime fraction can be viewed using the report variable “VRF Heat Pump Runtime Fraction” (ref: Output:Variable).

Since manufacturers data do not typically provide information defining the cycling losses of VRF AC systems, a typical part-load fraction correlation for a conventional DX refrigeration system (e.g., residential or small commercial unit) may be substituted here as:

$$CyclingRatioFrac = 0.85 + 0.15(CyclingRatio) \quad (16.462)$$

The electrical power consumed by the heat pump condenser is then calculated based on the heat pump’s rated electric power consumption (including condenser fan power), the actual operating conditions, and the cycling ratio of the refrigeration system. Performance correction factors are used here to correct for off-design performance as follows:

16.7.1.13 Cooling Energy Input Ratio Modifier Function of Low Temperature

As described previously (Ref. Application of Dual Performance Curves), the cooling energy input ratio modifier curve can either be applied as a single curve object as shown below, or applied using dual performance curve objects. If the *Condenser Type* is WaterCooled, then the cooling energy input ratio modifier curve will be function of weighted average indoor air wet-bulb temperature and outdoor condenser entering water temperature. The equation form used for a single or dual performance curve application is shown here.

$$EIRFT_{cooling} = a + b(T_{wb,avg}) + c(T_{wb,avg})^2 + d(T_c) + e(T_c)^2 + f(T_{wb,avg})(T_c) \quad (16.463)$$

where $EIRFT_{cooling}$ is the cooling energy input ratio modifier (function of temperature).

16.7.1.14 Cooling Energy Input Ratio Modifier Function of Part-Load Ratio

The cooling energy input ratio calculation is based on 2 EIR curves. One is used when the heat pump part-load ratio is less than or equal to 1, and a second curve is used to describe the variation of cooling energy input ratio when the part-load ratio is greater than 1. The part-load ratio curve when $PLR > 1$ is not a required input and when not used, the energy use is assumed to be constant when $PLR > 1$.

$$\begin{aligned} &IF (PLR \leq 1) THEN \\ &\quad EIRFPLR_{cooling} = a + b(PLR) + c(PLR)^2 + d(PLR)^3 \\ &ELSE \\ &\quad EIRFPLR_{cooling} = e + f(PLR) + g(PLR)^2 + h(PLR)^3 \end{aligned} \quad (16.464)$$

where:

$EIRFPLR_{cooling}$ is the cooling energy input ratio correction factor (function of part-load ratio)

a-d are the coefficient for cooling energy input ratio correlation when part-load ratio ≤ 1

e-h are the coefficient for cooling energy input ratio correlation when part-load ratio > 1 .

The total power consumed by the heat pump condenser in cooling mode is based on the user specified coefficient of performance (COP) and calculated as:

$$CoolingPower = \left(\frac{\dot{Q}_{cooling,total,rated} CAPFT_{cooling}}{COP_{cooling,reference}} \right) (EIRFT_{cooling}) (EIRFPLR_{cooling}) (HPRTF) \quad (16.465)$$

The cooling COP is then calculated as the ratio of the outdoor unit cooling capacity divided by the total electric consumption rate of all components associated with the outdoor unit. Although included in the equation, defrost power is typically 0 during cooling mode operation.

$$COP_{cooling} = \frac{\dot{Q}_{cooling,total}}{CoolingPower + P_{CrankCaseHeater} + P_{EvapCoolerPower} + P_{defrost}} \quad (16.466)$$

where:

$COP_{cooling}$ is the operating coefficient of performance, report variable “VRF Heat Pump Cooling COP”

$CoolingPower$ is the operating electric consumption rate (W), report variable “VRF Heat Pump Cooling Electric Power”

$P_{CrankcaseHeater}$ is the report variable for electric consumption rate of crankcase heater (W)

$P_{EvapCoolerPump}$ is the report variable for electric consumption rate of evaporatively-cooled condenser water pump (W)

$P_{defrost}$ is the report variable for average defrost power for the simulation time step (W).

When operating in heat recovery mode, equations similar to those used for available cooling capacity are used to model heating electric consumption rate.

$$HREIRMod_{HP,cooling} = a + b(T_{ent}) + c(T_{ent})^2 + d(T_{cond}) + e(T_{cond})^2 + f(T_{ent})(T_{cond}) \quad (16.467)$$

This equation can be used to provide a constant fractional difference for cooling electric consumption rate in heat recovery mode (i.e., only a is non-zero) or a fractional term that varies with indoor and outdoor conditions. With very limited performance data available at this time, it is recommended that only the constant (a) term be used at this time. When the VRF system is not operating in heat recovery mode, this fraction is set to 1. The cooling electric consumption rate in heat recovery mode is then:

$$CoolingPower_{HR} = CoolingPower (HREIRMod_{HP,cooling}) \quad (16.468)$$

$$Power_{HR} = k_{EIR,cool} (CoolingPower_{HR}) + (1 - k_{EIR,cool}) (CoolingPower_{HR}) \left(1 - e^{(-t/\tau_{c,EIR,cool})} \right) \quad (16.469)$$

where:

$k_{EIR,cool}$ is the fraction of steady-state cooling electric consumption rate at beginning of heat recovery mode

$\tau_{c,EIR,cool}$ is the time constant to reach steady-state operation, 5 time constants equals 99% of steady-state capacity (hr)

$CoolingPower_{HR}$ is the cooling electric consumption rate in heat recovery mode (W)

$(1 - e^{(-t/\tau_{c,EIR,cool})})$ is the multiplier used during the transition period from cooling mode to heat recovery mode. This multiplier can be viewed using the report variable “VRF Heat Pump Heat Recovery Status Change Multiplier” (ref: Output:Variable).

16.7.1.15 Heating Operation

Calculations of the heat pump’s heating performance is nearly identical to the calculations described above for cooling operation.

The sum of the individual zone total heating requirements are used to calculate the performance of the outdoor condensing unit. The operating capacity of the indoor heating coils are calculated based on the indoor heating coil’s nominal heating capacity and the actual operating conditions. A capacity correction factor is used to correct for off-design performance as follows:

Heating Combination Ratio Correction Factor (function of capacity ratio)

The heating combination ratio correction factor is defined as the total terminal unit rated heating capacity divided by the heat pump’s rated heating capacity. In some instances, the cooling combination ratio may be used to define the correction factor used to modify the heat pump’s rated heating capacity and is manufacturer specific. The combination ratio is important when multiple terminal units (or DX coils) are attached to a single variable-speed condensing unit. If the combination ratio is less than 1, the condenser has sufficient capacity to meet the indoor terminal unit’s capacity request. However, if the combination ratio is determined to be greater than 1, the maximum heating capacity available from the heat pump’s condenser may be higher than the user specified rated heating capacity. The combination ratio capacity correction factor is based on a linear, quadratic or cubic curve and provides a multiplier > 1 to correct for combination ratio’s greater than 1. For example, a combination ratio of 1.3 (130%) may result in a combination ratio capacity correction factor of 1.06 (outdoor condenser can actually provide 106% of rated capacity). The heating combination ratio correction factor is applied to heating performance calculations. If the heating combination ratio correction curve name is not specified by the user, the heating combination ratio correction factor ($CR_{heating,correction}$) in the following equation is assumed to be equal to 1.

$$CR_{heating} = \frac{\sum_{i=1}^n \dot{Q}_{coil(i),heating,rated}}{\dot{Q}_{heating,total,rated}} \quad (16.470)$$

$$CR_{heating,correction} = a + b(CR_{heating}) + c(CR_{heating})^2 + d(CR_{heating})^3 \quad (16.471)$$

$$CR_{heating,correction} = MAX(1.0, CR_{heating,correction}) \quad (16.472)$$

where:

$\dot{Q}_{coil(i),heating,rated}$ is the rated total heating capacity in zone i (W)

$\dot{Q}_{heating,total,rated}$ is the rated total heating capacity of heat pump (W)

$CR_{heating,correction}$ is the heating Combination Ratio capacity correction factor at rated conditions
 $a - d$ are the cubic equation coefficients for heating combination ratio correction factor

$CR_{heating}$ is the combination ratio in heating mode (total rated indoor terminal unit capacity divided by the rated condenser heating capacity) (reported to eio file).

16.7.1.16 Heating Capacity Ratio Modifier (function of temperature)

As described previously (Ref. Application of Dual Performance Curves), the heating capacity ratio modifier curve can either be applied as a single curve object as shown below, or applied using dual performance curve objects. The single curve object application is described here.

The heat pump's heating capacity ratio modifier (function of temperature) is determined by averaging the zone heating coil inlet air dry-bulb temperature for all operating heating coils. A zone load-weighted average is used when calculating the performance of the heat pump condenser. This weighted-average heating coil inlet air dry-bulb temperature and the outdoor condenser entering air wet-bulb temperature are then used to calculate the heat pump's temperature correction factor in heating mode.

Note that some manufacturers do not provide performance data as a function of outdoor wet-bulb temperature. In this case, substituting outdoor dry-bulb temperature is permitted and the Heating Performance Curve Outdoor Temperature Type input should be specified as DryBulbTemperature. This also means that performance curve coefficients for both capacity (CAPFT) and energy (EIRFT) should be calculated using indoor and outdoor dry-bulb temperature.

$$T_{db,avg} = \sum_1^i (T_{db,i}) \left(\frac{\dot{Q}_{zone(i)}}{\dot{Q}_{zone,total}} \right) \quad (16.473)$$

$$CAPFT_{HP,heating} = a + b(T_{db,avg}) + c(T_{db,avg})^2 + d(T_c) + e(T_c)^2 + f(T_{db,avg})(T_c) \quad (16.474)$$

$$CAPFT_{coil,heating} = a + b(T_{db,i}) + c(T_{db,i})^2 + d(T_c) + e(T_c)^2 + f(T_{db,i})(T_c) \quad (16.475)$$

where:

$T_{db,i}$ is the dry-bulb temperature of the air entering the heating coil in zone i (°C)

$T_{db,avg}$ is the weighted-average dry-bulb temperature of the air entering all operating heating coils (°C)

$CAPFT_{heating}$ is the heating Capacity Correction Factor (function of temperature)

$a - f$ are the bi-quadratic equation coefficients

T_c is the wet-bulb temperature of the air entering an air-cooled condenser (°C).

The total terminal unit heating capacity required is the simple sum of the terminal unit capacity. If the heat pump is off or there is no zone heating requirement, the terminal unit total heating requirement will be zero. The heating coils capacity includes the impacts of fan heat and any outdoor air provided to the zone.

$$\dot{Q}_{heating,TerminalUnits} = \sum_1^i \left(\dot{Q}_{coil(i),heating,total} \right) (PLR(i)) \quad (16.476)$$

where:

$\dot{Q}_{heating,TerminalUnits}$ is the heat pump's outdoor condenser total zone heating requirement (W)

$\dot{Q}_{coil(i),heating,total}$ is the zone terminal unit total heating capacity (W), report variable “Zone VRF Air Terminal Total Heating Rate”.

The piping correction factor is then used to adjust the zone heating requirement to account for piping losses in the AC refrigeration system.

16.7.1.17 Piping Correction Factor in heating mode

The piping correction factor in heating mode is calculated based on the length of the farthest terminal unit and the difference in height from the highest to lowest terminal unit. The piping losses are fixed throughout the simulation (i.e., these losses are not based on which terminal units are requesting refrigerant). Coefficients a-f in the following equations are inputs in the piping correction factor for length in heating mode curve object. The curve may use either one or two independent variables. Coefficient g is a direct input to the VRF model as piping correction factor for height in heating mode coefficient. The equivalent piping length in heating mode ($P_{EQ,heating}$) is also a direct input in the VRF model. The vertical height (P_H), the difference between the highest and lowest terminal unit (e.g., 12 m higher than condenser – 3 m lower than condenser = 9 m height), is a common input for both cooling and heating.

$$P_{correction,heating} = a + b(P_{EQ,heating}) + c(P_{EQ,heating})^2 + d(P_{EQ,heating})^3 + g(P_H) \quad (16.477)$$

or

$$P_{correction,heating} = a + b(P_{EQ,heating}) + c(P_{EQ,heating})^2 + d(CR_{heating}) + e(CR_{heating})^2 + f(P_{EQ,heating})(CR_{heating}) + g(P_H) \quad (16.478)$$

where:

$P_{correction,heating}$ is the piping correction factor in heating mode

a-f are the equation coefficients for piping correction factor in heating mode

g is the user specified piping correction factor for height in heating mode coefficient

$P_{EQ,heating}$ is the equivalent piping length for heating specified by the user (m)

P_H is the user specified vertical height used for piping correction factor (m).

The heat pump's total available heating capacity is then determined using the previously described modifiers.

$$\dot{Q}_{HP,heating,total} = \dot{Q}_{heating,total,rated} (CAPFT_{HP,heating}) (CR_{heating,correction}) \quad (16.479)$$

16.7.1.18 Heat Recovery Heating Capacity Modifier

When operating in heat recovery mode, the heat pump's available heating capacity is typically different than the available capacity when operating in heating only mode. This modifier is used to adjust the available heating capacity using a fraction when heat recovery is active. This fraction is based on a bi-quadratic equation with weighted average indoor temperature (i.e., the indoor terminal units weighted average inlet temperatures) and outdoor temperatures used as the independent terms.

$$HRCapMod_{HP,heating} = a + b(T_{ent}) + c(T_{ent})^2 + d(T_{cond}) + e(T_{cond})^2 + f(T_{ent})(T_{cond}) \quad (16.480)$$

This equation can be used to provide a constant fractional difference for available heating capacity in heat recovery mode (i.e., only a is non-zero) or a fractional term that varies with indoor and outdoor conditions. With very limited performance data available at this time, it is recommended that only the constant (a) term be used at this time. The available heating capacity in heat recovery mode is then:

$$\dot{Q}_{HR,heating,total} = \dot{Q}_{HP,heating,total} (HRCapMod_{HP,heating}) \quad (16.481)$$

16.7.1.19 Transition from Heating Only mode to Heat Recovery mode

When the VRF system transitions from heating only operation to heat recovery operation, this transition takes some finite amount of time. During the transition period the available heating capacity can change significantly. As described for the transition from cooling only operating to heat recovery mode, the initial heat recovery heating capacity fraction and heat recovery heating capacity time constant are used to model the transition from heating only mode to heat recovery mode. The initial heat recovery heating capacity fraction identifies the fraction of available heat recovery mode heating capacity at the start of the transition period, the heat recovery heating capacity time constant identifies the time needed to recover to 99% of the steady-state value. This exponential model used for modeling the transition period can be turned off by setting the initial heat recovery heating capacity fraction to 1.0.

16.7.1.20 Heat Recovery Heating Capacity Fraction and Time Constant

When the heat pump changes operating modes (i.e., from heating only to heat recovery mode), the transition does not happen immediately. There is a time delay, and a period of time where the available heating capacity is different from the steady-state capacity available after the system has had time to adjust. When this type of transition is modeled, an exponential decay curve is used. At the start of the transition period, only a fraction (k_{heat}) of the steady-state capacity in heat recovery mode is available. The remaining capacity is recovered over a period of 5 time constants ($t_{c,heat}$) and is modeled with the following equation. This equation was used to replicate both the cooling capacity and condenser power curves in the previous figure.

$$\dot{Q}_{HR,avail,heating} = k_{heat} \left(\dot{Q}_{HR,heating,total} \right) + (1 - k_{heat}) \left(\dot{Q}_{HR,heating,total} \right) \left(1 - e^{(-t/\tau_{c,heat})} \right) \quad (16.482)$$

where:

k_{heat} is the fraction of steady-state heating capacity at beginning of heat recovery mode

$\tau_{c,heat}$ is the time constant to reach steady-state operation, 5 time constants equals 99% of steady-state capacity (hr)

$\dot{Q}_{HR,avail,heating}$ is the available heating capacity in heat recovery mode (W)

$\left(1 - e^{(-t/\tau_{c,heat})} \right)$ is the multiplier used during the transition period from heating mode to heat recovery mode. This multiplier can be viewed using the report variable “VRF Heat Pump Heat Recovery Status Change Multiplier” (ref: Output:Variable).

16.7.1.21 Defrost Energy Input Ratio Modifier (function of temperature)

The defrost energy input ratio (EIR) modifier curve (function of temperature) is a bi-quadratic curve with two independent variables: heating coil average entering air wet-bulb temperature and outdoor air dry-bulb temperature. The output of this curve is multiplied by the heating coil capacity, the fractional defrost time period and the runtime fraction of the heating coil to give the defrost power at the specific temperatures at which the coil is operating. The use of outdoor wet-bulb temperature is explicit in this curve object and the defrost equation below and is independent of the selection for Heating Performance Curve Outdoor Temperature Type.

$$DefrostEIRTempModFac = a + b(T_{wb,avg}) + c(T_{wb,avg})^2 + d(T_c) + e(T_c)^2 + f(T_{wb,avg})(T_c) \quad (16.483)$$

The heat pump condenser's total heating load is then calculated as the quotient of the total terminal unit capacity and the piping correction factor. Additional load due to defrost is also included (see following section).

$$\dot{Q}_{heating,total} = \left(\frac{\dot{Q}_{heating,TerminalUnits}}{P_{correction,heating}} \right) + \dot{Q}_{defrost} \quad (16.484)$$

The heat pump's total (gross) heating capacity is then calculated based on the capacity correction factor as a function of temperatures. The impact of defrost on total heat pump heating capacity is also accounted for (see following section). The part-load ratio of the heat pump condenser can then be calculated.

$$\dot{Q}_{HP,total} = \dot{Q}_{total,rated} (CAPFT_{HP,heating}) (CR_{heating,correction}) (HCAP_{defrost}) \quad (16.485)$$

$$PLR = \frac{\dot{Q}_{heating,total}}{\dot{Q}_{HP,total}} \quad (16.486)$$

where:

$\dot{Q}_{HP,total}$ is the heat pump total available heating capacity (W)

PLR is the heat pump part-load ratio

$HCAP_{defrost}$ is the heating capacity correction factor for defrost mode.

As described for cooling operation, the available heating capacity of the heat pump is compared to the requested heating capacity of all indoor terminal units. If the requested heating capacity of all indoor terminal units is greater than the available heating capacity of the heat pump, one or more of the indoor terminal unit's capacity is limited such that the sum of the zone terminal unit heating demand plus piping losses is equal to the available heat pump heating capacity (including the impact due to defrost).

The electrical power consumed by the heat pump condenser is calculated based on the heat pump's nominal electric power consumption in heating mode and the actual operating conditions. A performance correction factor is used to correct for off-design performance as follows:

Heating Part-Load Fraction Correlation (function of heat pump cycling ratio)

The part-load fraction correlation (function of heat pump cycling ratio) is a linear, quadratic or a cubic curve with the independent variable being cycling ratio (part-load ratio / minimum part-load ratio). The output of this curve is used in combination with the rated EIR and EIR modifier

curves to give the “effective” EIR for a given simulation time step. The cycling ratio correlation accounts for startup losses of the heat pump’s compression system.

$$CyclingRatioFrac = a + b (CyclingRatio) + c (CyclingRatio)^2 \quad (16.487)$$

or

$$CyclingRatioFrac = a + b (CyclingRatio) + c (CyclingRatio)^2 + d (CyclingRatio)^3 \quad (16.488)$$

where

$$CyclingRatio = \frac{PLR}{PLR_{\min}} \quad (16.489)$$

The cycling ratio can be viewed using the report variable “VRF Heat Pump Cycling Ratio” (ref: Output:Variable).

The cycling ratio correlation should be normalized to a value of 1.0 when the cycling ratio equals 1.0 (i.e., no efficiency losses when the compressor(s) run continuously for the simulation time step). For cycling ratio values between 0 and 1 ($0 \leq CyclingRatio < 1$), the following rules apply:

$$CyclingRatioFrac \geq 0.7 \text{ and } CyclingRatioFrac \geq CyclingRatio$$

If $CyclingRatioFrac < 0.7$ a warning message is issued, the program resets the $CyclingRatioFrac$ value to 0.7, and the simulation proceeds. The runtime fraction of the heat pump is defined as $CyclingRatio/CyclingRatioFrac$. If $CyclingRatioFrac < CyclingRatio$, then a warning message is issued and the runtime fraction of the heat pump is limited to 1.0.

$$Heat\ Pump\ Runtime\ Fraction (HPRTF) = \frac{CyclingRatio}{CyclingRatioFrac} \quad (16.490)$$

The heat pump runtime fraction can be viewed using the report variable “VRF Heat Pump Runtime Fraction” (ref: Output:Variable).

Since manufacturers data do not typically provide information defining the cycling losses of VRF AC systems, a typical part-load fraction correlation for a conventional DX refrigeration system (e.g., residential or small commercial unit) may be substituted here as:

$$CyclingRatioFrac = 0.85 + 0.15(CyclingRatio) \quad (16.491)$$

Heating Energy Input Ratio Modifier (function of temperature)

As described previously (Ref. Application of Dual Performance Curves), the heating energy input ratio modifier curve can either be applied as a single curve object as shown below, or applied using dual performance curve objects. The single curve object application is discussed here.

$$EIRFT_{heating} = a + b (T_{db,avg}) + c (T_{db,avg})^2 + d (T_c) + e (T_c)^2 + f (T_{db,avg}) (T_c) \quad (16.492)$$

where $EIRFT_{heating}$ = heating energy input ratio correction factor (function of temperature) (0-1).

Heating Energy Input Ratio Modifier (function of part-load ratio)

IF (PLR ≤ 1) THEN

$$EIRFPLR_{heating} = a + b(PLR) + c(PLR)^2 + d(PLR)^3 \quad (16.493)$$

ELSE

$$EIRFPLR_{heating} = e + f(PLR) + g(PLR)^2 + h(PLR)^3$$

where:

$EIRFPLR_{heating}$ is the heating energy input ratio modifier (function of part-load ratio)

a-d are the coefficients for the heating energy input ratio modifier when part-load ratio ≤ 1

e-h are the coefficients for the heating energy input ratio modifier when part-load ratio > 1

The total power consumed by the heat pump condenser in heating mode is then calculated. A correction for power consumed due to defrost is also included (see following section).

The total power consumed by the heat pump condenser in heating mode is based on the user specified coefficient of performance (COP). A correction for power consumed due to defrost is also included (see following section).

$$HeatingPower = \left(\frac{\dot{Q}_{heating, total, rated} CAPFT_{heating}}{COP_{heating, reference}} \right) (EIRFT_{heating}) (EIRFPLR_{heating}) * (HPRTF) (EIR_{defrost}) \quad (16.494)$$

The heating COP is then calculated as the ratio of the outdoor unit heating capacity divided by the total electric consumption rate of all components associated with the outdoor unit. Evaporatively-cooled condenser pump power is typically 0 during heating mode operation.

$$COP_{heating} = \dot{Q}_{heating, total} / (HeatingPower + P_{CrankcaseHeater} + P_{EvapCoolerPower} + P_{defrost}) \quad (16.495)$$

where:

$COP_{heating}$ is the operating coefficient of performance, report variable “VRF Heat Pump Heating COP”

HeatingPower is the operating electric consumption rate (W), report variable “VRF Heat Pump Heating Electric Power”.

When operating in heat recovery mode, equations similar to those used for available heating capacity are used to model operating power.

$$HREIRMod_{HP, heating} = a + b(T_{ent}) + c(T_{ent})^2 + d(T_{cond}) + e(T_{cond})^2 + f(T_{ent})(T_{cond}) \quad (16.496)$$

This equation can be used to provide a constant fractional difference for heating electric consumption rate in heat recovery mode (i.e., only *a* is non-zero) or a fractional term that varies with indoor and outdoor conditions. With very limited performance data available at this time, it is recommended that only the constant (a) term be used at this time. When the VRF system is not operating in heat recovery mode, this fraction is set to 1. The available heating electric consumption rate in heat recovery mode is then calculated as:

$$HeatingPower_{HR} = HeatingPower (HREIRMod_{HP, heating}) \quad (16.497)$$

$$Power_{HR} = k_{EIR,heat} (HeatingPower_{HR}) + (1 - k_{EIR,heat}) (HeatingPower_{HR}) \left(1 - e^{(-t/\tau_{c,EIR,heat})}\right) \quad (16.498)$$

where:

$k_{EIR,heat}$ is the fraction of steady-state heating electric consumption rate at beginning of heat recovery mode

$\tau_{c,EIR,heat}$ is the time constant to reach steady-state operation, 5 time constants equals 99% of steady-state capacity (hr)

$HeatingPower_{HR}$ is the heating electric consumption rate in heat recovery mode (W)

$\left(1 - e^{(-t/\tau_{c,EIR,heat})}\right)$ = The multiplier used during the transition period from heating mode to heat recovery mode. This multiplier can be viewed using the report variable “VRF Heat Pump Heat Recovery Status Change Multiplier” (ref: Output:Variable).

16.7.1.22 Operating Coefficient of Performance

Similar to the cooling and heating COP report variables, a report variable is included to identify the overall COP of the system. The numerator represents the total cooling and heating coil capacities (or loads) where piping losses have been accounted for. If heat recovery is not used only one of these terms is non-zero. When heat recovery is used, one or both of these terms can be non-zero, therefore, the operating COP includes recovered energy. The denominator includes the electric consumption rates of all system components. For water-cooled VRF AC systems, the plant pump power is not included.

$$COP_{operating} = \frac{(\dot{Q}_{cooling,TerminalUnits} + \dot{Q}_{heating,TerminalUnits})}{(OutdoorUnitPower + P_{CrankcaseHeater} + P_{EvapCoolerPower} + P_{defrost} + P_{TU,fan} + P_{TU,parasitic})} \quad (16.499)$$

where:

$OutdoorUnitPower$ is the cooling or heating electric consumption rate of outdoor unit (W)

$P_{TU,fan}$ is the electric consumption rate of all terminal unit fans (W)

$P_{TU,parasitic}$ is the electric consumption rate of all terminal unit parasitic electric (W).

16.7.1.23 Defrost Adjustment Factors

Frost formation on the outdoor coil, and the need to periodically defrost this coil, has a significant impact on heating capacity and energy use by the DX heating system. This model uses a timed reverse-cycle defrost model. If the outdoor air dry-bulb temperature is below the specified maximum temperature for defrost operation, then the model calculates adjustment factors for heating capacity and input power due to frost formation. This method of accounting for the impacts of frosting/defrost was taken from the model used in DOE-2.1E (ESTSC 2001, Miller and Jaster 1985).

The model first estimates the outdoor coil temperature according to a linear empirical relationship with outdoor air dry-bulb temperature as the independent variable.

$$T_{coil,out} = 0.82T_{db,o} - 8.589 \quad (16.500)$$

The difference between the outdoor air humidity ratio (from the weather file) and the saturated air humidity ratio at the estimated outdoor coil temperature is then calculated, and this value is used as an indication of frost formation on the outdoor coil.

$$\Delta\omega_{coil,out} = MAX [1.0E - 6, \omega_{outdoor} - \omega_{sat} (T_{coil,out}, OutBaroPress)] \quad (16.501)$$

Frost formation on the outdoor coil must be periodically removed. The fraction of compressor runtime when the coil is being defrosted is entered by the user. Adjustment factors to total heating coil capacity and input power due to frost formation on the outdoor coil are calculated by an empirical model with $\Delta\omega_{coil,out}$ as the independent variable as shown below.

$$HCAP_{defrost} = 0.909 - 107.33 (\Delta\omega_{coil,out}) \quad (16.502)$$

$$EIR_{defrost} = 0.9 - 36.45 (\Delta\omega_{coil,out}) \quad (16.503)$$

If the outdoor air dry-bulb temperature is *above* the specified maximum temperature for defrost operation, the fractional defrost time period is set to zero and the heating capacity/input power multipliers are set to unity (1).

16.7.1.24 Defrost Operation

If the fractional defrost time period is greater than zero for the simulation time step, then the model calculates the electrical power used during defrost. The additional heating load due to defrost (indoor cooling during defrost) is also calculated so that it may be added to the existing heating load when calculating input power for the compressor(s) and outdoor coil fan(s).

$$Q_{defrost} = 0.01 (t_{frac,defrost}) (7.222 - T_{db,o}) \left(\frac{Q_{total,rated}}{1.01667} \right) \quad (16.504)$$

$$P_{defrost} = DefrostEIRTempModFac \left(\frac{Q_{total,rated}}{1.01667} \right) (t_{frac,defrost}) (RTF) \quad (16.505)$$

where:

$Q_{defrost}$ is the additional indoor heating load due to reverse-cycle defrost (W)

$Q_{total,rated}$ is the total full-load heating capacity of the coil at rated conditions (W)

$P_{defrost}$ is the report variable for average defrost power for the simulation time step (W)

$DefrostEIRTempModFac$ is the energy input ratio modifier curve applicable during defrost

$t_{frac,defrost}$ is the defrost time period fraction specified by user

$$RTF = \left(\frac{PLR}{PartLoadFrac} \right) = runtime \text{ fraction of the heating coil} \quad (16.506)$$

16.7.2 Physics based VRF Heat Pump Model (VRF-FluidTCtrl-HP)

16.7.2.1 Overview

This section describes the Physics based VRF Model (VRF-FluidTCtrl) to simulate the energy performance of Variable Refrigerant Flow (VRF) systems in the heat pump (HP) operation mode, i.e., either cooling or heating is provided but not simultaneously.

Compared with the empirical system curves based VRF-SysCurve model, the VRF-FluidTCtrl model adheres to a physics-based development providing the ability to simulate the refrigerant loop performance and consider the dynamics of more operational parameters. This is essential for the representation of many enhanced control logics, e.g., the adjustment of superheating degrees during low load operations. Furthermore, this model implements component-level curves rather than the system-level curves, and thus requires much fewer curves as model inputs. The definition of VRF performance data for simulation as part of ASHRAE Standard 205 will ensure VRF manufacturers provide adequate data to create the required performance curves.

The main features of the VRF-FluidTCtrl model include:

- Introduction of separate curves for capacities and power inputs of indoor and outdoor units instead of overall curves for the entire system.
- Allowing of variable evaporating and condensing temperatures in the indoor and outdoor units under various operational conditions.
- Allowing of variable fan speed based on the temperature and zone load in the indoor unit.
- Allowing of further modifications of operational parameters (e.g., evaporating temperature, superheating degrees, and supply air flow rate) during low load conditions.
- Development of a physics-based model to calculate thermal loss in the refrigerant piping network (varies with refrigerant flow rate, operational conditions, pipe length, and pipe and insulation materials) instead of a constant correction factor.

These features enhance the simulation accuracy of the VRF system performance in both heating and cooling modes, especially during low load operations. In addition, these features enable the modeling of a multi-stage control strategy to adjust the system capacity during low load conditions, as shown in Figure VRF-FluidTCtrl-1. Moreover, the VRF-FluidTCtrl model enables the potential simulation of demand response of VRF systems by directly slowing down the speed of compressors in the outdoor units with inverter technology.

Note that a number of calculation steps are coupled together in the VRF-FluidTCtrl model, for instance, the piping loss calculation and the system performance calculation. More specifically, the piping loss changes the operating conditions of the system, which may lead to a different control strategy and thus in reverse affect the amount of piping loss. This makes it difficult to obtain an analytical solution for a number of operational parameters (e.g., enthalpy of refrigerant entering the indoor unit), and therefore numerical iterations are employed to address this problem (refer to Figure VRF-FluidTCtrl-3 for more details). Therefore, the VRF-FluidTCtrl model can have a longer execution time to perform the simulation than the VRF-SysCurve model.

The object connections for VRF-FluidTCtrl model is similar to those for VRF-SysCurve model. The difference lies in the object used to describe a specific components. For example, VRF-SysCurve model uses *AirConditioner:VariableRefrigerantFlow* object to describe the VRF outdoor unit performance, while in VRF-FluidTCtrl model the *AirConditioner:VariableRefrigerantFlow:FluidTemperatureControl* object is used.

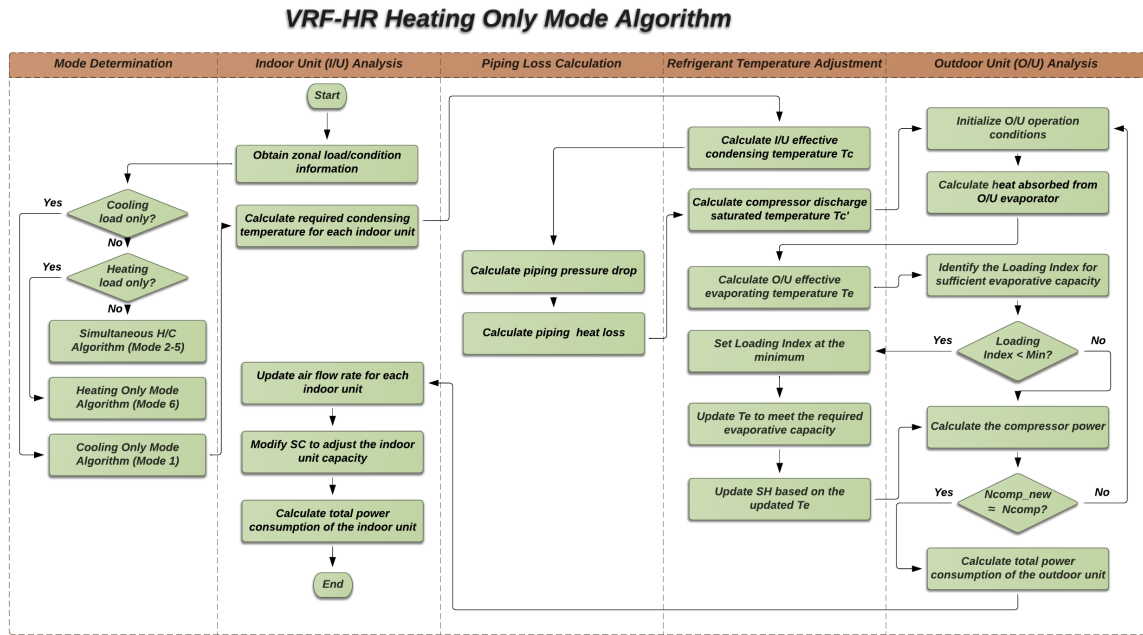

Figure 16.63: Flow Chart of the VRF-FluidTCtrl Model – Heating Mode

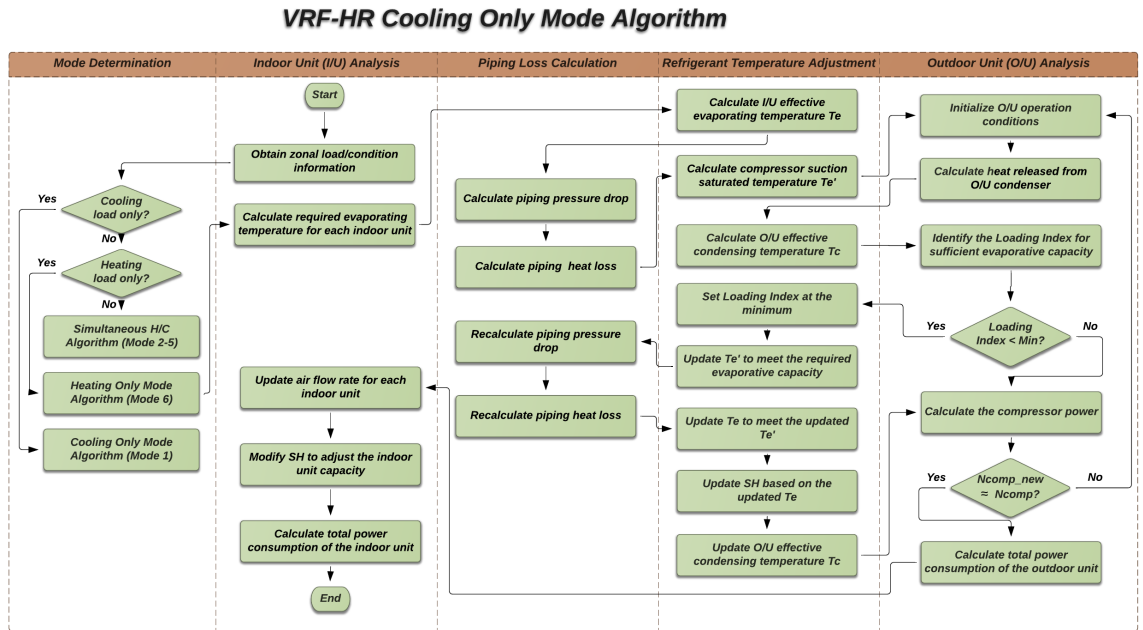

Figure 16.64: Flow Chart of the VRF-FluidTCtrl Model – Cooling Mode

16.7.2.2 Model Description

Figures 16.61, 16.62, 16.63, and 16.64 illustrate the overall logic of the VRF-FluidTCtrl algorithms. Detailed calculation procedures and explanations of equations are described in the following sections.

The VRF-FluidTCtrl algorithms are described in details below, including the models of both the indoor and outdoor unit(s) of the VRF system. Because of the different control algorithms used in the outdoor unit for cooling and heating modes, the heating and cooling modes are described separately.

16.7.2.2.1 Modeling of the indoor unit (I/U) – Part I

Step 1.1: Obtaining zonal load/condition information

Obtain the following information for each zone from the zone modules within EnergyPlus:

- zone sensible loads $Q_{in,sensible}$
- zone total loads $Q_{in,total}$
- indoor air temperature T_{in}
- indoor air humidity ratio W_{in}

The operation mode of the VRF system can therefore be determined from $Q_{in,sensible}$.

Step 1.2: Calculate I/U required evaporator/condenser temperature

Evaluate the required coil surface air temperature T_{fs} and the required evaporator/condenser refrigerant temperature $T_{e,req}/T_{c,req}$ for each indoor unit.

Assuming the coil air flow rate is at the maximum ($G_{a,rate}$), the entering air temperature after the indoor coil fan can be calculated for each indoor unit:

$$T_{coil,in} = T_{in} + Q_{fan}/(G_{a,rate} \times c_p \times \rho_{in}) \quad (16.507)$$

where:

c_p is the air heat capacity (kJ/(kg·K))

$G_{a,rate}$ is the volumetric flow rate of the air through the indoor unit, at the rated conditions (m³/s)

Q_{fan} is the sensible heat released by fan (W)

$T_{coil,in}$ is the temperature of air entering the indoor coil (°C)

ρ_{in} is the density of indoor air, $f_\rho(T_{in}, W_{in})$ (kg/m³).

The supply air temperature T_{out} can be calculated by:

$$T_{out} = T_{coil,in} - Q_{in,sensible}/(G_{a,rate} \times c_p \times \rho_{in}) \quad (16.508)$$

where T_{out} is the temperature of the air leaving the indoor unit (supply air) (°C).

The coil surface air temperature T_{fs} can be calculated, given the bypass factor BF :

$$T_{fs} = T_{coil,in} - (T_{coil,in} - T_{out})/(1 - BF) \quad (16.509)$$

where:

BF is the bypass factor (different values for cooling mode and heating mode)

T_{fs} is the indoor unit coil surface air temperature (°C).

In the cooling mode, the superheating degree SH is given and thus the required evaporating temperature $T_{e_{req}}$ for the associated indoor unit can be obtained:

$$T_{e_{req}} = T_{fs} - [A_c \cdot SH^2 + B_c \cdot SH + C_c] \quad (16.510)$$

Where

A_c, B_c, C_c are coefficients

SH is the superheating degrees for the indoor unit ($^{\circ}\text{C}$)

SH_{ref} is the reference superheating degrees for the indoor unit (e.g., 3) ($^{\circ}\text{C}$)

$T_{e_{req}}$ is the required evaporating temperature for a specific indoor unit ($^{\circ}\text{C}$).

In the heating mode, the subcooling degree SC is given and thus the required condensing temperature $T_{c_{req}}$ for the associated indoor unit can be obtained:

$$T_{c_{req}} = T_{fs} + [A_h \cdot SC^2 + B_h \cdot SC + C_h] \quad (16.511)$$

where:

A_h, B_h, C_h are coefficients

SC is the subcooling degrees for the indoor unit ($^{\circ}\text{C}$)

SC_{ref} is the reference subcooling degrees for the indoor unit (e.g., 5) ($^{\circ}\text{C}$)

$T_{c_{req}}$ is the required condensing temperature for a specific indoor unit ($^{\circ}\text{C}$).

Step 1.3: Calculate effective evaporating /condensing temperature

There are two refrigerant temperature control strategies for the indoor unit: (1) *ConstantTemp*, (2) *VariableTemp*.

- In the *ConstantTemp* strategy, T_e and T_c are kept at constant values provided by the user.
- In the *VariableTemp* strategy, T_e and T_c are determined using the equations below:

In the cooling mode:

$$T_e = \min\{\max[\min(T_{e_{req,i}}), T_{e_{min}}], T_{e_{max}}\} \quad (16.512)$$

where:

$T_{e_{req,i}}$ is the required evaporating temperature for the i th indoor unit ($^{\circ}\text{C}$)

$T_{e_{min}}$ is the minimum evaporating temperature for the indoor unit (e.g. 3) ($^{\circ}\text{C}$)

$T_{e_{max}}$ is the maximum evaporating temperature for the indoor unit (e.g. 13) ($^{\circ}\text{C}$).

In the heating mode:

$$T_c = \min\{\max[\min(T_{c_{req,i}}), T_{c_{min}}], T_{c_{max}}\} \quad (16.513)$$

where:

$T_{c_{req,i}}$ is the required condensing temperature for the i th indoor unit ($^{\circ}\text{C}$)

$T_{c_{min}}$ is the minimum condensing temperature for the indoor unit (e.g. 42) ($^{\circ}\text{C}$)

$T_{c_{max}}$ is the maximum condensing temperature for the indoor unit (e.g. 46) ($^{\circ}\text{C}$).

16.7.2.2.2 Modeling of the outdoor unit (O/U) - Cooling Mode

Step 2c.1: Piping loss calculation in the cooling mode

Piping loss occurs when the refrigerant flows through the main pipe connecting the indoor and outdoor units. It includes both the refrigerant pressure drop and heat loss. It affects the VRF system operation in several ways. First, the heat loss creates an extra load to the system and leads to higher energy consumptions. Second, the pressure drop and heat loss changes the operational conditions of the compressor (i.e., compressor suction pressure and compressor suction temperature) and thus affects its operational performance. Therefore, the piping loss calculation is critical for the analysis of the whole system.

Note that the change of compressor operational conditions may lead to different control strategies of the system, which in reverse affects the amount of piping loss. So the piping loss analysis and system performance analysis are coupled together. Numerical iterations are designed to address the coupling effect, as described below.

Calculate the refrigerant flow rate for each indoor unit using assumed h_{Hexin} :

$$G_i = Q_i / (h_{Hexout,i} - h_{Hexin}) \quad (16.514)$$

where:

G_i is the refrigerant flow rate for the i^{th} indoor unit (kg/s)

Q_i is the total cooling load of the i^{th} zone (W)

h_{Hexin} is the enthalpy of the refrigerant entering the indoor unit (kJ/kg)

$h_{Hexout,i}$ is the enthalpy of the refrigerant leaving a specific indoor unit (kJ/kg)

$h_{Hexout,i}$ is a function of P_e , T_e , and SH_i . It can be calculated using refrigerant thermodynamic property equations $f_{g_h}(P_e, T_e + SH_i)$.

The enthalpy of the refrigerant in the main loop h_{Hexout} can be obtained by calculating the weighted average of the enthalpy of the refrigerant in each indoor unit:

$$h_{Hexout} = \sum (h_{Hexout,i} \times G_i / G_{tot}) \quad (16.515)$$

$$G_{tot} = \sum G_i \quad (16.516)$$

where:

G_{tot} is the refrigerant flow rate in the main loop (kg/s)

h_{Hexout} is the enthalpy of the main loop refrigerant leaving indoor units (kJ/kg).

The viscosity of the refrigerant within the pipe can be calculated via:

$$k_{v,1} = P_e / 4926000 \quad (16.517)$$

$$k_{v,2} = h_{Hexout} / 383.55 \quad (16.518)$$

$$k_{v,3} = (T_{Hexout} + 273.15) / 344.39 \quad (16.519)$$

$$\begin{aligned} \mu = & 10^6 \times (4.302 \times k_{v,1} + 0.81622 \times k_{v,1}^2 - 120.98 \times k_{v,2} + 139.17 \times k_{v,2}^2 \\ & + 118.76 \times k_{v,3} + 81.04 \times k_{v,3}^2 + 5.7858 \times k_{v,1} \times k_{v,2} \\ & - 8.3817 \times k_{v,1} \times k_{v,3} - 218.48 \times k_{v,2} \times k_{v,3} + 21.58) \end{aligned} \quad (16.520)$$

where:

μ is the viscosity of the refrigerant within the pipe (Pa-s)

$k_{v,i}$ is the coefficients to calculate the refrigerant viscosity

T_{Hexout} is the temperature of main loop refrigerant leaving indoor units, $f_{g_t}(P_e, h_{Hexout})$ ($^{\circ}\text{C}$)

f_{g_t} are functions calculating the temperature of superheating refrigerant.

Given h_{Hexout} and $P_e = f_{s_p}(T_e)$, the following dimensionless quantities describing the refrigerant flow state can be obtained:

$$Re = G_{tot}/3600/(0.25 \times \pi \times D^2) \times D/\mu \quad (16.521)$$

$$Pr = \mu \times f_{g_Cp}(P_e, h_{Hexout}) \times 0.001/f_{g_l}(P_e, h_{Hexout}) \quad (16.522)$$

$$Nu = 0.023 \times Re^{0.8} \times Pr^{0.3} \quad (16.523)$$

$$St = Nu/Re/Pr \quad (16.524)$$

where:

P_e is the evaporating pressure (Pa)

Re is the Reynolds number

Pr is the Prandtl number

Nu is the Nusselt number

St is the Stanton number

μ is the viscosity of the refrigerant within the pipe (Pa-s)

f_{s_p} are functions calculating the pressure of saturated refrigerant

f_{g_Cp} are functions calculating the specific heat of superheating refrigerant

f_{g_l} are functions calculating the conductivity of superheating refrigerant.

Then the piping pressure loss ΔP_{pipe} can be obtained using the above dimensionless quantities:

$$\Delta P_{pipe} = 8 \times St \times Pr^{2/3} \times L/D \times f_{g_p}(P_e, h_{Hexout}) \times V^2/2 + H \times f_{g_p}(P_e, h_{Hexout}) \times 9.80665 \quad (16.525)$$

$$P_s = P_e - \Delta P_{pipe} \quad (16.526)$$

where:

f_{g_p} are functions calculating the density of superheating refrigerant

D is the main pipe diameter (m)

H is the height difference between the outdoor unit node and indoor unit node of the main pipe (m)

L is the main pipe length (outdoor unit to the first branch joint) (m)

P_s is the compressor suction pressure (Pa)

ΔP_{pipe} is the pressure drop in the pipe (Pa)

V is the refrigerant flow velocity (m/s).

The suction saturated temperature T'_e (i.e., saturated vapor temperature corresponding to the compressor suction pressure) can be obtained via refrigerant thermodynamic property equations:

$$T'_e = f_{s_t}(P_e - \Delta P_{pipe}) \quad (16.527)$$

where:

f_{s_t} are functions calculating the temperature of saturated refrigerant

T'_e is the suction saturated temperature at the compressor inlet (°C).

The heat loss through the pipe can be obtained via:

$$k_1 = Nu \times f_{g_l}(P_e, h_{Hexout}) \quad (16.528)$$

$$k_2 = 2 \times \lambda_i / Ln(1 + 2 \times W_i / D) \quad (16.529)$$

$$k_3 = h \times (D + 2 \times W_i) \quad (16.530)$$

$$Q_{pipe} = (\pi \times L) \times (T_a - T_{Hexout}) / (1/k_1 + 1/k_2 + 1/k_3) \quad (16.531)$$

where:

f_{g_l} are functions calculating the conductivity of superheating refrigerant

Q_{pipe} is the heat loss through the pipe (W)

T_a is the average of outdoor air temperature and indoor temperature (°C)

T_{Hexout} is the temperature of main pipe refrigerant leaving indoor units (°C)

w_i is the pipe insulation thickness (m)

k_i are coefficients for the piping loss calculation.

Note that Q_{pipe} is calculated using an assumed h_{Hexin} . Its value affects the compressor operation calculations as shown in Steps 2c.2 - 2c.6 and may change the value of condensing temperature T_c . This leads to an updated $h_{Hexin} = f(P_c, T_c - SC)$. If the difference between the calculated h_{Hexin} and the assumed h_{Hexin} is higher than the assigned tolerance (5%), a new round of iteration is performed using the calculated h_{Hexin} .

Step 2c.2: Initialize O/U operation conditions

The compressor operation is coupled with a number operational parameters, which makes it difficult to obtain an analytical solution. In the algorithm, an iterative approach is designed to obtain the energy consumption of the compressor (Step 2c.2 – 2c.6).

For the first iteration,

- Initialize outdoor unit SC with the reference value (from IDF input, e.g., 5°C)
- Initialize the compressor power N_{comp} with the value calculated from the reference COP (e.g., 3.5):

$$N'_{comp} = \frac{\sum_i Q_{in,total,i}}{COP} \quad (16.532)$$

where:

N_{comp} is the compressor power (W)

N'_{comp} is the assumed compressor power for the first iteration (W)

$Q_{in,total,i}$ is the total cooling load for zone i (W).

For the following iterations,

- Initialize SC with the calculated value in the previous iteration
- Initialize the compressor power N_{comp} with the calculated value in the previous iteration

The heat rate released from the outdoor unit can be calculated by:

$$Q_{out} = \sum_i Q_{in,total,i} + N_{comp} + Q_{pipe} \quad (16.533)$$

where:

Q_{out} is the heat rate released from the outdoor unit (W)

Q_{pipe} is the heat loss through the pipe (W).

Step 2c.3: Calculate O/U effective condensing temperature

(1) Calculate the required coil surface air temperature T_{fs}' for the outdoor unit.

The temperature of the air leaving the outdoor unit T_{out}' can be calculated by:

$$T_{out}' = T_{in}' + Q_{out}/(G_{a,rate}' \times c_p \times \rho_{in}') \quad (16.534)$$

where:

$G_{a,rate}'$ is the volumetric flow rate of the air through the outdoor unit, at the rating conditions (m^3/s)

T_{out}' is the temperature of the air leaving the outdoor unit ($^{\circ}C$)

T_{in}' is the temperature of the air entering the outdoor unit, i.e., outdoor air ($^{\circ}C$)

ρ_{in}' is the air density at outdoor conditions, $f_p(T_{in}', W_{in}')$ (kg/m^3).

The condenser surface temperature T_{fs}' can be calculated by:

$$T_{fs}' = T_{in}' + (T_{out}' - T_{in}')/(1 - BF_c') \quad (16.535)$$

where BF_c' is the bypass factor for the outdoor unit.

(2) Calculate required condensing temperature for the outdoor unit T_{creq} and then the effective condensing temperature T_c (between $42-46^{\circ}C$)

$$T_{creq} = T_{fs}' + [A_h \cdot SC^2 + B_h \cdot SC + C_h] \quad (16.536)$$

$$T_c = T_{creq} \quad (16.537)$$

where:

A_h, B_h, C_h are coefficients

SC is the subcooling degrees for the outdoor unit ($^{\circ}C$)

SC_{ref} is the reference subcooling degrees for the outdoor unit ($^{\circ}C$)

T_{creq} is the required condensing temperature for the outdoor unit ($^{\circ}C$)

T_c is the effective condensing temperature ($^{\circ}C$).

Step 2c.4: Calculate required Loading Index

Loading Index is used to describe the operational mode of the compressor system. The first index represents minimal capacity operation, while the last index represents full capacity operation.

The required Loading Index can be calculated by the following procedures.

- Calculate the evaporative capacity at a variety of Loading Index:

$$M_{cap} = (r_1 + r_2 T_c + r_3 T_e' + r_4 T_c^2 + r_5 T_c T_e' + r_6 T_e'^2) \quad (16.538)$$

$$Q_{rps} = C_{cap,system} \times M_{cap} \times Q_{ref} \quad (16.539)$$

where:

$C_{cap,system}$ is the evaporative capacity correction factor, describing the possible system configuration difference between test bed and real system (a constant value obtained from manufacturer data)

r_1, \dots, r_6 are the empirical coefficients corresponding to rps

rps is the compressor speed (r/s)

T_e' is the suction saturated temperature at the compressor inlet (°C)

T_c is the effective condensing temperature (°C)

M_{cap} is the multiplier for the evaporative capacity calculation (–)

Q_{rps} is the evaporative capacity corresponding to rps (W)

Q_{ref} is the rated evaporative capacity (W).

An example of resulting capacity for different rps (at $T_c=36^\circ\text{C}$ and $T_e'=9^\circ\text{C}$) is presented in Table 16.13.

Table 16.13: Evaporative capacity at different Loading Index

Loading Index (rps)	Evaporative Capacity (kW), $T_c=36^\circ\text{C}$, $T_e'=9^\circ\text{C}$	Loading Index (rps)	Evaporative Capacity (kW), $T_c=36^\circ\text{C}$, $T_e'=9^\circ\text{C}$
1 (18)	3.951	2 (25)	5.400
3 (30)	6.435	4 (36)	8.516
5 (45)	10.756	6 (60)	14.445
7 (75)	18.412	8 (90)	22.045
9 (108)	26.162		

b. Find the rps range that covers the required evaporative capacity $Q_{rps,modify}$.

$$Q_{rps,modify} = C_{cap,operation} \times (\sum Q_{in,total} + Q_{pipe}) \quad (16.540)$$

$$C_{cap,operation} = C_{cap,density} \times C_{cap,enthalpy} \quad (16.541)$$

$$C_{cap,density} = \rho_{test}/\rho_{real} \quad (16.542)$$

$$C_{cap,enthalpy} = \frac{h_{Evapout,test} - h_{Evapin,test}}{h_{Compin,real} - h_{Evapin,real}} \quad (16.543)$$

$$h_{Compin,real} = h_{Hexout,real} + Q_{pipe}/G_{tot} \quad (16.544)$$

where:

$C_{cap,operation}$ is the evaporative capacity correction factor, describing the operational difference between test cases and real cases (i.e., SH and SC)

$C_{cap,density}$ is the evaporative capacity correction factor, describing the variations of refrigerant density at test conditions and real operational conditions

$C_{cap,enthalpy}$ is the evaporative capacity correction factor, describing the variations of refrigerant enthalpy at test conditions and real operational conditions

G_{tot} is the refrigerant flow rate in the main loop (kg/s)

$h_{Evapin,real}$ is the enthalpy of refrigerant entering the evaporators (IU) at real conditions (kJ/kg)

$h_{Evapout,real}$ is the average enthalpy of refrigerant leaving the evaporators (IU) at real conditions (kJ/kg)

$h_{Evapin,test}$ is the enthalpy of refrigerant entering the evaporator at test conditions (i.e., SC at test conditions (e.g., 5°C) and T_c) (kJ/kg)

$h_{Evapout,test}$ is the enthalpy of refrigerant leaving the evaporator at test conditions (i.e., SH at test conditions (e.g., 8°C) and T_e) (kJ/kg)

h_{Compin} is the enthalpy of refrigerant entering the compressor (kJ/kg)

Q_{pipe} is the heat loss through the pipe (W).

For example, if the required capacity is 8 kW, the rps range is 30 to 36.

- c. Calculate the rps that meets the required capacity by interpolation. In the above example, the resulting rps is 34.5 rps .
- d. If the calculated rps is lower than the minimum rps (e.g. 18 rps), go to Step 2c.5, otherwise skip Step 2c.5 and directly go to Step 2c.6.

Step 2c.5: Modify evaporating temperature to further reduce outdoor unit capacity

If the calculated rps is lower than the minimum rps (e.g. 18 rps), it means that the zone cooling load is even lower than the system evaporative capacity corresponding to the minimum compressor speed. In this situation, the evaporating temperature T_e as well as the superheating degree SH is modified to further reduce the outdoor unit capacity. More specifically:

- a. Set rps at its minimum value (e.g., 18 rps).
- b. Update T_e' to meet the required evaporative capacity, using equations described in Step 2c.4a.
- c. Update T_e to meet the updated T_e' . Note that due to the T_e updates, the refrigerant state and flow rate are changed and thus the piping loss analysis should also be repeated (Step 2c.1). So is the calculation of $C_{cap,operation}$ (Step 2c.2 - 2c.3).
- d. SH can be updated based on the updated T_e , using the equations shown in Step 1.2.

Step 2c.6: Calculate the compressor power

(1) Calculate the compressor power by the following procedures.

- a. Calculate the compressor power at a variety of loading index using the following equation. The resulting table from the same example used above is shown below in Table 16.14.

$$M_{comp} = c_1 + c_2 T_c + c_3 T_e' + c_4 T_c^2 + c_5 T_c T_e' + c_6 T_e'^2 \quad (16.545)$$

$$N_{comp,rps} = M_{comp} \times N_{comp,ref} \quad (16.546)$$

where:

c_1, \dots, c_6 are the empirical coefficients corresponding to rps

T_e' is the suction saturated temperature at the compressor inlet ($^{\circ}\text{C}$)

T_c is the effective condensing temperature ($^{\circ}\text{C}$)

M_{comp} is the multiplier for the compressor power calculation (-)

$N_{comp,ref}$ is the rated compressor power (W)

$N_{comp,rps}$ is the compressor power corresponding to rps (W).

Table 16.14: Outdoor unit compressor power at different Loading Index

Loading Index (rps)	Evaporative Capacity (kW), $T_c=36^{\circ}\text{C}$, $T_e'=9^{\circ}\text{C}$
1 (18)	3.951
2 (25)	5.400
3 (30)	6.435
4 (36)	8.516
5 (45)	10.756
6 (60)	14.445
7 (75)	18.412
8 (90)	22.045
9 (108)	26.162

- b. According to the rps range determined, calculate the compressor power N_{comp} by interpolation.
In the above example, the compressor power is 1.155 kW.

(2) Compare the calculated N_{comp} above with the initialized N_{comp}' in Step 2c.2:

- If $N_{comp}' - N_{comp} > \delta$ then go to Step 2c.2 for a new round of iteration.
- Else, end the iteration and go to Step 2c.7.

Step 2c.7: Total power consumption of the outdoor unit

Calculate the total electric power consumption by the outdoor unit:

$$N_{out} = N_{fan} + N_{comp}/e_{inv} \quad (16.547)$$

where:

e_{inv} is the efficiency of the inverter of compressor

N_{fan} is the electric power consumption by the outdoor fan (W)

N_{out} is the total electric power consumption by the outdoor unit (W).

16.7.2.3 Modeling of the outdoor unit (O/U) - Heating Mode

Step 2h.1: Piping loss calculation in the heating mode

Similarly to that in the cooling mode, the piping loss analysis in the heating mode needs to address the coupling effect between the piping loss and system operations. However, due to the control strategy difference between the two modes, the piping loss algorithm in the heating mode requires different calculation steps and more numerical iterations, as shown below.

Calculate the refrigerant flow rate for each indoor unit using assumed h_{Hexin} :

$$G_i = Q_i / (h_{Hexin} - h_{Hexout,i}) \quad (16.548)$$

where:

G_i is the refrigerant flow rate for the i^{th} indoor unit (kg/s)

Q_i is the total heating load of the i^{th} zone (W)

h_{Hexin} is the enthalpy of the refrigerant entering the indoor unit (kJ/kg)

$h_{Hexout,i}$ is the enthalpy of the refrigerant leaving a specific indoor unit (kJ/kg)

$h_{Hexout,i}$ is a function of P_c , T_c , and SC_i . It can be calculated using refrigerant thermodynamic property equations $f_{gh}(P_c, T_c - SC_i)$.

The refrigerant flow rate in the main loop can be obtained by summing up the flow rate in each indoor unit:

$$G_{tot} = \sum G_i \quad (16.549)$$

where G_{tot} refrigerant flow rate in the main loop (kg/s).

Calculate the average refrigerant pressure and enthalpy within the pipes, using assumed piping pressure loss ΔP_{pipe} and h_{Tdi} :

$$P_{ave} = P_c + \Delta P_{pipe} / 2 \quad (16.550)$$

$$h_{ave} = (h_{Hexin} + h_{Tdi}) / 2 \quad (16.551)$$

where:

h_{ave} is the average refrigerant enthalpy within the main pipe (kJ/kg)

h_{Hexin} is the enthalpy of the refrigerant entering the indoor unit (kJ/kg)

h_{Tdi} is the enthalpy of the refrigerant leaving the compressor (kJ/kg)

P_{ave} is the average refrigerant pressure within the main pipe (Pa)

P_c is the condensing pressure (Pa)

ΔP_{pipe} is the pressure drop in the main pipe (Pa).

The viscosity of the refrigerant within the pipe can be calculated given P_{ave} and h_{ave} , using the following equations:

$$k_{v,1} = P_{ave} / 4926000 \quad (16.552)$$

$$k_{v,2} = h_{ave} / 383.55 \quad (16.553)$$

$$k_{v,3} = (T_{ave} + 273.15) / 344.39 \quad (16.554)$$

$$\begin{aligned}\mu = & 10^6 \times (4.302 \times k_{v,1} + 0.81622 \times k_{v,1}^2 - 120.98 \times k_{v,2} + 139.17 \times k_{v,2}^2 \\ & + 118.76 \times k_{v,3} + 81.04 \times k_{v,3}^2 + 5.7858 \times k_{v,1} \times k_{v,2} \\ & - 8.3817 \times k_{v,1} \times k_{v,3} - 218.48 \times k_{v,2} \times k_{v,3} + 21.58)\end{aligned}\quad (16.555)$$

where:

μ is the viscosity of the refrigerant within the pipe (Pa-s)

$k_{v,i}$ are coefficients to calculate the refrigerant viscosity

h_{ave} is the average refrigerant enthalpy within the pipes (kJ/kg)

P_{ave} is the average refrigerant pressure within the pipes (Pa)

T_{ave} is the average temperature of refrigerant leaving indoor units, which corresponds to P_{ave} and h_{ave} (°C)

Given P_{ave} and h_{ave} , the following dimensionless quantities describing the refrigerant flow state can be obtained:

$$Re = G_{tot}/3600/(0.25 \times \pi \times D^2) \times D/\mu \quad (16.556)$$

$$Pr = \mu \times f_{g_{C_p}}(P_{ave}, h_{ave}) \times 0.001/f_{g_{\lambda}}(P_{ave}, h_{ave}) \quad (16.557)$$

$$Nu = 0.023 \times Re^{0.8} \times Pr^{0.4} \quad (16.558)$$

$$St = Nu/Re/Pr \quad (16.559)$$

where:

Re is the Reynolds number

Pr is the Prandtl number

Nu is the Nusselt number

St is the Stanton number

μ is the viscosity of the refrigerant within the pipe (Pa-s)

$f_{g_{C_p}}$ are functions calculating the specific heat of superheating refrigerant

$f_{g_{\lambda}}$ are functions calculating the conductivity of superheating refrigerant.

Then, the piping pressure loss ΔP_{pipe} can be obtained using the above dimensionless quantities:

$$\Delta P_{pipe} = 8 \times St \times Pr^{2/3} \times L/D \times f_{g_{\rho}}(P_{ave}, h_{ave}) \times V^2/2 - H \times f_{g_{\rho}}(P_{ave}, h_{ave}) \times 9.80665 \quad (16.560)$$

where:

$f_{g_{\rho}}$ are functions calculating the density of superheating refrigerant

D is the main pipe diameter (m)

H is the height difference between the outdoor unit node and indoor unit node of the main pipe (m)

L is the main pipe length (outdoor unit to the first branch joint) (m)

St is the Stanton number

Re is the Reynolds number

Pr is the Prandtl number

ΔP_{pipe} is the pressure drop in the pipe (Pa)

V is the refrigerant flow velocity (m/s).

Compare the calculated ΔP_{pipe} and the one assumed above. If the difference is higher than the assigned tolerance (5%), a new round of iteration is performed using the calculated ΔP_{pipe} .

The compressor discharge saturated temperature T'_c (i.e., saturated vapor temperature corresponding to compressor discharge pressure) can be obtained via:

$$T'_c = f_{st}(P_c + \Delta P_{pipe}) \quad (16.561)$$

where:

f_{st} are functions calculating the temperature of saturated refrigerant

T'_c is the discharge saturated temperature at the compressor outlet (°C)

P_c is the condensing pressure (Pa)

ΔP_{pipe} is the pressure drop in the pipe (Pa).

The heat loss through the pipe can be obtained via:

$$k_1 = Nu \times f_{g\lambda}(P_{ave}, h_{ave}) \quad (16.562)$$

$$k_2 = 2 \times \lambda_i / Ln(1 + 2 \times W_i / D) \quad (16.563)$$

$$k_3 = h \times (D + 2 \times W_i) \quad (16.564)$$

$$Q_{pipe} = (\pi \times L) \times (T_a - T_{Hexin}) / (1/k_1 + 1/k_2 + 1/k_3) \quad (16.565)$$

where:

$f_{g\lambda}$ are functions calculating the conductivity of superheating refrigerant

Q_{pipe} is the heat loss through the pipe (W)

T_a is the average of outdoor air temperature and indoor temperature (°C)

T_{Hexin} is the average of entering indoor units (°C)

w_i is the pipe insulation thickness (m)

k_i is the coefficients for the piping loss calculation.

The enthalpy of the refrigerant entering the indoor unit can be updated using the calculated Q_{pipe} :

$$h_{Tdi} = h_{Hexin} + Q_{pipe} / G_{tot} \quad (16.566)$$

where:

h_{Hexin} is the enthalpy of the refrigerant entering the indoor unit (kJ/kg)

h_{Tdi} is the enthalpy of the refrigerant leaving the compressor (kJ/kg)

G_{tot} is the refrigerant flow rate in the main loop (kg/s).

Compare the calculated h_{Tdi} and the one assumed above. If the difference is higher than the assigned tolerance (5%), a new round of iteration is performed using the calculated h_{Tdi} .

Note that Q_{pipe} is calculated using an assumed h_{Hexin} at the beginning of the piping loss algorithm. Its value affects the compressor operation calculations as shown in Step 2h.2~2h.6 and may change the value of evaporating temperature T_e . This leads to an updated $h_{Hexin} = f(P_e, T_e + SH, N_{comp}, G_{tot})$. If the difference between the calculated result and the assumed value is

higher than the assigned tolerance (5%), a new round of iteration is performed using the calculated h_{Hexin} .

Step 2h.2: Initialize O/U operation conditions

Similar to that in cooling mode, an iteration approach is designed to determine the energy consumption of the compressor (Step 2h.2 to Step 2h.6).

For the first iteration,

- Initialize outdoor unit SH with the reference value (from IDF input, e.g., 1.5°C)
- Initialize the compressor power N_{comp} with the value calculated from the reference COP (e.g., 3.5):

$$N'_{comp} = \frac{\sum_i Q_{in,total,i}}{COP} \quad (16.567)$$

where:

N_{comp} is the compressor power (W)

N'_{comp} is the assumed compressor power for the first iteration (W)

$Q_{in,total,i}$ is the total heating load for zone i (W).

For the following iterations:

- Initialize SH with the calculated value in the previous iteration
- Initialize the compressor power N_{comp} with the calculated value in the previous iteration

Calculate the heat rate extracted by the outdoor unit by:

$$Q_{out} = \sum_i Q_{in,total,i} + Q_{pipe} - N_{comp} \quad (16.568)$$

where:

Q_{out} is the heat rate extracted by the outdoor unit (W)

Q_{pipe} is the heat loss through the pipe (W).

Step 2h.3: Calculate O/U effective evaporating temperature

- (1) Calculate the required coil surface air temperature T_{fs}' for the outdoor unit.

The enthalpy of the air leaving the outdoor unit can be calculated by:

$$H_{fs}' = H_{in}' - Q_{out}/(G_{a,rate}' \times \rho_o)/(1 - BF') \quad (16.569)$$

The coil surface air temperature T_{fs}' can be calculated from the H_{fs}' :

$$\text{if } H_{fs}' < H_{98\%,W_o}, \text{ then } T_{fs}' = f(H_{fs}', 98\%) \quad (16.570)$$

$$\text{if } H_{fs}' \geq H_{98\%,W_o}, \text{ then } T_{fs}' = f(H_{fs}', W_o) \quad (16.571)$$

where:

BF' is the bypass factor for the outdoor unit

$G_{a,rate}'$ is the volumetric flow rate of the air through the outdoor unit, at the rating conditions (m^3/s)

H_{fs}' is the enthalpy of the air leaving the outdoor unit (kJ/kg)

H_{in}' is the enthalpy of the air entering the outdoor unit, i.e., outdoor air (kJ/kg)

W_o is the humidity ratio of the outdoor air (kg/kg)

ρ_o is the density of the outdoor air (kg/m^3).

- (2) Calculate required evaporating temperature for the outdoor unit $T_{e,req}$ and then the effective evaporating temperature T_e .

$$T_{e,req} = T_{fs}' - [A_c' \cdot SH^2 + B_c' \cdot SH + C_c'] \quad (16.572)$$

$$T_e = T_{e,req} \quad (16.573)$$

where:

A_c', B_c', C_c' are coefficients

SH is the superheating degrees for the outdoor unit ($^{\circ}\text{C}$)

SH_{ref} is the reference superheating degrees for the outdoor unit ($^{\circ}\text{C}$)

$T_{e,req}$ is the required evaporating temperature for the outdoor unit ($^{\circ}\text{C}$)

T_e is the effective evaporating temperature ($^{\circ}\text{C}$).

Step 2h.4: Calculate required compressor Loading Index

Calculate the required compressor Loading Index by the following procedures.

- a. Calculate the evaporative capacity at a variety of speeds:

$$M_{cap} = C_{cap,system} \times (r_1 + r_2 T_c' + r_3 T_e + r_4 T_c'^2 + r_5 T_c' T_e + r_6 T_e^2) \quad (16.574)$$

$$Q_{rps} = C_{cap,system} \times M_{cap} \times Q_{ref} \quad (16.575)$$

where:

$C_{cap,system}$ is the evaporative capacity correction factor, describing the possible system configuration difference between test bed and real system (obtained from manufacturer data)

r_1, \dots, r_6 is the empirical coefficients corresponding to rps

rps is the compressor speed (r/s)

T_e is the effective evaporating temperature ($^{\circ}\text{C}$)

M_{cap} is the multiplier for the evaporative capacity calculation (-)

T_c' is the discharge saturated temperature at the compressor outlet ($^{\circ}\text{C}$)

Q_{rps} is the evaporative capacity corresponding to rps (W)

Q_{ref} is the rated evaporative capacity (W).

An example of resulting capacity for different rps (at $T_c' = 36^{\circ}\text{C}$ and $T_e = 9^{\circ}\text{C}$) is presented in Table 3.

Table 3– evaporative capacity at different Loading Index

- b. Find the rps range that covers the required evaporative capacity $Q_{rps,modify}$.

$$Q_{rps,modify} = C_{cap,operation} \times (\sum Q_{in,total} + Q_{pipe} - N_{comp}) \quad (16.576)$$

$$C_{cap,operation} = C_{cap,density} \times C_{cap,enthalpy} \quad (16.577)$$

$$C_{cap,density} = \rho_{test}/\rho_{real} \quad (16.578)$$

$$C_{cap,enthalpy} = \frac{h_{Evapout,test} - h_{Condout,test}}{h_{Compin,real} - h_{Condout,real}} \quad (16.579)$$

where:

$C_{cap,operation}$ is the evaporative capacity correction factor, describing the operational difference between test cases and real cases (i.e., SH and SC)

$C_{cap,density}$ is the evaporative capacity correction factor, describing the variations of refrigerant density at test conditions and real operational conditions

$C_{cap,enthalpy}$ is the evaporative capacity correction factor, describing the variations of refrigerant enthalpy at test conditions and real operational conditions

$h_{Condout,test}$ is the enthalpy of refrigerant leaving the condensers (IU) at test conditions which corresponds to SH at test conditions (e.g., 8°C) and Te (kJ/kg)

$h_{Condout,real}$ is the average enthalpy of refrigerant leaving the condensers (IU) at real conditions (kJ/kg)

$h_{Compin,real}$ is the enthalpy of refrigerant entering the compressor at real conditions which corresponds to SH and Te at real conditions (kJ/kg)

Q_{pipe} is the heat loss through the pipe (W).

For example, if the required capacity is 8 kW, the rps range is 30 to 36 rps based on Table 3.

- c. Calculate the rps that meets the need by interpolation. In the above example, the resulting rps is 34.5 rps .
- d. If the calculated rps is lower than the minimum rps (e.g. 18 rps), go to Step 2h.5; otherwise, skip Step 2h.5 and go to Step 2h.6.

Step 2h.5: Modify evaporating temperature to further reduce outdoor unit capacity

If the calculated rps is lower than the minimum rps (e.g. 18 rps), it means that the zone heating load (indoor unit side) is so low that it leads to an evaporative capacity (outdoor unit side) which is even lower than the system evaporative capacity corresponding to the minimum compressor speed. In this situation, the evaporating temperature Te as well as the superheating degree SH is modified to further reduce the outdoor unit capacity. More specifically:

- a. Set rps at its minimum value (e.g., 18 rps).
- b. Update Te to meet the required evaporative capacity, using equations described in Step 2h.4a.
- c. SH for each indoor unit can be updated using the equations shown in Step 1.2.

It should be noted that, different from the corresponding step in the cooling mode (Step 2c.5), the Te and SH updates in the heating mode do not affect the refrigerant state and flow rate calculations (as shown in Step 2h.1). Therefore, the piping loss analysis does not need to be repeated here.

Step 2h.6: Calculate the compressor power

- (1) Calculate the compressor power by the following procedures.
 - a. Calculate the compressor power at a variety of Loading Index using the following equation. The resulting table (Table 3.3) from the same example is shown below.

$$M_{comp} = c_1 + c_2 T_c' + c_3 T_e + c_4 T_c'^2 + c_5 T_c' T_e + c_6 T_e^2 \quad (16.580)$$

$$N_{comp,rps} = M_{comp} \times N_{comp,ref} \quad (16.581)$$

where:

c_1, \dots, c_6 empirical coefficients corresponding to rps

T_e is the effective evaporating temperature ($^{\circ}\text{C}$)

$T_{e,ref}$ is the reference evaporating temperature ($^{\circ}\text{C}$)

T_c' is the discharge saturated temperature at the compressor outlet ($^{\circ}\text{C}$)

$T_{c,ref}$ is the reference condensing temperature ($^{\circ}\text{C}$)

M_{comp} is the multiplier for the compressor power calculation (-)

$N_{comp,ref}$ is the rated compressor power (W)

$N_{comp,rps}$ is the compressor power corresponding to rps (W).

Table 3.3 – Outdoor unit compressor power at different Loading Index

- b. According to the rps range determined, calculate the compressor power N_{comp} by interpolation. In the above example, the compressor power is 1.155 kW.
- (2) Compare the calculated N_{comp} above with the initialized N_{comp}' in Step 2h.2:
 - If $N_{comp}' - N_{comp} > \delta$ then go to Step 2h.2 for a new round of iteration.
 - Else, end the iteration and go to Step 2h.7.

Step 2h.7: Total power consumption of the outdoor unit

Same as that in the cooling mode (Step 2c.7)

16.7.2.4 Modeling of the indoor unit (I/U) - Part II - Cooling Mode

Step 3c.1: Update air flow rate for each indoor unit

- (1) Calculate coil surface temperature for each indoor unit:

$$T_{fs} = T_e + [A_c \cdot SH^2 + B_c \cdot SH + C_c] \quad (16.582)$$

where:

T_e is the evaporating temperature decided in the outdoor unit calculations ($^{\circ}\text{C}$)

T_{fs} is the coil surface temperature ($^{\circ}\text{C}$)

SH is the superheating degrees decided in the outdoor unit calculations ($^{\circ}\text{C}$).

- 2) Calculate the enthalpy of the air at the coil surface, H_{fs} :

$$\text{if } T_{fs} < T_{98\%,W_{in}}, \text{ then } H_{fs} = f(T_{fs}, 98\%) \quad (16.583)$$

$$\text{if } T_{fs} \geq T_{98\%,W_{in}}, \text{ then } H_{fs} = f(T_{fs}, W_{in}) \quad (16.584)$$

where:

$T_{98\%,W_{in}}$ is the dew point temperature of the indoor air ($^{\circ}\text{C}$)

H_{fs} is the enthalpy of the air at the coil surface (kJ/kg).

3) Calculate the required air flow rate G_a for each indoor unit:

$$G_a = Q_{in,total} / [(H_{coil,in} - H_{fs}) \times (1 - BF) \times \rho_{in}] \quad (16.585)$$

where:

$Q_{in,total}$ is the total cooling load for the zone (W)

$H_{coil,in}$ is the enthalpy of the entering air of the indoor unit (kJ/kg)

ρ_{in} is the density of indoor air, $f_{\rho}(T_{in}, W_{in})$ (kg/m^3).

4) Decide whether to modify SH for further indoor unit capacity reduction.

- If $G_a < G_{a,min}$ (e.g., $0.7 \times G_{a,rate}$) go to Step 3c.2
- Else, directly go to Step 3c.3

Step 3c.2: Modify SH to adjust the indoor unit capacity

Set G_a at its minimum value (e.g., $0.7 \times G_{a,rate}$).

The required coil surface temperature T_{fs} can be determined as described in Step 1.2.

Given T_{fs} and T_e , SH can be determined using the equation shown in Step 1.3.

- If $SH > 15^{\circ}\text{C}$, Set SH as 15°C . On/Off control strategy may be implemented when needed.

Step 3c.3: Total power consumption of the indoor unit

The power consumption of the indoor unit comes from the fan operations. This can be calculated using the existing VAV fan model in EnergyPlus. Please refer to the current EnergyPlus Engineering Reference for more details.

16.7.2.5 Modeling of the indoor unit (I/U) - Part II - Heating Mode

Step 3h.1: Update air flow rate for each indoor unit.

1) Calculate coil surface temperature for all the indoor units:

$$T_{fs} = T_c - [A_h \cdot SC^2 + B_h \cdot SC + C_h] \quad (16.586)$$

where:

T_c is the condensing temperature decided in the outdoor unit calculations ($^{\circ}\text{C}$)

T_{fs} is the coil surface temperature ($^{\circ}\text{C}$)

SC is the subcooling degrees decided in the outdoor unit calculations ($^{\circ}\text{C}$).

- 2) Calculate the required air flow rate G_a for each indoor unit:

$$G_a = Q_{in,total} / [(T_{fs} - T_{coil,in}) \times (1 - BF) \times \rho_{in}] \quad (16.587)$$

where:

$Q_{in,total}$ is the total heating load for the zone (W)

$T_{coil,in}$ is the temperature of the entering air of the indoor unit (°C)

ρ_{in} is the density of indoor air, $f_\rho(T_{in}, W_{in})$ (kg/m³).

- 3) Decide whether to modify SH for further indoor unit capacity reduction

- If $G_a < G_{a,min}$ (e.g., $0.7 \times G_{a,rate}$) go to Step 3h.2
- Else, directly go to Step 3h.3

Step 3h.2: Modify SC to modify the indoor unit capacity

Set G_a at its minimum value ($0.7 \times G_{a,rate}$).

The required coil surface temperature T_{fs} can be determined as described in Step 2.

Given T_{fs} and T_e , SC can be determined using the equation shown in Step 1.3.

- If $SC > 20^\circ\text{C}$, Set SC as 20°C . On/Off control strategy may be implemented when needed.

Step 3h.3: Total power consumption of the indoor unit

Calculate electric power consumption by the indoor unit using the existing VAV fan model in EnergyPlus. Please refer to the current EnergyPlus Engineering Reference for more details.

16.7.2.5.1 Additional energy consumption by defrost and crankcase heater

There may be additional energy consumption due to the defrost operation and crankcase heater operation. These components have no impact on the heat pump operations. The calculation methods in the VRF-FluidTCtrl model are the same as those in VRF-SysCurve model. Please refer to the VRF-SysCurve section for more details.

16.7.3 Physics based VRF Heat Recovery Model (VRF-FluidTCtrl-HR)

16.7.3.1 Overview

16.7.3.1.1 Introduction of VRF-HR Systems

This section introduces the model to simulate the energy performance of Variable Refrigerant Flow (VRF) systems with heat recovery (HR) configurations, which is capable of achieving heat recovery from cooling zones to heating zones and providing simultaneous zone cooling and heating operations. The model is developed for the 3-pipe VRF-HR systems, which are the dominant system configuration in the current VRF-HR market.

Compared with the VRF-HP system, VRF-HR is more complicated in terms of system configuration and operational controls. Figure 16.65 shows the schematic chart of a typical 3-pipe VRF-HR system. As can be seen in the figure, it has dedicated refrigerant pipes for suction gas,

liquid and discharge gas. To enable simultaneous cooling and heating, complex refrigerant management loop and more system components are implemented, including one additional heat exchanger in the outdoor unit (OU) and multiple Branch Selector (BS) Units. The two heat exchangers in the outdoor unit can work at different evaporator/condenser combinations to enable specific operational modes to handle diverse and changing indoor heating/cooling load requirements. The Four-Way Directional Valves (FWV) and BS units enable the system to provide separate refrigerant piping connections for different operational modes. This leads to varying refrigerant flow directions and different control logics for various operational modes, and therefore specific algorithm is needed for different major operational modes.

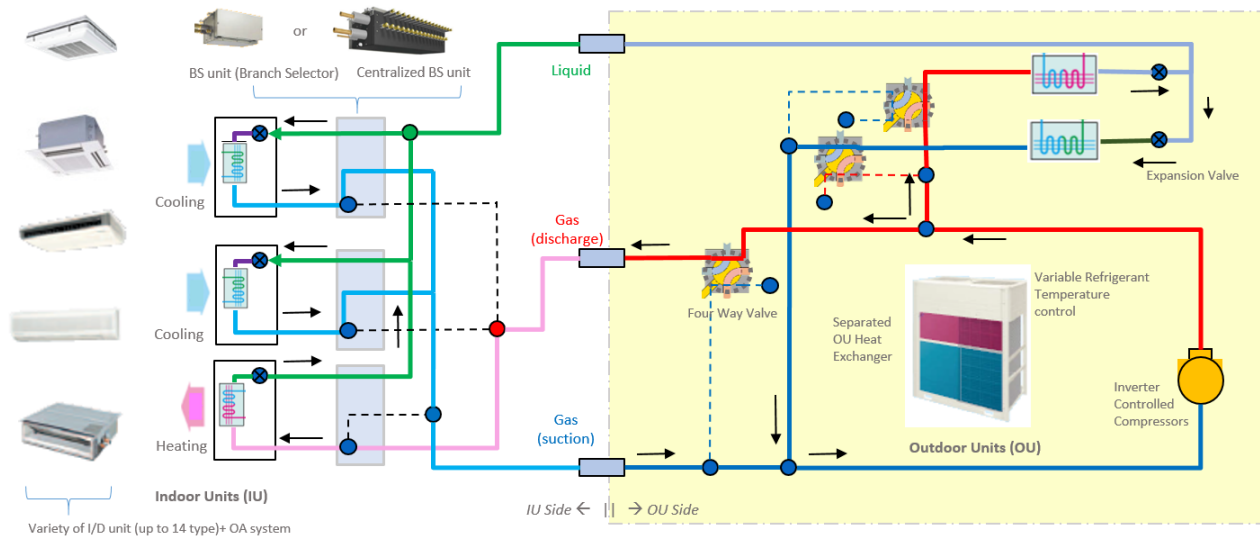

Figure 16.65: Schematic chart of a 3-pipe VRF-HR system

16.7.3.1.2 VRF-HR operational modes

Depending on the indoor cooling/heating requirements and the outdoor unit operational states, the operations of the VRF-HR system can be categorized into six modes:

- Mode 1: Cooling load only. No heating load. Both OU heat exchangers operate as condensers.
- Mode 2: Simultaneous heating and cooling. The sum of the zone cooling loads and compressor heat is much larger than the sum of the zone heating loads. Both OU heat exchangers operate as condensers.
- Mode 3: Simultaneous heating and cooling. The sum of the zone cooling loads and compressor heat is slightly larger than the sum of the zone heating loads. One OU heat exchanger operates as a condenser while the other as an evaporator.
- Mode 4: Simultaneous heating and cooling. The sum of the zone cooling loads and compressor heat is slightly smaller than the sum of the zone heating loads. One OU heat exchanger operates as a condenser while the other as an evaporator.

- Mode 5: Simultaneous heating and cooling. The sum of the zone cooling loads and compressor heat is much smaller than the sum of the zone heating loads. Both OU heat exchangers operate as evaporators.
- Mode 6: Heating load only. No cooling load. Both OU heat exchangers operate as evaporators.

Figure 16.66: System-level Heat Balance Diagram for the Six VRF-HR Operational Modes

The system-level heat balance diagram for all the six operational modes are shown in Figure 16.66. Note that the heat recovery loss (HR loss) only exists in Mode 3 and Mode 4, in which the OU evaporator and condenser run simultaneously. In these modes, the following two items are at similar levels: (a) sum of IU heating loads and IU condenser side piping loss, and (b) sum of IU cooling loads, IU evaporator side piping loss and heat released by the compressor. Take Mode 3 for example, item (b) is higher than item (a), and therefore the system requires the operation of OU condenser to release the extra heat to ensure the system-level heat balance. However, the extra heat is at a relatively low level so that the system needs to release more heat than required via OU condenser and meanwhile runs OU evaporator to ensure the heat balance as well as system reliability. This leads to the presence of HR loss.

16.7.3.1.3 System operation at various modes

With the help of FWV and BS units, every operational mode has its own refrigerant piping connections to achieve different refrigerant flow directions, as shown in Figure 16.67. This leads to different refrigerant operations and piping loss situations, as shown in the Pressure-Enthalpy Diagrams in Figure 16.68.

Take Mode 3 for instance, the system utilizes one OU heat exchanger as an evaporator and the other as a condenser. The superheated refrigerant coming out of the compressor is divided into two parts. One part passes through the OU condenser within which the refrigerant is condensed and subcooled (segment 2-4'), while the other part passes through the IU condenser to satisfy the indoor heating requirements (segment 3-4). Note that before entering the IU condenser, the second part of the refrigerant flow passes through the main discharge gas pipe connecting the indoor and outdoor units, where the refrigerant pressure drop and heat loss occurs. This leads to extra heating load and a lower condensing temperature level at IU condenser than that at OU condenser. The two parts of refrigerant leaving condensers are then expanded through expansion valves following segment 4''-5/5' and pass through the IU evaporator (segment 5-6) and OU evaporator (segment 5'-1'). Similarly to the refrigerant passing through the main discharge gas pipe, the refrigerant leaving IU evaporators passes through the main suction gas pipe where the refrigerant pressure drop and heat loss occurs (segment 6-1''). This leads to extra cooling load and a higher evaporating temperature level at IU evaporator than that at OU evaporator. Finally, the refrigerant flow leaving the OU evaporator and that leaving the main discharge gas pipe are combined (segment 1'/1''-1) and enter the compressors for the next cycle. In this regard, the system provides simultaneous heating and cooling to the indoor environment.

A number of operational parameters are controlled to ensure system heat balance and stable and reliable system operation, including evaporating temperature levels, condensing temperature levels, superheating and sub-cooling degrees, and the refrigerant flow rates at various components. The operational control logics for various modes are different and therefore particular algorithm needs to be designed for different operational modes in the new VRF-HR model.

16.7.3.2 Model Description

The algorithm of the VRF-HR Cooling Only Mode and Heating Only Mode are the same as those in the VRF-HP Cooling Mode (Figure 16.64) and Heating Mode (Figure 16.63), respectively. The holistic logics of the VRF-HR Simultaneous Heating and Cooling Mode are illustrated in Figure 16.69. In general, the effective evaporating temperature and/or condensing temperature for the indoor units is first determined based on the load requirements and indoor unit configurations. Then the pressure and heat losses through the main pipe are calculated at the given operational conditions. After that, the effective condensing temperature and/or evaporating temperature of the outdoor unit is calculated, taking into account the piping loss. With the above calculations, the compressor speed can be determined using the performance curves describing the evaporative capacity of the system at specific condensing/evaporating temperature combinations at various compressor speeds. Finally, the compressor power at that speed is calculated and the total electric power consumption by the outdoor unit is obtained. Note that particular control logics are designed for various operational modes, and therefore lead to different refrigerant temperature adjustments. Also, note that a number of calculation steps are coupled together, for instance, the piping loss calculation and the system performance calculation. More specifically, the piping loss changes the operating conditions of the system, which may lead to a different control strategy and thus affect the amount of piping loss. This makes it difficult to obtain an analytical solution for a number of operational parameters (e.g., enthalpy of refrigerant entering the indoor unit), and therefore numerical iterations are employed to address this problem.

Detailed calculation procedures for the VRF-HR Simultaneous Heating and Cooling Mode are summarized as follows.

Table 1: Piping Diagrams for All Six VRF-HR Operational Modes

<p>Mode 1: Cooling Only</p> <p>Cooling Only</p> 	<p>Mode 2: Cooling Dominant w/o HR loss</p> <p>Cooling Dominant w/o HR Loss</p>

<p>Note:</p> <p>The number of indoor evaporators/condensers indicates the indoor load conditions. For example, 2 evaporators and 1 condenser indicates the cooling dominant condition; 3 evaporators and non condenser indicates cooling only condition.</p> <div> Condenser</div> <div> Evaporator</div>	

Figure 16.67: Piping diagrams for the six VRF-HR operational modes

Figure 10 displays six T-h diagrams illustrating different operating modes of a heat exchanger network. The diagrams show temperature (T) on the y-axis and enthalpy (h) on the x-axis. The modes are defined as follows:

- Mode 1: Cooling Only**: Shows a single process stream (SC) being cooled from (4) to (2) and then (1). The cooling water (CW) is heated from (5) to (6). The heat exchanger (HE) is represented by a green curve.
- Mode 2: Cooling Dominant w/o HR loss**: Shows a process stream (SC) being cooled from (4) to (2) and then (1). The cooling water (CW) is heated from (5) to (6). The heat exchanger (HE) is represented by a green curve. The diagram shows the temperature profiles for the process stream (SC) and the cooling water (CW) without heat recovery loss.
- Mode 3: Cooling Dominant w/ HR loss**: Shows a process stream (SC) being cooled from (4) to (2) and then (1). The cooling water (CW) is heated from (5) to (6). The heat exchanger (HE) is represented by a green curve. The diagram shows the temperature profiles for the process stream (SC) and the cooling water (CW) with heat recovery loss.
- Mode 4: Heating Dominant w/ HR loss**: Shows a process stream (SC) being heated from (4) to (2) and then (1). The heating water (HW) is cooled from (5) to (6). The heat exchanger (HE) is represented by a green curve. The diagram shows the temperature profiles for the process stream (SC) and the heating water (HW) with heat recovery loss.
- Mode 5: Heating Dominant w/o HR loss**: Shows a process stream (SC) being heated from (4) to (2) and then (1). The heating water (HW) is cooled from (5) to (6). The heat exchanger (HE) is represented by a green curve. The diagram shows the temperature profiles for the process stream (SC) and the heating water (HW) without heat recovery loss.
- Mode 6: Heating Only**: Shows a process stream (SC) being heated from (4) to (2) and then (1). The heating water (HW) is cooled from (5) to (6). The heat exchanger (HE) is represented by a green curve. The diagram shows the temperature profiles for the process stream (SC) and the heating water (HW) without heat recovery loss.

Figure 16.68: Illustration of the six VRF-HR operational modes on Pressure-Enthalpy diagrams

Step 1: Obtaining zonal load/condition information

The following information for each zone from the zone modules within EnergyPlus are obtained:

- zone sensible loads $Q_{in,sensible}$
- zone total loads $Q_{in,total}$
- indoor air temperature T_{in}
- indoor air humidity ratio W_{in}

If there are only zone cooling loads and no zone heating loads, go to the VRF-HR Cooling Only Mode, the algorithms of which is the same as those for the VRF-HP Cooling Mode. If there are only zone heating loads and no zone cooling loads, go to the VRF-HR Heating Only Mode, the algorithms of which is the same as those for the VRF-HP Heating Mode. Otherwise, go to the VRF-HR Simultaneous Heating and Cooling Mode as described below.

Step 2: Calculate IU required evaporating temperature and/or the condensing temperature Evaluate the required coil surface air temperature T_{fs} and then the required evaporator refrigerant temperature $T_{e,req}$ for each indoor unit with cooling requirements. Likewise, evaluate the required condenser refrigerant temperature $T_{c,req}$ for each indoor unit with heating requirements. (Refer to Step 1.2 in the VRF-FluidTCtrl-HP model for more details.)

Step 3: Calculate IU effective evaporating temperature T_e and/or the condensing temperature T_c There are two refrigerant temperature control strategies for the indoor unit: (1) *ConstantTemp*, (2) *VariableTemp*.

- In the *ConstantTemp* strategy, T_e and T_c are kept at constant values provided by the user.
- In the *VariableTemp* strategy, T_e and T_c are determined using the required evaporating/condensing temperature calculated in Step 2.

(Refer to Step 1.3 in the VRF-FluidTCtrl-HP model for more details.)

Step 4: IU condenser side piping loss calculations

This section calculates the IU condenser side piping loss, which occurs at the High and Low Pressure Gas Pipe where the refrigerant flowing from the OU compressor outlets to the IU condensers. It includes both the refrigerant pressure drop ΔP_{pipe} and heat loss Q_{pipe} . Note that the change of compressor operational conditions may lead to different control strategies of the system, which in reverse affects the amount of piping loss. So the piping loss analysis and system performance analysis are coupled together. Numerical iterations are designed to address the coupling effect.

At this step, the compressor discharge saturated temperature T'_c (i.e., saturated vapor temperature corresponding to compressor discharge pressure) can be obtained using the calculated refrigerant pressure drop ΔP_{pipe} .

(Refer to Step 2h.1 in the VRF-FluidTCtrl-HP model for more details.)

Step 5: IU evaporator side piping loss calculations

This section calculates the IU evaporator side piping loss, which occurs at Suction Gas Pipe where the refrigerant flowing from the IU evaporators to the OU compressor inlets. Similarly to the IU condenser side piping loss, it includes both the refrigerant pressure drop ΔP_{pipe} and heat loss Q_{pipe} .

At this step, the compressor suction saturated temperature T'_e (i.e., saturated vapor temperature corresponding to compressor suction pressure) can be obtained using the calculated refrigerant pressure drop ΔP_{pipe} .

Note that one key input of the IU evaporator side piping loss calculations is the enthalpy of the refrigerant at IU evaporator inlets. It is assumed to be equal to the average enthalpy of the refrigerant at IU condenser outlets, which is obtained in the IU condenser side piping loss calculations.

(Refer to Step 2c.1 in the VRF-FluidTCtrl-HP model for more details.)

Step 6: Determine the operational mode for simultaneous heating and cooling operations

As noted earlier, simultaneous heating and cooling operations include the following modes:

- Mode 2: Cooling dominant w/o HR loss
- Mode 3: Cooling dominant w/ HR loss
- Mode 4: Heating dominant w/ HR loss
- Mode 5: Heating dominant w/o HR loss

This section determines the operational mode based on the load requirements and operational conditions:

- a. Calculate the Loading Index LI_1 satisfying IU cooling load (Refer to Step 2c.4 in the VRF-FluidTCtrl-HP model for more details.)
- b. Calculate the Loading Index LI_2 satisfying IU heating load (Refer to Step 2h.4 in the VRF-FluidTCtrl-HP model for more details.)
- c. If $LI_1 \leq LI_2$, the system operates at Mode 5
- d. If $LI_1 > LI_2$ and $Te' < T_o - T_{diff}$, the system operates at Mode 2 (T_o : outdoor air dry-bulb temperature; T_{diff} : a constant value representing the difference between OU evaporating temperature and outdoor air temperature during simultaneous heating and cooling)
- e. If $LI_1 > LI_2$ and $Te' \geq T_o - T_{diff}$, the system operates at Mode 3 or 4 (these two modes can be handled by one set of algorithms)

Step 7: OU operation analysis at Mode 5

If $Te' < T_o - T_{diff}$, perform the following procedures:

- a. Select the compressor speed corresponding to LI_2
- b. Calculate the compressor power corresponding to LI_2 and the previously obtained T_c and Te' (Refer to Step 2c.6 in the VRF-FluidTCtrl-HP model for more details.)
- c. Calculate the evaporative capacity $Cap_{tot,evap}$ provided by the compressor at LI_2 and the previously obtained T_c and Te' (Refer to Step 2c.4 in the VRF-FluidTCtrl-HP model for more details.)
- d. Calculate the OU evaporator load $Cap_{ou,evap}$ based on system-level heat balance
- e. Obtain the OU fan flow rate $m_{air,evap}$ corresponding to $Cap_{ou,evap}$, and thus the fan power (Refer to Step 2c.3 in the VRF-FluidTCtrl-HP model for more details.)

If $Te' \geq T_o - T_{diff}$, perform the following procedures:

- a. Select the compressor speed corresponding to LI_1
- b. Perform iterations between step b-i to identify the compressor Loading Index and power consumption.

- c. Initialized compressor power $Ncomp_{ini}$
- c.1 For the 1st iteration step, calculate $Ncomp = f_{pow,comp}(T_c, T_o - 5, LI_2)$
- c.2 For the following iteration steps, update $Ncomp = (Ncomp_{ini} + Ncomp_{new})/2$
- d. Calculate the OU evaporator load $Cap_{ou,evap}$ based on system-level heat balance
- e. Obtain the OU evaporating temperature Te' level using $Cap_{ou,evap}$ and the rated air flow rate (Refer to Step 2c.3 in the VRF-FluidTCtrl-HP model for more details.)
- f. Update T_e level and IU evaporator side piping loss, corresponding to Te' update
- g. Identify the compressor Loading Index LI_{new} to provide sufficient evaporative capacity $Cap_{tot,evap}$ at updated Te' level (Refer to Step 2c.4 in the VRF-FluidTCtrl-HP model for more details.)
- h. Calculate the compressor power $Ncomp_{new}$ corresponding to LI_{new} and the updated Te' (Refer to Step 2c.6 in the VRF-FluidTCtrl-HP model for more details.)
- i. Compare $Ncomp_{new}$ and $Ncomp_{ini}$. Start a new round of iteration if the difference is greater than the tolerance.

Step 8: OU operation analysis at Mode 2

- a. Select the compressor speed corresponding to LI_1
- b. Calculate the compressor power corresponding to LI_1 and the previously obtained T_c and Te' (Refer to Step 2c.6 in the VRF-FluidTCtrl-HP model for more details.)
- c. Calculate the evaporative capacity $Cap_{tot,evap}$ provided by the compressor at LI_1 and the previously obtained T_c and Te' (Refer to Step 2c.4 in the VRF-FluidTCtrl-HP model for more details.)
- d. Calculate the OU condenser load $Cap_{ou,cond}$ based on system-level heat balance
- e. Obtain the OU fan flow rate $m_{air,cond}$ corresponding to $Cap_{ou,cond}$, and thus the fan power

Step 9: OU operation analysis at Mode 3 or 4

- a. Select the compressor speed corresponding to LI_1
- b. Perform iterations between step b-e to identify the updated Te' level within the range of T_o-5 and the original Te' .
- c. Calculate the evaporative capacity $Cap_{tot,evap}$ provided by the compressor at LI_1 and the previously obtained T_c and assumed Te' (Refer to Step 2c.4 in the VRF-FluidTCtrl-HP model for more details.)
- d. Calculate the OU evaporator load $Cap_{tot,evap}$ at assumed Te' level and rated fan flow rate (Refer to Step 2h.3 in the VRF-FluidTCtrl-HP model for more details.)
- e. Perform iterations to identify the updated Te' level to ensure the heat balance for the b. and c. calculations

- f. Update T_e level and IU evaporator side piping loss, corresponding to Te' update
- g. Calculate the compressor power corresponding to LI_1 and the updated Te' (Refer to Step 2c.6 in the VRF-FluidTCtrl-HP model for more details.)
- h. Calculate the OU condenser load $Cap_{ou,cond}$ based on system-level heat balance
- i. Obtain the OU fan flow rate $m_{air,cond}$ corresponding to $Cap_{ou,cond}$, and thus the fan power

Step 10: Modify IU operational parameters for capacity adjustments

The air flow rate and SH/SC value of each indoor unit can be manipulated to adjust the cooling/heating capacity. (Refer to Step 3c and 3h in the VRF-FluidTCtrl-HP model for more details.)

16.7.4 Zone Terminal Unit List

The zone terminal unit list identifies the terminal units that are connected to a single variable refrigerant flow heat pump. The zone terminal unit list is used exclusively in the variable refrigerant flow (VRF) heat pump object (ref: AirConditioner:VariableRefrigerantFlow) and VRF zone terminal units (ref: ZoneHVAC:TerminalUnit:VariableRefrigerantFlow). Up to 20 terminal units may be connected to a single VRF outdoor condensing unit. This list is extensible if additional indoor terminal units are required. The following figure shows the connection scheme between the zone terminal units, the zone terminal unit list, and finally the VRF AC system. The zone terminal units are connected to the zone through zone inlet and outlet zone nodes. Each zone terminal unit is entered in a list which represents all terminal units connected to a single VRF AC system. And finally, the zone terminal unit list name is entered in the corresponding VRF AC object.

16.8 Heat Exchangers

16.8.1 Air System Air-To-Air Sensible and Latent Effectiveness Heat Exchanger

16.8.1.1 Overview

The input object `HeatExchanger:AirToAir:SensibleAndLatent` provides a model for a generic, sensible and latent air-to-air heat exchanger that is an HVAC air system component that consists of a heat exchanger and primary/secondary airflow bypass dampers. The specific configuration of the component is shown in the following figure.

Figure 16.71: Schematic of the Sensible and Latent Air-to-Air Heat Exchanger

The sensible and latent air-to-air heat exchanger is typically used for exhaust or relief air heat recovery. Heat exchanger performance can be specified to transfer sensible energy, latent energy or both between the supply and exhaust air streams. The input requires no geometric data. Performance is defined by specifying sensible and/or latent effectiveness at 75% and 100% of the nominal (rated) supply air flow rate in both heating and cooling conditions (Table 16.15).

Table 16.15: Operating Conditions for Defining Heat Exchanger Performance

Parameter	Conditions	
	Heating	Cooling
Entering supply air temperature:		
Dry-bulb	1.7°C (35°F)	35°C (95°F)
Wet-bulb	0.6°C (33°F)	26°C (78°F)
Entering exhaust air temperature:		

Table 16.15: Operating Conditions for Defining Heat Exchanger Performance

Parameter	Conditions	
	Heating	Cooling
Dry-bulb	21°C (70°F)	24°C (75°F)
Wet-bulb	14°C (58°F)	17°C (63°F)

Note: Conditions consistent with the Air-Conditioning and Refrigeration Institute's Standard 1060 (ARI 2001).

Heat exchange between the supply and exhaust air streams occurs whenever the unit is scheduled to be available (availability schedule) and supply/exhaust air flows are present. This heat exchanger object can be used in conjunction with a conventional air-side economizer (i.e., specify an appropriate economizer control type in the Controller:OutdoorAir object), whereby heat exchange is suspended whenever the air-side economizer is active (i.e., air flow is fully bypassed around a fixed-plate heat exchanger or the rotation of a rotary heat exchanger is stopped). This object is also able to suspend heat exchange for the purpose of providing free cooling operation in the absence of a conventional air-side economizer (i.e., specify MinimumFlowWithBypass in the Controller:Outside Air object). Suspension of heat exchange during economizer mode may be customized as necessary using the economizer lockout field. Note that the Economizer Type must be set to something other than NoEconomizer for this control interaction to function.

Several methods of frost control are available to warm the heat exchanger core to prevent frost formation. Available methods are preheat, exhaust only, exhaust air recirculation, and minimum exhaust temperature. Preheat frost control uses a separate heater object placed in the supply inlet air stream to keep the air temperature above the frost threshold temperature. All other frost control methods are modeled within this heat exchanger object.

This heat exchanger object can also control the supply air outlet temperature to a setpoint when a setpoint manager and temperature schedule are used. This temperature control is accomplished through wheel speed modulation or bypassing supply air around the heat exchanger to maintain the desired setpoint and avoid overheating or overcooling the supply air.

16.8.1.2 Model Description

The heat exchanger object models energy transfer between the supply air stream and the exhaust air stream according to the effectiveness values that are specified by the user in the input data file (see IO Reference Document, HeatExchanger:AirToAir:SensibleAndLatent). The operating volumetric air flow rate through the heat exchanger (i.e., the average of the actual supply and exhaust air flow rates for the simulation time step) should be between 50% and 130% of the nominal supply air flow rate specified for the heat exchanger. Operating air flow rates outside this range result in a warning message and a recommendation to adjust air flow rates to within the appropriate range.

The user must enter the sensible and latent effectiveness of the heat exchanger for heating and cooling conditions (Table 16.15) with balanced air flow (supply flow equal to the exhaust flow) at two flow rates: 75% and 100% of the nominal supply air flow rate. Heat exchanger manufacturers can typically provide this performance information, and it is also available for equipment contained in ARI's Certified Product Directory for Air-to-Air Energy Recovery Ventilation Equipment (ARI 2003). Values may be entered for sensible effectiveness, latent effectiveness, or both. The model assumes default values of 0.0 for sensible and latent effectiveness, thus requiring the user to input representative values for the heat exchanger being modeled.

To obtain the “operating” effectiveness of the heat exchanger at different air flow rates, the model first calculates the average volumetric air flow rate through the heat exchanger (average of the supply and exhaust air flow rates) for each simulation time step. Air flows through the heat exchanger may be unbalanced (supply greater than exhaust, or vice versa), but an unbalanced air flow ratio greater than 2:1 is not recommended (beyond this range a warning message is issued). The model determines the operating effectiveness of the heat exchanger by linear interpolation or extrapolation of the 100% flow and 75% flow effectiveness values specified in the input data file, using the average volumetric air flow rate through the heat exchanger. Extrapolation is allowed down to 50% and up to 130% of the nominal supply air flow rate (beyond this range a warning message is issued).

$$\varepsilon_{operating,sensible} = \varepsilon_{sensible,75\%flow} + (\varepsilon_{sensible,100\%flow} - \varepsilon_{sensible,75\%flow}) \left(\frac{HX_{flowratio} - 0.75}{1 - 0.75} \right) \quad (16.588)$$

$$\varepsilon_{operating,latent} = \varepsilon_{latent,75\%flow} + (\varepsilon_{latent,100\%flow} - \varepsilon_{latent,75\%flow}) \left(\frac{HX_{flowratio} - 0.75}{1 - 0.75} \right) \quad (16.589)$$

where:

$\varepsilon_{operating,sensible}$ is the operating sensible effectiveness of the heat exchanger

$\varepsilon_{operating,latent}$ is the operating latent effectiveness of the heat exchanger

$\varepsilon_{sensible,75\% flow}$ is the sensible effectiveness at 75% airflow condition

$\varepsilon_{sensible,100\% flow}$ is the sensible effectiveness at 100% airflow condition

$\varepsilon_{latent,75\% flow}$ is the latent effectiveness at 75% airflow condition

$\varepsilon_{latent,100\% flow}$ is the latent effectiveness at 100% airflow condition

$HX_{flowratio}$ is the ratio of the average operating volumetric air flow rate [(supply flow plus exhaust flow) / 2.0] to the nominal supply air flow rate.

If the heat exchanger's supply air inlet temperature is less than the exhaust air inlet temperature, the operating sensible and latent effectivenesses are calculated using the 75% and 100% heating condition values; otherwise, the 75% and 100% cooling effectiveness values are used in Equations 16.588 and 16.589.

The supply air conditions leaving the heat exchanger are determined using the heat exchanger operating effectiveness calculated above, the ratio of the air stream with the minimum heat capacity rate to the supply air stream heat capacity rate, and the difference in temperature or humidity ratio between the supply and exhaust inlet air:

$$\dot{m}c_{p,min} = MIN(\dot{m}c_{p,sup}, \dot{m}c_{p,exh}) \quad (16.590)$$

$$T_{SupAirOut} = T_{SupAirIn} + \varepsilon_{operating,sensible} \left(\frac{\dot{m}c_{p,min}}{\dot{m}c_{p,sup}} \right) (T_{ExhAirIn} - T_{SupAirIn}) \quad (16.591)$$

$$\omega_{SupAirOut} = \omega_{SupAirIn} + \varepsilon_{operating,latent} \left(\frac{\dot{m}cp,min}{\dot{m}cp,sup} \right) (\omega_{ExhAirIn} - \omega_{SupAirIn}) \quad (16.592)$$

where:

$\dot{m}c_{p,min}$ is the minimum heat capacity rate (W/K)

$\dot{m}c_{p,sup}$ is the heat capacity rate of the supply air stream (W/K)

$\dot{m}c_{p,exh}$ is the heat capacity rate of the exhaust air stream (W/K)

$T_{SupAirOut}$ is the supply air temperature leaving the heat exchanger (°C)

$T_{SupAirIn}$ is the supply air inlet temperature (°C)

$T_{ExhAirIn}$ is the exhaust air inlet temperature (°C)

$\omega_{SupAirOut}$ is the supply air humidity ratio leaving the heat exchanger (kg/kg)

$\omega_{SupAirIn}$ is the supply air inlet humidity ratio (kg/kg)

$\omega_{ExhAirIn}$ is the exhaust air inlet humidity ratio (kg/kg).

Using the supply air outlet temperature and humidity ratio, the enthalpy of the supply air leaving the heat exchanger is calculated.

$$h_{SupAirOut} = PsyHFnTdbW(T_{SupAirOut}, \omega_{SupAirOut}) \quad (16.593)$$

where:

$h_{SupAirOut}$ is the enthalpy of the supply air leaving the heat exchanger (J/kg)

$PsyHFnTdbW$ is a psychrometric routine calculating air enthalpy as a function of temperature and humidity ratio.

If the predicted conditions of the supply air leaving the heat exchanger exceed the saturation curve ($>100\%$ RH), then the temperature and humidity ratio of the air are reset to saturated conditions ($= 100\%$ RH) at the enthalpy condition calculated above ($h_{SupAirOut}$).

Next, the sensible and total heat recovery rates of the heat exchanger are calculated:

$$\dot{Q}_{Sensible} = (\dot{m}c_{p,sup})(T_{SupAirIn} - T_{SupAirOut}) \quad (16.594)$$

$$\dot{Q}_{Total} = \dot{m}_{SupAir}(h_{SupAirIn} - h_{SupAirOut}) \quad (16.595)$$

where:

$\dot{Q}_{Sensible}$ is the sensible heat recovery rate (W)

\dot{Q}_{Total} is the total heat recovery rate (W)

$h_{SupAirIn}$ is the supply air inlet enthalpy (J/kg)

\dot{m}_{SupAir} is the mass flow rate of the supply air stream (kg/s).

The conditions of the exhaust (secondary) air leaving the heat exchanger are then calculated:

$$T_{ExhAirOut} = T_{ExhAirIn} + \frac{\dot{Q}_{Sensible}}{\dot{m}c_{p,exh}} \quad (16.596)$$

$$h_{ExhAirOut} = h_{ExhAirIn} + \frac{\dot{Q}_{Total}}{\dot{m}_{ExhAir}} \quad (16.597)$$

$$\omega_{ExhAirOut} = PsyWFnTdbH(T_{ExhAirOut}, h_{ExhAirOut}) \quad (16.598)$$

where:

$T_{ExhAirOut}$ is the exhaust air temperature leaving the heat exchanger ($^{\circ}\text{C}$)

$h_{ExhAirOut}$ is the exhaust air enthalpy leaving the heat exchanger (J/kg)

\dot{m}_{ExhAir} is the mass flow rate of the exhaust air stream (kg/s)

$\omega_{ExhAirOut}$ is the exhaust air humidity ratio leaving the heat exchanger (kg/kg)

$PsyWFnTdbH$ is a psychrometric routine calculating air humidity ratio as a function of temperature and enthalpy.

As was done for the supply air, calculated exhaust air conditions beyond the saturation curve are reset to saturation conditions at the calculated air enthalpy value.

Once the air conditions leaving each side of the heat exchanger (supply and exhaust) are calculated, this air is blended with any bypass air that was directed around the heat exchanger core to determine the final air conditions leaving the heat exchanger unit. These outlet air conditions are used in Equations 16.594 and 16.595 to determine the sensible and total heat recovery rate for the overall heat exchanger unit. The latent heat recovery rate for the overall unit is then calculated as the difference between the total and sensible heat recovery rates:

$$\dot{Q}_{Latent} = \dot{Q}_{Total} - \dot{Q}_{Sensible} \quad (16.599)$$

Heat recovery electric power is the electric consumption rate of the unit in watts. The nominal electric power rate for the heat exchanger is specified in the input data file, and can be used to model controls (transformers, relays, etc.) and/or a motor for a rotary heat exchanger. The model assumes that this electric power is consumed whenever the heat exchanger is scheduled to operate and supply/exhaust air flow rates exist. The electric power is assumed to be zero for all other

times or if heat exchange is suspended to provide free cooling (economizer operation). None of this electric power is assumed to contribute thermal load to either of the heat exchanger air streams.

At the end of each HVAC simulation time step, this object reports the sensible, latent and total heat recovery rates for the overall unit as calculated above. The heat recovery rates are reported separately for times when the supply air is heated and when it is cooled (Ref: HeatExchanger:AirToAir:SensibleAndLatent in the EnergyPlus Input Output Reference). The heat recovery electric power is also reported for each simulation time step. In addition to the heat recovery rates and electric power, heating/cooling energy transferred to the supply air and the electric energy consumption by the heat exchanger unit are calculated for the time step being reported as follows:

$$Q_{SensibleCooling} = \dot{Q}_{SensibleCooling} * TimeStepSys * 3600 \quad (16.600)$$

$$Q_{LatentCooling} = \dot{Q}_{LatentCooling} * TimeStepSys * 3600 \quad (16.601)$$

$$Q_{TotalCooling} = \dot{Q}_{TotalCooling} * TimeStepSys * 3600 \quad (16.602)$$

$$Q_{SensibleHeating} = \dot{Q}_{SensibleHeating} * TimeStepSys * 3600 \quad (16.603)$$

$$Q_{LatentHeating} = \dot{Q}_{LatentHeating} * TimeStepSys * 3600 \quad (16.604)$$

$$Q_{TotalHeating} = \dot{Q}_{TotalHeating} * TimeStepSys * 3600 \quad (16.605)$$

$$E_{HXUnit} = P_{HXUnit} * TimeStepSys * 3600 \quad (16.606)$$

where:

$Q_{SensibleCooling}$ is the output variable ‘Heat Exchanger Sensible Cooling Energy, J’

$\dot{Q}_{SensibleCooling}$ is the output variable ‘Heat Exchanger Sensible Cooling Rate, W’ which is equal to $\dot{Q}_{Sensible}$ during times when the supply air is cooled

$TimeStepSys$ is the HVAC system simulation time step, hr

$Q_{LatentCooling}$ is the output variable ‘Heat Exchanger Latent Cooling Energy, J’

$\dot{Q}_{LatentCooling}$ is the output variable ‘Heat Exchanger Latent Cooling Rate, W’ which is equal to \dot{Q}_{Latent} during times when the supply air is dehumidified

$Q_{TotalCooling}$ is the output variable ‘Heat Exchanger Total Cooling Energy, J’

$\dot{Q}_{TotalCooling}$ is the output variable ‘Heat Exchanger Total Cooling Rate, W’ which is equal to \dot{Q}_{Total} during times when the supply air enthalpy is reduced

$Q_{SensibleHeating}$ is the output variable ‘Heat Exchanger Sensible Heating Energy, J’

$\dot{Q}_{SensibleHeating}$ is the output variable ‘Heat Exchanger Sensible Heating Rate, W’ which is equal to $\dot{Q}_{Sensible}$ during times when the supply air is heated

$Q_{LatentHeating}$ is the output variable ‘Heat Exchanger Latent Heating Energy, J’ and also the output variable ‘Heat Exchanger Latent Gain Energy, J’

$\dot{Q}_{LatentHeating}$ is the output variable ‘Heat Exchanger Latent Gain Rate, W’ which is equal to \dot{Q}_{Latent} during times when the supply air is humidified

$Q_{TotalHeating}$ is the output variable ‘Heat Exchanger Total Heating Energy, J’

$\dot{Q}_{TotalHeating}$ is the output variable ‘Heat Exchanger Total Heating Rate, W’ which is equal to \dot{Q}_{Total} during times when the supply air enthalpy is increased

E_{HXUnit} is the output variable ‘Heat Exchanger Electric Energy, J’

P_{HXUnit} is the output variable ‘Heat Exchanger Electric Power, W’.

16.8.1.3 Frost Control Methods

In cold weather, frost can form on the heat exchanger causing a reduction in air flow and heat recovery performance. Various strategies can be employed to limit frost formation. Heat exchangers that transfer total energy (sensible plus latent) usually have a lower frost threshold temperature than sensible-only heat exchangers. Frost threshold temperatures for sensible-only heat exchangers may be -1°C to -12°C for plate and rotary heat exchangers respectively, while those for comparable total (sensible plus latent) heat exchangers may be 10°C lower. The frost threshold temperature for a specific application is dependent on the exhaust air dry-bulb temperature and relative humidity, heat exchanger type (e.g., sensible-only or total heat exchange, flat plate or rotary), and the heat exchanger effectiveness. Consult manufacturer’s literature to obtain specific frost threshold temperatures for the heat exchanger being modeled.

Four frost control strategies can be modeled for this air-to-air heat exchanger unit. Each of these four strategies is discussed in detail below.

16.8.1.4 Preheat

One method to control frost formation is to preheat the cold outdoor (supply) air entering the heat exchanger. When a preheat coil is used for frost control, a separate heating coil object must be placed in the supply air stream at the inlet to the heat exchanger (Coil:Heating:Water, Coil:Heating:Electric or Coil:Heating:Fuel). The preheat coil should be controlled to maintain a minimum supply air inlet temperature thereby eliminating frost buildup on the heat exchanger core. When modeling preheat frost control, specify “None” as the frost control method in the heat exchanger object. When modeling this heat exchanger as part of an air loop, refer to the objects AirLoopHVAC:OutdoorAirSystem and SetpointManager:Scheduled the EnergyPlus Input Output Reference for additional information on specifying a preheat coil and controlling its supply air temperature. This frost control method is not currently available when this heat exchanger is being used as part of the compound object ZoneHVAC:EnergyRecoveryVentilator.

16.8.1.5 Exhaust Only

This method of frost control bypasses the incoming supply air around the heat exchanger core thereby warming the core using the exiting exhaust air. This method is similar to ‘supply air off’ frost control where the supply air fan is turned off for a predetermined period of time while the exhaust air fan continues to operate. For the ‘supply air off’ method, the supply air flow is stopped for a period of time thereby reducing the ventilation air supplied to the zone(s). In addition, the building may be negatively pressurized for the period of time that the supply air flow is stopped since the exhaust air fan continues to operate. On the other hand, the ‘exhaust only’ method of frost control modeled by EnergyPlus continues to provide outdoor ventilation air to the zone(s), but this air is simply bypassed around the heat exchanger core for a portion of the time and the potential problem with negatively pressurizing the building is avoided. Since the supply airflow rate through the heat exchanger core is purposely reduced to control frost formation, average volumetric

airflow rates below 50% of nominal are allowed when this frost control is active and no warning message is issued.

The user enters a threshold temperature, an initial defrost time fraction, and a rate of defrost time fraction increase. When the temperature of the supply air (e.g., outdoor air) entering the heat exchanger is equal to or below the specified threshold temperature, the fractional amount of time that the supply air is bypassed around the heat exchanger core is determined from the following equation:

$$X_{DefrostTime} = X_{Initial} + X_{RateofIncrease}(T_{Threshold} - T_{SupAirIn}) \quad (16.607)$$

where:

$X_{DefrostTime}$ is the fractional time period for frost control ($0 \leq X_{DefrostTime} \leq 1$)

$X_{Initial}$ is the initial defrost time fraction

$X_{RateofIncrease}$ is the rate of defrost time fraction increase (K^{-1})

$T_{Threshold}$ is the threshold temperature ($^{\circ}C$)

$T_{SupAirIn}$ is the supply air inlet temperature ($^{\circ}C$).

During the defrost time, supply air flow is fully bypassed around the heat exchanger core and no heat transfer takes place. For the remainder of the time period, no air is bypassed and full heat exchange is achieved. The average supply air flow bypassed around the heat exchanger core is calculated as follows:

$$\dot{m}_{SupAirBypass} = (X_{DefrostTime})\dot{m}_{SupAir} \quad (16.608)$$

To determine the average heat transfer rates for the simulation time step, the supply air outlet conditions are first calculated as if the heat exchanger were not in defrost mode (see previous section, Model Description). The sensible and total heat transfer rates are then calculated and multiplied by the fractional time period that the heat exchanger is *not* in defrost mode ($1 - X_{DefrostTime}$).

$$\dot{Q}_{Sensible} = (1 - X_{DefrostTime})(\dot{m}c_{p,sup})(T_{SupAirIn} - T_{SupAirOut}) \quad (16.609)$$

$$\dot{Q}_{Total} = (1 - X_{DefrostTime})\dot{m}_{SupAir}(h_{SupAirIn} - h_{SupAirOut}) \quad (16.610)$$

Once the average heat transfer rates are determined, the average conditions of the supply air exiting the overall heat exchanger unit are calculated as follows:

$$T_{SupAirOut} = T_{SupAirIn} - \frac{\dot{Q}_{Sensible}}{\dot{m}c_{p,sup}} \quad (16.611)$$

$$h_{SupAirOut} = h_{SupAirIn} - \frac{\dot{Q}_{Total}}{\dot{m}_{SupAir}} \quad (16.612)$$

$$\omega_{SupAirOut} = PsyWFnTdbH(T_{SupAirOut}, h_{SupAirOut}) \quad (16.613)$$

As described previously, if the predicted conditions of the exiting supply air exceed the saturation curve ($>100\%$ RH), then the temperature and humidity ratio of the air are reset to saturated conditions ($= 100\%$ RH) at the enthalpy condition calculated above ($h_{SupAirOut}$). If the supply air temperature is reset, the average sensible heat transfer rate is recalculated before the exhaust air outlet conditions are determined:

$$T_{ExhAirOut} = T_{ExhAirIn} + \frac{\dot{Q}_{Sensible}}{\dot{m}c_{p,exh}} \quad (16.614)$$

$$h_{ExhAirOut} = h_{ExhAirIn} + \frac{\dot{Q}_{Total}}{\dot{m}_{ExhAir}} \quad (16.615)$$

$$\omega_{ExhAirOut} = PsyWFnTdbH(T_{ExhAirOut}, h_{ExhAirOut}) \quad (16.616)$$

16.8.1.6 Exhaust Air Recirculation

This method of frost control routes exhaust (outlet) air back through the supply side of the heat exchanger to warm the core. Since this method routes exhaust air back into the building, the building is typically not depressurized when this frost control is active. However, the incoming supply (outdoor ventilation) air flow is stopped for the fractional period of time that frost control is active. If significant periods of time exist when outdoor temperatures are below the selected threshold temperature and outdoor ventilation air is continuously required, an alternative method of frost control should be considered.

The user enters a threshold temperature, an initial defrost time fraction, and a rate of defrost time fraction increase. When the temperature of the inlet supply air (e.g., outdoor air) is equal to or below the specified threshold temperature, the fractional amount of time that this heat exchanger frost control strategy is active is determined from the following equation:

$$X_{DefrostTime} = X_{Initial} + X_{RateofIncrease}(T_{Threshold} - T_{SupAirIn}) \quad (16.617)$$

The air mass flow rate of the supply air leaving the heat exchanger unit is then calculated using the defrost time fraction calculated above the mass flow rates of supply and exhaust air entering the unit.

$$\dot{m}_{SupAirOut} = (1 - X_{DefrostTime})\dot{m}_{SupAirIn} + X_{DefrostTime}\dot{m}_{ExhAirIn} \quad (16.618)$$

The model assumes that no heat exchange occurs during defrost, and the average supply supply air conditions are simply a blend of the conditions when the unit is *not* in defrost and the exhaust air inlet conditions during defrost operation:

$$T_{SupAirOut} = \frac{(1 - X_{DefrostTime})\dot{m}_{SupAirIn}T_{SupAirOut,NoDefrost} + X_{DefrostTime}\dot{m}_{ExhAirIn}T_{ExhAirIn}}{\dot{m}_{SupAirOut}} \quad (16.619)$$

$$\omega_{SupAirOut} = \frac{(1 - X_{DefrostTime})\dot{m}_{SupAirIn}\omega_{SupAirOut,NoDefrost} + X_{DefrostTime}\dot{m}_{ExhAirIn}\omega_{ExhAirIn}}{\dot{m}_{SupAirOut}} \quad (16.620)$$

$$h_{SupAirOut} = PsyHFnTdbW(T_{SupAirOut}, \omega_{SupAirOut}) \quad (16.621)$$

The operating effectivenesses of the heat exchanger are initially calculated according to Equations 16.588 and 16.589 assuming no defrost operation. Since the supply air flow across the heat

exchanger core is not reduced during defrost operation, the sensible and latent effectiveness are therefore derated (for reporting purposes) in direct proportion to the fraction of time that frost control is *not* active.

$$\varepsilon_{operating,sensible} = (1 - X_{DefrostTime})\varepsilon_{operating,sensible} \quad (16.622)$$

$$\varepsilon_{operating,latent} = (1 - X_{DefrostTime})\varepsilon_{operating,latent} \quad (16.623)$$

Since the exhaust outlet air is recirculated through the supply side of the heat exchanger core, the incoming supply air and exiting exhaust air flows are stopped for the fraction of the time when frost control is active. The average air mass flow rate at the supply air inlet and the exhaust air outlet nodes are therefore reduced accordingly.

$$\dot{m}_{SupAirIn} = (1 - X_{DefrostTime})\dot{m}_{SupAirIn} \quad (16.624)$$

$$\dot{m}_{ExhAirOut} = (1 - X_{DefrostTime})\dot{m}_{ExhAirOut} \quad (16.625)$$

The conditions of the exiting (outlet) exhaust air (temperature, humidity ratio and enthalpy) are reported as the values when frost control is *not* active (i.e., the conditions when exhaust air is actually leaving the unit).

16.8.1.7 Minimum Exhaust Temperature

With this frost control method, frost formation is avoided by continuously maintaining the temperature of the exhaust air leaving the heat exchanger core above a specified setpoint. The minimum exhaust air temperature is maintained by modulating heat exchanger rotational speed or by bypassing supply air around a plate heat exchanger. For this frost control method, the user must only enter the threshold (minimum) temperature.

For the case of modulating heat exchanger rotation, the operating effectivenesses and outlet air conditions are first calculated as if the heat exchanger is *not* in defrost mode (see Model Description). If the resulting temperature of the exhaust air leaving the heat exchanger core is below the specified threshold temperature, then the operating effectivenesses are reduced as follows:

$$X_{DefrostTime} = \frac{(T_{Threshold} - T_{ExhAirOut})}{(T_{ExhAirIn} - T_{ExhAirOut})} \quad (16.626)$$

$$\varepsilon_{operating,sensible} = (1 - X_{DefrostTime})\varepsilon_{operating,sensible} \quad (16.627)$$

$$\varepsilon_{operating,latent} = (1 - X_{DefrostTime})\varepsilon_{operating,latent} \quad (16.628)$$

The supply air and exhaust air outlet conditions are then recalculated using these reduced effectiveness values. Finally the sensible, latent and total heat recovery rates are calculated along with the unit's electric power and electric consumption.

The calculation procedure is slightly different for the case of a plate heat exchanger where the supply air is bypassed around the heat exchanger core. Since the volumetric air flow rate through the heat exchanger core is reduced when frost control is active, an iterative process is used to determine the operating effectiveness of the heat exchanger. The operating effectivenesses and

outlet air conditions are first calculated as if the heat exchanger is *not* in defrost mode (see Model Description). If the resulting temperature of the exhaust air leaving the heat exchanger core is below the specified threshold temperature, then the fractional defrost time is calculated as follows:

$$X_{DefrostTime} = \frac{(T_{Threshold} - T_{ExhAirOut})}{(T_{ExhAirIn} - T_{ExhAirOut})} \quad (16.629)$$

The iteration process then begins to determine the heat exchanger effectiveness and the exhaust air outlet temperature as if frost control were active. The operating mass flow rate through the supply side of the heat exchanger core is calculated.

Beginning of iteration process:

$$\dot{m}_{SupAirCore} = (1 - X_{DefrostTime})\dot{m}_{SupAirIn} \quad (16.630)$$

$$\dot{m}_{SupAirBypass} = (X_{DefrostTime})\dot{m}_{SupAirIn} \quad (16.631)$$

The ratio of average volumetric flow rate through the heat exchanger core to heat exchanger's nominal volumetric flow rate ($HX_{flowratio}$) is then determined and used to calculate the operating effectiveness of the heat exchanger using Equations 16.588 and 16.589. Since the supply airflow rate through the heat exchanger core is purposely reduced to control frost formation, average volumetric airflow rates below 50% of nominal are allowed and no warning message is issued. Supply air outlet temperature (leaving the heat exchanger core), sensible heat transfer, and exhaust air outlet temperature are then calculated using the revised heat exchanger effectiveness.

$$T_{SupAirOut} = T_{SupAirIn} + \varepsilon_{operating,sensible} \left(\frac{\dot{m}c_{p,min}}{\dot{m}c_{p,sup}} \right) (T_{ExhAirIn} - T_{SupAirIn}) \quad (16.632)$$

$$\dot{Q}_{Sensible} = (1 - X_{DefrostTime}) (\dot{m}c_{p,sup}) (T_{SupAirInlet} - T_{SupAirOutlet}) \quad (16.633)$$

$$T_{ExhAirOut} = T_{ExhAirIn} + \frac{\dot{Q}_{Sensible}}{\dot{m}c_{p,exh}} \quad (16.634)$$

The error between the exhaust outlet temperature and the threshold temperature for frost control and a new defrost time fraction are subsequently calculated.

$$Error = T_{ExhAirOut} - T_{Threshold} \quad (16.635)$$

$$X_{DefrostTime} = X_{DefrostTime} \left(\frac{T_{ExhAirIn} - T_{ExhAirOut}}{T_{ExhAirIn} - T_{Threshold}} \right) \quad (16.636)$$

End of iteration process:

The iteration process ends when the calculated error is within an error tolerance of 0.001. The air streams passing through the heat exchanger core and bypassing the core through the bypass damper are then blended together to provide the air conditions leaving the heat exchanger unit. Finally the sensible, latent and total heat recovery rates are calculated along with the unit's electric power and electric consumption.

16.8.1.8 Economizer Operation

A conventional air-side economizer may be used in conjunction with this heat exchanger object. The air-side economizer is specified through the use of an outside air controller (see object: Controller:OutdoorAir). Specify the appropriate economizer control type, and provide the required control points and air flow rates as defined in the outside air controller object. Energy transfer provided by the heat exchanger will be suspended whenever free cooling is available (i.e., when the air-side economizer is activated) and *the user specified economizer lockout input is specified as Yes*. For plate heat exchangers, heat transfer is suspended by fully bypassing the supply and exhaust air around the heat exchanger core. For rotary heat exchangers, air flows continue through the core but it is assumed that heat exchanger rotation is stopped.

Heat exchange can also be suspended for the purposes of providing free cooling operation in the absence of a conventional air-side economizer. In this case specify “MinimumFlowWithBypass” as the economizer choice and again provide the required control points as defined in the outside air controller object. Energy transfer provided by the heat exchanger will be suspended whenever free cooling is available and *the user specified economizer lockout input is specified as Yes*, however the supply air flow rate will remain at the minimum value specified in the outside air controller object. Note that the Economizer Type must be set to something other than NoEconomizer for this control interaction to function.

If economizer operation is not required, specify “NoEconomizer” as the economizer control type in the outside air controller object. The heat exchanger will operate according to its availability schedule and free cooling will not be provided. . If economizer operation *is* required and the heat exchanger *should not* provide free cooling, specify the input for the heat exchanger’s economizer lockout as No and heat recovery will remain active during economizer mode.

Heat recovery for this heat exchanger may also be suspended during a high humidity control event (see object Controller:OutdoorAir) in a similar manner. Specifying Yes for economizer lockout will also suspend heat recovery when high humidity control is activated. The default value for economizer lockout is Yes and must be specifically entered as No to disable the economizer or high humidity control lockout feature.

16.8.1.9 Supply Air Outlet Temperature Control

This heat exchanger object can also control the supply air outlet temperature to a setpoint to avoid overheating or overcooling the supply air. This temperature control is accomplished through wheel speed modulation or bypassing supply air around the heat exchanger. To model this temperature control, the user must specify ‘Yes’ for the Supply Air Outlet Temperature Control field in this heat exchanger object, and a separate setpoint manager (see object: SetpointManager:Scheduled) and temperature schedule must be specified for the heat exchanger unit’s supply air outlet node.

This control strategy is typically used in conjunction with economizer operation (see object Controller:OutdoorAir), and an example control profile is shown in the figure below. When the outdoor air temperature falls to the specified maximum limit for economizer operation, heat exchange is suspended (air is fully bypassed around the heat exchanger core or heat exchanger rotation is stopped). The figure below shows economizer operation being initiated based on outdoor temperature but other triggers can be used (e.g. differential temperature [outdoor temperature with respect to exhaust air temperature], single point enthalpy or differential enthalpy). Heat exchange remains suspended until the outdoor temperature falls to the minimum temperature (temperature

lower limit) for economizer control. The setpoint for the supply air outlet temperature control should match the economizer temperature lower limit.

As the outdoor air temperature falls further below the setpoint for the supply air outlet temperature (same as the economizer lower temperature limit), the heat exchanger bypass dampers will modulate closed to maintain the desired supply air temperature for a plate heat exchanger. For a rotary heat exchanger the rotary heat exchanger speed will gradually increase to maintain the desired supply air temperature. Modulation of heat exchanger performance will continue until the supply air temperature setpoint can no longer be maintained. This control will attempt to achieve the desired temperature set point whether the heat exchanger is cooling or heating the supply air stream. Care should be used to set the supply outlet air temperature set point to the desired value for proper control.

Figure 16.72: Air to Air Heat Exchanger with Supply Air Temperature Control

Other types of temperature setpoint control may also be used. For example, the operation described here is used to minimize heating energy and proper control of the supply air temperature set point could also be used to minimize cooling energy or minimize both heating and cooling energy.

16.8.2 Air System Air-To-Air Flat Plate Heat Exchanger

16.8.2.1 Overview

The input object `HeatExchanger:AirToAir:FlatPlate` provides an NTU – effectiveness model of a static flat plate air-to-air heat exchanger. Humidity issues are ignored in this model. A full, detailed description of the model can be found in the reference.

The inputs for the model are the design values for the primary air flow rate, primary air inlet and outlet temperature, secondary air flow rate, and secondary air inlet temperature. No design UAs are required: instead, the ratio (at design conditions) of the primary hA to the secondary hA (r_{hA}) is input. The flow configuration is also an input (counter, parallel, or crossflow).

An important feature of this model is that the heat exchanger total UA is a time varying function of the primary and secondary mass flow rates and inlet temperatures.

16.8.2.2 Model Description

The design inlet / outlet conditions determine a design effectiveness eff_{des} . From the design capacity flow ratio, the flow arrangement, and eff_{des} , the NTU – effectiveness formulas give the NTU_{des} and UA_{des} .

The time varying calculations proceed as follows. First, the UA is determined:

$$UA = UA_{des}(r_{hA} + 1) / ((\dot{m}_{p,des}T_{p,des} / \dot{m}_pT_p)^{.78} + r_{hA}(\dot{m}_{s,des}T_{s,des} / \dot{m}_sT_s)^{.78}) \quad (16.637)$$

where *des* means *design*, *p* means *primary*, *s* means *secondary*, T is air stream temperature, and \dot{m} is air stream mass flow rate. From the UA and the capacity flow ratio the NTU is determined: $NTU = UA/C_{\min}$. Then the NTU – effectiveness formulas are used to calculate the effectiveness. From the effectiveness and the inlet conditions, outlet conditions are determined.

16.8.2.3 Economizer Operation

A conventional air-side economizer may be used in conjunction with this heat exchanger object. The air-side economizer is specified through the use of an outside air controller (see object: `Controller:OutdoorAir`). Specify the appropriate economizer control type, and provide the required control points and air flow rates as defined in the outside air controller object. Energy transfer provided by the heat exchanger will be suspended whenever free cooling is available (i.e., when the air-side economizer is activated) or high humidity control is active and *the user specified economizer lockout input is specified as Yes*. For this flat plate heat exchanger, heat transfer is suspended by fully bypassing the supply and exhaust air around the heat exchanger core. If the economizer lockout is specified as No, the flat plate heat exchanger is operational even when economizer or high humidity mode is active. The default value for economizer lockout is Yes and must be specifically entered as No to disable the economizer or high humidity control lockout feature.

16.8.3 Air System Air-To-Air Balanced Flow Desiccant Heat Exchanger

16.8.3.1 Overview

The input object `HeatExchanger:Desiccant:BalancedFlow` provides a model for a desiccant heat exchanger that is an HVAC component used to model both temperature (sensible) and moisture (latent) heat exchange between two air streams (Figure 16.73). The model assumes balanced air flow through the regeneration and process sides of the heat exchanger (i.e., regeneration and process air volume flow rates and face velocities are the same). Heat exchanger performance is specified through a performance data type object (e.g., `Heat Exchanger:Desiccant:BalancedFlow:Performance Data Type 1`). Refer to the EnergyPlus Input Output Reference for the specific input syntax for this desiccant heat exchanger object.

Figure 16.73: Schematic of the Balanced Flow Desiccant Heat Exchanger

EnergyPlus has another air-to-air heat exchanger object for modeling sensible and latent heat transfer between two air streams that uses the input object `HeatExchanger:AirToAir:SensibleAndLatent`. That heat exchanger model uses effectiveness values specified by the user to determine exiting air conditions from each side of the heat exchanger. In contrast, the balanced flow desiccant heat exchanger references a performance data type object (e.g., `HeatExchanger:Desiccant:BalancedFlow:PerformanceDataType1`) which defines the model equations, user-specified model coefficients, and min/max limits for the model's independent and dependent variables.

16.8.3.2 Model Description

This heat exchanger is a simple object that performs three basic functions:

1. Informs the associated performance data type object (e.g., `HeatExchanger:Desiccant:BalancedFlow:PerformanceDataType1`) if it should calculate heat exchange for a simulation time step, or if heat exchange is suspended for the time step (i.e., bypass air flow around a fixed-plate heat exchanger or stop the rotation of a rotary heat exchanger),
2. Passes the process and regeneration air inlet conditions (e.g., dry-bulb temperature, humidity ratio, air mass flow rate) to the associated performance data type object, and
3. Reports the total, sensible and latent cooling/heating rates and electric power based on the results from the performance data type model that is specified.

While the desiccant heat exchanger object's availability to provide heat exchange between the two air streams is determined by the user-specified availability schedule, other objects that call this heat exchanger object can also control its heat exchange during a simulation time step. Currently, this desiccant heat exchanger model can be referenced by two compound objects: `CoilSystem:Cooling:DX:HeatExchangerAssisted` and `Dehumidifier:Desiccant:System`, both of which are used to provide enhanced dehumidification over conventional systems. If this heat exchanger is referenced by a compound object, the compound object will control heat exchanger operation (i.e., tell the heat exchanger if heat exchange is needed or not for each simulation time step). Details for how the compound objects control exchanger operation are described elsewhere in this document (ref. `CoilSystem:Cooling:DX:HeatExchangerAssisted` and `Dehumidifier:Desiccant:System`).

This desiccant heat exchanger object may also be specified directly in a `AirLoopHVAC` (air loop `BranchList`) or in an `AirLoopHVAC:OutdoorAirSystem:EquipmentList` without being referenced by a compound object. If specified directly in a `AirLoopHVAC` loop or `AirLoopHVAC:OutdoorAirSystem:EquipmentList`, then the heat exchanger can be controlled to provide heat exchange based on a maximum and/or minimum humidity setpoint placed on the process air outlet node (ref. `SetpointManagers`). If no humidity setpoints are provided on this node, then heat exchange will be provided whenever the heat exchanger is available to operate (via its availability schedule) and there is a temperature and/or humidity ratio difference between the two air streams. Further details regarding heat exchanger control via humidity setpoints on the process air outlet node are described in the section for the associated data type object (e.g., `HeatExchanger:Desiccant:BalancedFlow:PerformanceDataType1`).

The balanced flow desiccant heat exchanger model first checks for three conditions to be true before calling the specified performance data type model to calculate heat exchanger performance:

- Non-zero air mass flow rates on the process and regeneration inlet air nodes,
- Desiccant heat exchanger is available to operate based on its availability schedule,
- If a compound object is calling this desiccant heat exchanger, it is requesting that heat exchange be provided.

If any of these conditions is false, then heat exchange is suspended and the model simply passes the air conditions on the process and regeneration air inlet nodes to the respective outlet air nodes. In addition, the heat exchanger electric power is set to zero.

If all of the above conditions are true, then heat exchange is active and the specified performance data type model is called to calculate the process and regeneration outlet air conditions and heat exchanger electric power. Immediately before this call to the performance data type model, a check is made to determine if the operating air flow rates through the heat exchanger (i.e., the actual air flow rates for the simulation time step) are equal (balanced flow). If a difference of more than 2% exists between the process and regeneration air flow rates at any time during the simulation, a warning is issued.

After the specified performance data type model calculates the process/regeneration air outlet conditions and heat exchanger electric power, the balanced flow desiccant heat exchanger model uses that information to report overall performance. Specifically, the heat exchanger's sensible, latent and total heating and cooling rates are calculated for the process air side of the heat exchanger. Since energy must be conserved, the same heating or cooling rates apply to the regeneration air stream although they are opposite in heat transfer direction (e.g., a sensible cooling rate on the process air side of the heat exchanger would indicate an equivalent sensible heating rate on the regeneration air side).

$$\dot{Q}_{Sensible} = \dot{m}_{Proc} C_{p_{Proc,in}} (T_{Proc,out} - T_{Proc,in}) \quad (16.638)$$

$$\dot{Q}_{Total} = \dot{m}_{Proc} (h_{Proc,out} - h_{Proc,in}) \quad (16.639)$$

$$\dot{Q}_{Latent} = \dot{Q}_{Total} - \dot{Q}_{Sensible} \quad (16.640)$$

where:

$\dot{Q}_{Sensible}$ is the sensible heat transfer rate to the process air stream (W)

\dot{Q}_{Total} is the total heat transfer rate to the process air stream (W)

\dot{Q}_{Latent} is the latent heat transfer rate to the process air stream (W)

\dot{m}_{Proc} is the process air mass flow rate (kg/s)

$C_{p_{Proc,in}}$ is the specific heat of inlet process air (J/kg-K)

$T_{Proc,out}$ is the process air outlet temperature (°C)

$T_{Proc,in}$ is the process air inlet temperature (°C)

$h_{Proc,out}$ is the process air outlet enthalpy (J/kg)

$h_{Proc,in}$ is the process air inlet enthalpy (J/kg).

To simplify the accounting of heat exchanger performance, the sensible, latent, and total heat transfer rates for the process side of the heat exchanger are stored in cooling and heating report variables. For example, if the sensible heat transfer rate is negative, the absolute value is stored in a “cooling” rate report variable. Conversely, if the sensible heat transfer rate is positive, the value is stored in a “heating” rate report variable. Similar accounting is performed for the latent and total heat transfer rate variables as follows:

$$IF \left(\dot{Q}_{Sensible} \leq 0 \right) \dot{Q}_{SensibleCooling} = ABS \left(\dot{Q}_{Sensible} \right) \quad (16.641)$$

$$IF \left(\dot{Q}_{Sensible} > 0 \right) \dot{Q}_{SensibleHeating} = \dot{Q}_{Sensible} \quad (16.642)$$

$$IF \left(\dot{Q}_{Latent} \leq 0 \right) \dot{Q}_{LatentCooling} = ABS \left(\dot{Q}_{Latent} \right) \quad (16.643)$$

$$IF \left(\dot{Q}_{Latent} > 0 \right) \dot{Q}_{LatentHeating} = \dot{Q}_{Latent} \quad (16.644)$$

$$IF \left(\dot{Q}_{Total} \leq 0 \right) \dot{Q}_{TotalCooling} = ABS \left(\dot{Q}_{Total} \right) \quad (16.645)$$

$$IF \left(\dot{Q}_{Total} > 0 \right) \dot{Q}_{TotalHeating} = \dot{Q}_{Total} \quad (16.646)$$

At the end of each HVAC simulation time step, this object reports the sensible, latent and total cooling/heating energy and electric consumption for the heat exchanger as follows:

$$Q_{SensibleCooling} = \dot{Q}_{SensibleCooling} * TimeStepSys * 3600 \quad (16.647)$$

$$Q_{LatentCooling} = \dot{Q}_{LatentCooling} * TimeStepSys * 3600 \quad (16.648)$$

$$Q_{TotalCooling} = \dot{Q}_{TotalCooling} * TimeStepSys * 3600 \quad (16.649)$$

$$Q_{SensibleHeating} = \dot{Q}_{SensibleHeating} * TimeStepSys * 3600 \quad (16.650)$$

$$Q_{LatentHeating} = \dot{Q}_{LatentHeating} * TimeStepSys * 3600 \quad (16.651)$$

$$Q_{TotalHeating} = \dot{Q}_{TotalHeating} * TimeStepSys * 3600 \quad (16.652)$$

$$E_{HXUnit} = P_{HXUnit} * TimeStepSys * 3600 \quad (16.653)$$

where:

$Q_{SensibleCooling}$ is the output variable ‘Heat Exchanger Sensible Cooling Energy, J’

$\dot{Q}_{SensibleCooling}$ is the output variable ‘Heat Exchanger Sensible Cooling Rate, W’ which is equal to $\dot{Q}_{Sensible}$ during times when the process air is cooled

$TimeStepSys$ is the HVAC system simulation time step, hr

$Q_{LatentCooling}$ is the output variable ‘Heat Exchanger Latent Cooling Energy, J’

$\dot{Q}_{LatentCooling}$ is the output variable ‘Heat Exchanger Latent Cooling Rate, W’ which is equal to \dot{Q}_{Latent} during times when the process air is dehumidified

$Q_{TotalCooling}$ is the output variable ‘Heat Exchanger Total Cooling Energy, J’

$\dot{Q}_{TotalCooling}$ is the output variable ‘Heat Exchanger Total Cooling Rate, W’ which is equal to \dot{Q}_{Total} during times when the process air enthalpy is reduced

$Q_{SensibleHeating}$ is the output variable ‘Heat Exchanger Sensible Heating Energy, J’

$\dot{Q}_{SensibleHeating}$ is the output variable ‘Heat Exchanger Sensible Heating Rate, W’ which is equal to $\dot{Q}_{Sensible}$ during times when the process air is heated

$Q_{LatentHeating}$ is the output variable ‘Heat Exchanger Latent Gain Energy, J’

$\dot{Q}_{LatentHeating}$ is the output variable ‘Heat Exchanger Latent Gain Rate, W’ which is equal to \dot{Q}_{Latent} during times when the process air is humidified

$Q_{TotalHeating}$ is the output variable ‘Heat Exchanger Total Heating Energy, J’

$\dot{Q}_{TotalHeating}$ is the output variable ‘Heat Exchanger Total Heating Rate, W’ which is equal to \dot{Q}_{Total} during times when the process air enthalpy is increased

E_{HXUnit} is the output variable ‘Heat Exchanger Electric Energy, J’

P_{HXUnit} is the output variable ‘Heat Exchanger Electric Power, W’.

16.8.3.3 Economizer Operation

A conventional air-side economizer may be used in conjunction with this heat exchanger object. The air-side economizer is specified through the use of an outside air controller (see object: Controller:OutdoorAir). Specify the appropriate economizer control type, and provide the required control points and air flow rates as defined in the outside air controller object. Energy transfer provided by the heat exchanger will be suspended whenever free cooling is available (i.e., when the air-side economizer is activated) or high humidity control is active and *the user specified economizer lockout input is specified as Yes*. For the desiccant heat exchanger, heat transfer is assumed to be provided by a rotating heat exchanger core. For this reason, air continues to flow through the core when the outdoor air economizer is active but it is assumed that the rotation of the heat exchanger core is stopped. If the economizer lockout is specified as No, the desiccant heat exchanger is operational even when economizer or high humidity mode is active. This specific type of heat exchanger is typically *not* controlled by an outdoor air economizer. For this reason, the default value for economizer lockout is No and must be specifically entered as Yes to enable the economizer or high humidity control lockout feature.

16.8.3.4 Desiccant Heat Exchanger Performance Data

16.8.3.4.1 Overview

The input object HeatExchanger:Desiccant:BalancedFlow:PerformanceDataType1 specifies a performance model and model coefficients for a balanced flow desiccant heat exchanger. The HeatExchanger:Desiccant:BalancedFlow:PerformanceDataType1 object is referenced by a HeatExchanger:Desiccant:BalancedFlow object. This performance data object is used to specify the thermal performance and electric consumption of the heat exchanger. Some representative inputs for this object are provided in the EnergyPlus Reference DataSets (PerfCurves.idf).

This model predicts the regeneration air stream outlet temperature and humidity ratio values based on the entering regeneration and process air stream temperature, humidity ratio and face velocity. The process air stream outlet humidity ratio and temperatures are calculated based on a simple heat and moisture balance. The model requires that the user enter the nominal volumetric flow rate and a nominal face velocity, electric power consumption, empirical model coefficients for the regeneration outlet air temperature and humidity ratio equations, and the applicable minimum and maximum values for both the independent and dependent variables for the empirical model coefficients provided. Refer to the EnergyPlus Input Output Reference for details regarding the input syntax for this object.

16.8.3.4.2 Heat Exchanger Face Area and Air Velocity

The user is required to enter a nominal volumetric air flow rate and a nominal face velocity. From these inputs, a heat exchanger face area (applicable for both the regeneration and process sides of the heat exchanger) is calculated and used to determine the operating face velocity during the simulation.

$$A_{face} = \frac{V_{face,nom}}{\dot{v}_{face,nom}} \quad (16.654)$$

$$RFV = \frac{\dot{m}_{Reg,in}}{\rho_{std} A_{face}} \quad (16.655)$$

where:

A_{face} is the heat exchanger face area (m²)

$V_{face,nom}$ is the nominal air volume flow rate specified for the heat exchanger (m³/s)

$\dot{v}_{face,nom}$ is the nominal air face velocity specified for the heat exchanger (m/s)

RFV is the face velocity of the regeneration (and process) air stream (m/s)

$\dot{m}_{Reg,in}$ is the mass flow rate of the regeneration air stream (kg/s)

ρ_{std} is the density of air at standard temperature and pressure [dry air at 20°C] (m³/kg).

The face velocity calculated each simulation time step is used in the empirical equations (see ‘Model Calculations’ below) and should be within the minimum and maximum velocity boundaries specified for the model coefficients (see ‘Empirical Model Boundaries (Minimum and Maximum)’ below). When the calculated air velocity exceeds one of the boundaries, a warning is issued and the velocity is reset to the appropriate boundary value before being passed to the empirical equations for calculating regeneration air outlet temperature and humidity ratio. If the user is confident in their empirical model coefficients, the minimum and maximum velocity boundaries may be expanded slightly (caution should be used here) to allow extrapolation of the empirical equations during the simulation.

16.8.3.4.3 Model Calculations

The model coefficients may be obtained by curve fitting field measurements or the results from other computer models that accurately reflect the performance of a balanced flow desiccant heat exchanger. A wide range of data is necessary to properly define the performance of the desiccant heat exchanger such that all operating conditions expected during a simulation are included in the range of data used to obtain the model coefficients. The minimum and maximum boundaries for the independent variables used to generate the empirical model coefficients are used by this model to ensure that model extrapolation does not occur at any point during the simulation. For this reason, it is recommended that the widest possible range of data be used to determine the model coefficients.

The dry-bulb temperature of the regeneration outlet air is determined using the equation shown below.

$$RTO = B1 + B2 * RWI + B3 * RTI + B4 * \left(\frac{RWI}{RTI} \right) + B5 * PWI + B6 * PTI + B7 * \left(\frac{PWI}{PTI} \right) + B8 * RFV \quad (16.656)$$

where:

RTO is the regeneration outlet air dry-bulb temperature (°C)

RWI is the regeneration inlet air humidity ratio (kg/kg)

RTI is the regeneration inlet air dry-bulb temperature (°C)

PWI is the process inlet air humidity ratio (kg/kg)

PTI is the process inlet air dry-bulb temperature (°C)

RFV is the regeneration (and process) face velocity (m/s).

Similarly, the humidity ratio of the regeneration outlet air is defined using the same empirical equation form; however, different coefficients are used as follows:

$$RWO = C1 + C2 * RWI + C3 * RTI + C4 * \left(\frac{RWI}{RTI} \right) + C5 * PWI + C6 * PTI + C7 * \left(\frac{PWI}{PTI} \right) + C8 * RFV \quad (16.657)$$

where RWO is the regeneration outlet air humidity ratio (kg/kg).

If the regeneration outlet air conditions exceed the saturation curve, RTO and RWO are reset to saturated conditions (100% RH) at the enthalpy calculated based on the original RTO and RWO values.

Once the regeneration outlet air conditions are determined as described above, the dry-bulb temperature and humidity ratio differences across the regeneration side of the heat exchanger are calculated.

$$T_{diff} = RTO - T_{Reg,in} \quad (16.658)$$

$$w_{diff} = RWO - w_{Reg,in} \quad (16.659)$$

where:

$T_{Reg,in}$ is the actual regeneration inlet air dry-bulb temperature (°C)

$w_{Reg,in}$ is the actual regeneration inlet air humidity ratio (kg/kg)

T_{diff} is the regeneration air temperature difference based on empirical model (°C)

w_{diff} is the regeneration air humidity ratio difference based on empirical model (kg/kg)

The regeneration outlet air conditions described above represent the full load outlet conditions under steady-state operation. However, there are times when the heat exchanger may not operate for the entire simulation time step (i.e., bypass air flow around a fixed-plate heat exchanger or stop the rotation of a rotary heat exchanger for a portion of the time step). For example, the parent object calling this heat exchanger model may request that it only provide heat exchange for a portion of the time step ($HXPartLoadRatio$). Another example would be if this heat exchanger is *not* called by a parent object but is instead placed directly in a `AirLoopHVAC` or `AirLoopHVAC:OutdoorAirSystem` and a setpoint manager is used to place a minimum and/or maximum humidity ratio setpoint on the process air outlet node. For this case the humidity setpoints, if present, are used to calculate a part-load ratio for the heat exchanger assuming the full-load process air humidity ratio difference is equivalent (but opposite in sign) to the regeneration air humidity ratio difference (w_{diff}):

If $w_{diff} > 0$, then (Regen air humidified, process air dehumidified):

$$HXPartLoadRatio = \frac{w_{Proc,in} - w_{max,setpoint}}{w_{diff}} \quad (16.660)$$

Else, if $w_{diff} < 0$, then (Regen air dehumidified, process air humidified):

$$HXPartLoadRatio = \frac{w_{Proc,in} - w_{min,setpoint}}{w_{diff}} \quad (16.661)$$

And finally, $HXPartLoadRatio$ is constrained to be within the range 0 to 1.

If this heat exchanger is *not* being called by a parent object and no humidity setpoints are placed on the process air outlet node, then the model assumes that the heat exchanger operates for the entire simulation time step when it is available to operate (based on its availability schedule) and there is a temperature and/or humidity ratio difference between the two air streams.

EnergyPlus has an established convention for placing information on outlet air nodes. If the air flow rate is continuous but the device only operates for a portion of the simulation time step, then the average outlet conditions (temperature, humidity and enthalpy) are placed on the outlet air node. If the air flow rate cycles on and off during the simulation time step, then the full load outlet conditions are placed on the outlet air node along with the average air mass flow rate for the simulation time step. To account for these cases, this model uses the following logic:

If *FanOpMode* is equal to *CycFanCycComp* or if *RegAirInletIsOANode* is true then:

$$\begin{aligned} T_{Reg,out} &= T_{Reg,in} + T_{diff} \\ w_{Reg,out} &= w_{Reg,in} + w_{diff} \end{aligned} \quad (16.662)$$

Otherwise:

$$\begin{aligned} T_{Reg,out} &= T_{Reg,in} + T_{diff} \cdot HXPartLoadRatio \\ w_{Reg,out} &= w_{Reg,in} + w_{diff} \cdot HXPartLoadRatio \end{aligned} \quad (16.663)$$

where:

$T_{Reg,out}$ is the regeneration outlet air dry-bulb temperature (°C)

$w_{Reg,out}$ is the regeneration outlet air humidity ratio (kg/kg)

HXPartLoadRatio is the heat exchanger part-load ratio (determined by parent object calling this model, or calculated based on a minimum/maximum humidity ratio setpoints as shown above).

In the logic shown above, *RegAirInletIsOANode* is true if the regeneration air inlet node is an outside air node. If so, the model assumes that the air flow through the regeneration side of the heat exchanger cycles on and off as required during the simulation time step. Also, the regeneration outlet air humidity ratio is limited to be between 1E-5 and 1.0.

The regeneration outlet air enthalpy is then calculated using the regeneration outlet air temperature and humidity ratio.

$$h_{Reg,out} = PsyHFnTdbW(T_{Reg,out}, w_{Reg,out}) \quad (16.664)$$

Using the regeneration outlet air conditions, the heat transfer on the regeneration side of the heat exchanger is then calculated:

$$\dot{Q}_{Sensible,Reg} = \dot{m}_{Reg} C_{pReg,in} (T_{Reg,out} - T_{Reg,in}) \quad (16.665)$$

$$\dot{Q}_{Total,Reg} = \dot{m}_{Reg} (h_{Reg,out} - h_{Reg,in}) \quad (16.666)$$

where:

$\dot{Q}_{Sensible,Reg}$ is the sensible heat transfer rate to the regeneration air stream (W)

$\dot{Q}_{Total,Reg}$ is the total heat transfer rate to the regeneration air stream (W)

\dot{m}_{Reg} is the regeneration air mass flow rate (kg/s)

$C_{pReg,in}$ is the specific heat of inlet regeneration air (J/kg-K).

Since the model assumes that total and sensible heat transfer is conserved, these heat transfer rates are then used to calculate the process air outlet conditions:

$$h_{Proc,out} = h_{Proc,in} - \left(\frac{\dot{Q}_{Total,Reg}}{\dot{m}_{Proc}} \right) \quad (16.667)$$

$$T_{Proc,out} = T_{Proc,in} - \left(\frac{\dot{Q}_{Sensible,Reg}}{\dot{m}_{Proc} C_{p_{Proc,in}}} \right) \quad (16.668)$$

$$w_{Proc,out} = PsyWFnTdbH(T_{Proc,out}, h_{Proc,out}) \quad (16.669)$$

where:

$h_{Proc,out}$ is the process outlet air enthalpy (J/kg)

$T_{Proc,out}$ is the process outlet air dry-bulb temperature (°C)

$w_{Proc,out}$ is the process outlet air humidity ratio (kg/kg)

\dot{m}_{Proc} is the process air mass flow rate (kg/s)

$C_{p_{Proc,in}}$ is the specific heat of inlet process air (J/kg-K).

Like the regeneration outlet air conditions, the process outlet air conditions are also checked for exceeding saturated conditions and, if detected, the temperature and humidity ratio are reset assuming constant enthalpy.

$$T_{sat} = PsyTsatFnHPb(h_{Proc,out}, PB) \quad (16.670)$$

If $T_{sat} > T_{Proc,out}$, then:

$$\begin{aligned} T_{Proc,out} &= T_{sat} \\ w_{Proc,out} &= PsyWFnTdbH(T_{Proc,out}, h_{Proc,out}) \end{aligned} \quad (16.671)$$

Heat recovery electric power is the electric consumption rate of the unit in watts. The nominal electric power for the heat exchanger is specified in the input data file, and can be used to model controls (transformers, relays, etc.) and/or a motor for a rotary heat exchanger. The model assumes that this electric power is consumed whenever the heat exchanger operates. The electric power is assumed to be zero for all other times. None of this electric power is assumed to contribute thermal load to either of the heat exchanger air streams. As with the thermal performance of the heat exchanger, the power used by the heat exchanger is also proportional to the heat exchanger part load ratio.

$$P_{HXUnit} = P_{HX,nom} (HXPartLoadRatio) \quad (16.672)$$

where:

P_{HXUnit} is the output variable ‘Heat Exchanger Electric Power, W’ reported by the HeatExchanger:Desiccant:BalancedFlow object.

$P_{HX,nom}$ is the user specified ‘Nominal Electric Power, W’.

16.8.3.4.4 Empirical Model Boundaries (Minimum and Maximum)

Since this model uses empirical equations and extrapolation can cause unexpected results, the entering air conditions to both the regeneration and process sides of the heat exchanger are checked during each simulation time step to make sure they are within the valid range defined by the user. If any of the independent variables used in the equations for RTO and RWO above are outside the minimum and maximum limits specified for each independent variable, the values for these specific independent variables are limited to the appropriate boundary (min/max) value for use by the empirical equations and a warning is issued.

Additional model checks occur by testing the regeneration and process inlet air relative humidities. In this case, the process and regeneration inlet air relative humidities are calculated and compared to the minimum/maximum values specified by the user. If the calculated relative humidity exceeds the specified range at any point during the simulation when the heat exchanger is operating, a warning message is issued but the simulation proceeds.

If the user is confident in their empirical model coefficients, the minimum and maximum independent variable boundaries may be expanded (caution should be used here) to allow extrapolation of the empirical equations during the simulation.

In addition to checking the inlet air conditions, the model allows the user to specify limits for the regeneration air outlet conditions (RTO and RWO). If the calculated value for RTO or RWO exceeds the minimum/maximum limits specified by the user, then the calculated value is reset to the appropriate boundary (min/max) value and a warning message is issued.

This model also assumes that the performance of the desiccant heat exchanger (i.e., the output of the empirical equations) conforms to the following two guidelines.

1. The regeneration outlet air temperature (RTO) is always less than or equal to the regeneration inlet air temperature (T_{RegIn})
2. The regeneration outlet air humidity ratio (RWO) is always greater than or equal to the regeneration inlet air humidity ratio (w_{RegIn})

When the calculated regeneration outlet air conditions do not follow these guidelines, a warning is issued and the simulation proceeds.

16.8.4 Plant Loop Deep-Ground-To-Water Vertical U-Tube Field Heat Exchanger

This model (GroundHeatExchanger:System) is used to determine the borehole temperature response. Response factors, which are the non-dimensional temperature response of the borehole field to a heat pulse over a given time period, need to be precomputed before the model can simulate the ground heat exchanger. These response factors are referred to as g -functions. The variable time-step model presented here uses both long time-step g -functions and short time-step g -functions to predict the boreholes response to short term fluctuations in the load.

16.8.4.1 Long Time-Step Response Factors

Eskilson(1987) originally developed g -functions for various borehole configurations. He plotted the g -function curves for different sets of borehole spacing to borehole length ratio B/H typically for .05, 0.1, 0.15, 0.2, 0.3 and ∞ (∞ represents the single borehole configuration). For any other radius a simple relation between the two radii as given by Eskilson (1987) can be used. Eskilson gives the g -function curves for 38 different configurations.

Figure 16.74 shows the g -function plotted against the non-dimensional time defined as $\ln(t/t_s)$, $t_s = H^2/9\alpha$ for various configurations of vertical boreholes with B/H ratio of .1 along with single borehole. It is seen from this figure that the thermal interaction between boreholes increases with time and with the number of boreholes in field.

The g -functions developed by Eskilson are given only down to values of $\ln t/t_s = -4.5$, which for typical system and soil types can be on the order of 100 days. The values can be extended by

Figure 16.74: Short Time Step g Function Curve as an Extension of Long Time Step g Function Curves for Different Configuration of Boreholes (Eskilson 1987, Yavuzturk 1999).

the applying a line source model down to a time of $t = 5r_b^2/\alpha$. This time varies from 3-6 hours for a typical borehole field. This is because the analytical line source model, based on which the Eskilson model was developed, does not give a prompt increase in borehole wall temperature at $r = r_b$. It gives acceptable results only after the non-dimensional times of $\alpha t/r_b^2 > 5$. But to model short time responses of a borehole we need response factors which can give accurate results down to minutes.

In order to generate the long time-step response functions on the fly, EnergyPlus has two different models that make two different approximations for the calculation of the response functions. The first model uses uniform heat flux boundary conditions (UHFcalc model) – that is, it assumes that all boreholes have the same uniform heat flux. The heat flux may vary over time, but it is always uniform throughout the field. The second model uses uniform borehole wall temperatures (UBHWTcalc model) – the heat flux will vary between boreholes and vary vertically for each borehole.

Calculation of g -functions with uniform heat flux boundary conditions is simpler, but accuracy can decrease as the borehole-to-borehole interference increases. Consider a case with a large rectangular borefield, say 9x16 boreholes – if there is a significant annual imbalance in the heat rejection/heat extraction, the interior of the field will become thermally saturated, and the heat flux in the interior of the field will decrease over time. See Spitler, et al. (2020) for an illustration. The accuracy of using this approximation is discussed by Malayappan and Spitler (2013) with application to sizing of ground heat exchangers. As shown there, use of the UHFcalc model tends to overpredict the long-term temperature change for fields with significant borehole-to-borehole interference and significant annual heat rejection/heat extraction. In general, the UBHWTcalc model can be recommended for all applications, even though for a smaller numbers of boreholes the UHFcalc model offers sufficient accuracy.

For the UHFcalc model, EnergyPlus builds the model developed by Marcotte & Pasquier(2009) which uses a discretized line source model. The g -functions are generated using the following equation. The boreholes are discretized into segments. The temperature response of each segment on all other segments is then used to determine response factor for that particular geometry. The model estimates surface effects by creating “imaginary” boreholes which are mirrored about the ground surface.

$$g = \frac{1}{2H_T} \sum_{i=1}^N \sum_{j=1}^N \left(\int_{u_1^i}^{u_2^i} \int_{u_1^i}^{u_2^i} \frac{\text{erfc}\left(\frac{d(u_i, u_j)}{2\sqrt{\alpha t}}\right)}{d(u_i, u_j)} - \frac{\text{erfc}\left(\frac{d(u_i, u'_j)}{2\sqrt{\alpha t}}\right)}{d(u_i, u'_j)} \right) \quad (16.673)$$

where:

N is the number of boreholes

H_T is the length of borehole

α is the ground thermal diffusivity

t is the simulation time

u_1 is the starting discretization point for borehole

u_2 is the final discretization point for borehole

$d(u_i, u_j)$ is the distance between current point and point on other borehole

$d(u_i, u'_j)$ is the distance between current point and point on other imaginary borehole.

For the UBHWTcalc model, EnergyPlus builds on the model developed by Cimmino (2018a, 2018b, 2019), with improvements (Cook and Spitler 2021) to reduce memory consumption and increase speed. The general approach is similar to that of the UHFcalc model, but the heat flux is

adjusted for each segment to enforce the uniform borehole wall temperature model. Additionally, the methodology of Cimmino (UBHWTcalc) is a semi-analytical solution, so the solution is dependent on the number of segments used. The number of segments are adaptively discretized to approximate a uniform inlet fluid temperature (UIFT) g -function.

Cimmino (2015) introduced a UIFT g -function calculation that most closely matches physical reality. As boreholes are usually plumbed in parallel, the entering fluid temperatures are approximately uniform, and the actual distribution of heat within the field then depends on both the heat transfer outside the borehole and the heat transfer within the borehole. Thus, the g -function calculated with the UIFT boundary conditions depends on the flow rate and borehole thermal resistance in addition to the geometric configuration of the boreholes. Like, the UBHWT g -function calculation, the UIFT calculation also depends on the number of segments used – as the number of segments used increases, the solution converges.

So, though it's possible to find a converged solution for the UIFT g -function, it strictly speaking only applies when the borehole thermal resistance and flow rate remain fixed. Both commonly change during the system operation, as changing fluid temperatures affect the fluid properties. Therefore, the UIFT solution might be thought of as having a range of g -functions that change slightly with time. Therefore, in much the same way that radiation heat transfer within a zone is modeled with simplified methods because the occupants are likely to move the furniture, the UBHWT calculation can be used as a reasonable approximation to the UIFT calculation. As shown by Spitler, et al. (2020) the UIFT g -function can closely match the UIFT g -function, with considerably fewer segments. The number of segments required to closely approximate the UIFT g -function varies with the number of boreholes and the borehole depth. Therefore, the UBHWT model uses an adaptive discretization algorithm that uses a smaller number of segments than the UIFT calculation. This provides excellent accuracy while requiring less computational time and memory.

16.8.4.2 Short Time-Step Response Factors

The short timestep response is calculated by applying the model developed by Xu and Spitler (2006). This model maps the 2D geometry of the borehole onto a 1D radial geometry which preserves the thermal mass of the system, including the fluid. The multipole method (Claesson and Helström, 2011) is used to correct the conductivity of the pipe and grout so the correct borehole resistance is maintained. The temperature response of the 1D domain is solved using a finite volume approach. The temperature at the borehole wall is then used to compute the g -function for short time-steps.

16.8.4.3 Description of the Load Aggregation Scheme

A load aggregation scheme was developed for energy simulation software with variable short time steps down to one minute. A major issue in the development was the calculation of the g -functions. As discussed previously in the variable time step environments, the time step increments are not uniform. As a result, g -functions cannot be pre-calculated. Figure 16.75 shows a schematic of the variable time step ground loop heat exchanger model. The figure shows the larger monthly block loads, hourly loads and sub hourly loads and along with the time of occurrence of those loads. The figure also shows the time at which the g -functions are applied to different load blocks.

To calculate the response of a past load on the borehole temperature we apply the g -function corresponding to the time elapsed since the load was applied. This is easily understood from the

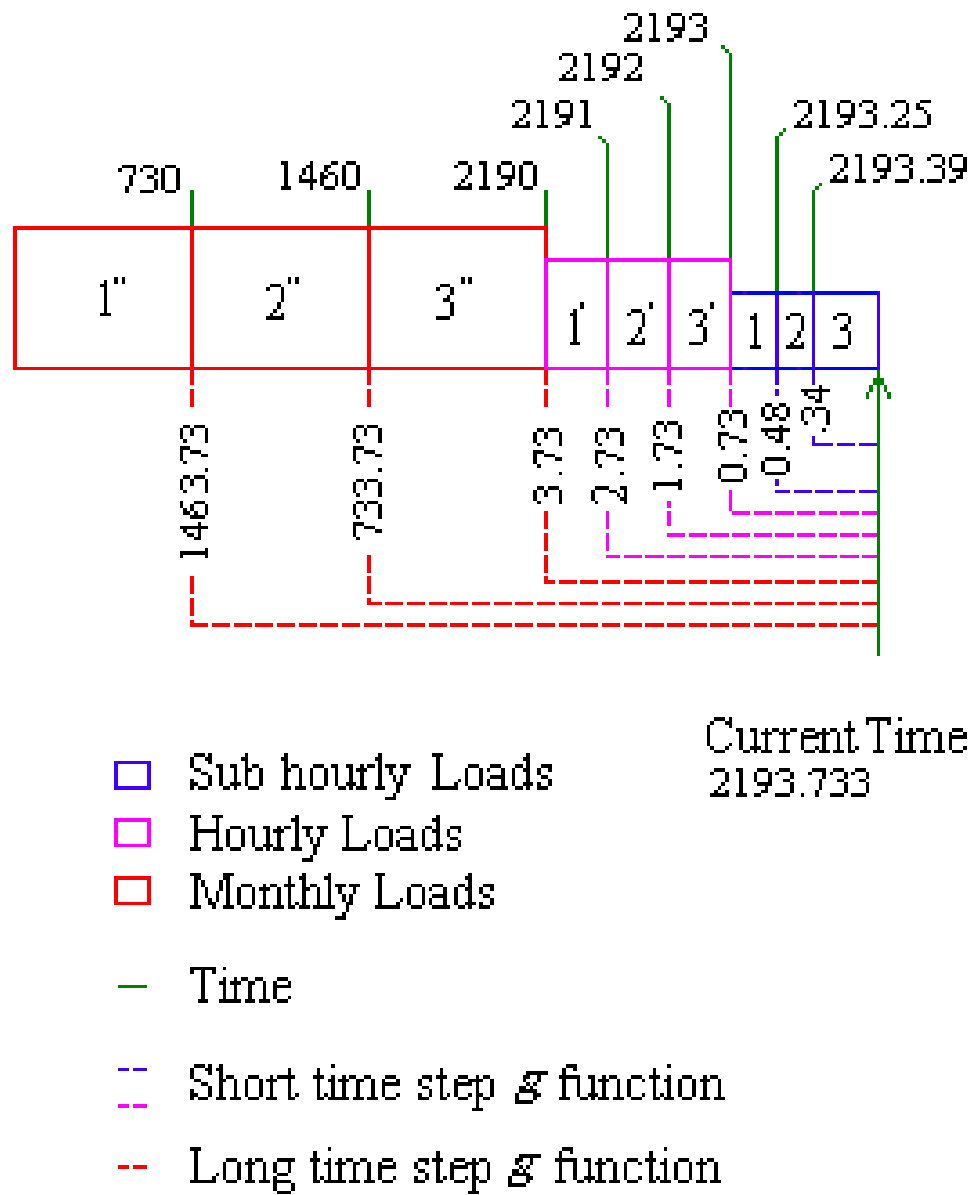

Figure 16.75: Schematic of Variable Time Step Model g Function Calculation.

schematic. For example, to calculate the response of the aggregated load 1” (at the end of 730hrs.) for the current time step (2193.733hrs) we apply a g -function at 1463.73hrs. The g -function for the same block 1” at the previous time step, which occurred at 2193.25 hrs, would be at 1463.25hrs. From the schematic it is also seen that for the other two aggregated monthly loads 2”, 3” the g -function are applied at 733.73 hrs and 3.73 hrs for the current time-step and at 733.25 hrs and 3.25 hrs respectively for the previous time-step. The same scheme applies to hourly and sub-hourly. Thus to estimate the time at which the past monthly, hourly or sub-hourly loads occur, we might be tempted to store the simulation times at each time step for the entire simulation, storing load times for the whole length of simulation for a multi year simulation with a variable short time step would require a large amount of memory. But little consideration shows that it is not necessary. Since the monthly and hourly loads occur at equal intervals of time 730hrs and 1hr respectively, the g -functions can be estimated with the current simulation time and the time at which the load block ends, which is a multiple of the monthly duration of the block size. Only the sub-hourly loads require storage of simulation times.

For example from the schematic (Figure 16.76), for the sub hourly load 1, which occurred at the end of 2193.25 a g -function at .48 hrs has to be applied and for the next load 2 a g -function at 0.34 hrs has to be applied. Since the time intervals are not even for the sub hourly loads, we need to store the time steps at which those loads occurred. These times are required to estimate the time elapsed between the current simulation time and the time at which the sub hourly loads occurred.

Thus, the algorithm keeps track of the sub hourly loads along with their time of occurrence for a user-defined length of time during which the sub hourly calculations are made. The algorithm also estimates the time weighted hourly load from their corresponding sub hourly loads as each hour passes. The sub-hourly loads are time weighted because of the irregular intervals at which the time-step occurs. This is also illustrated in Figure 16.76. The sub hourly loads 1,2 &3 occur for varying length of time. The load 3 occurs for a longer duration than 1 and 2 in that order. This implies that the load 3 has to be given more weight than 1 and 2. So the sub hourly loads for a particular hour are multiplied by the length of their respective period of occurrence and averaged over the hour. This is further explained by the schematic in Figure 2.3.

The bottom text in the boxes represents the magnitude of the sub hourly loads in W/m for each time step. The duration of the occurrence of each time-step for the each block is shown below the respective block. The first hourly load is given by the expression:

$$\bar{q}_1 = \left[\begin{array}{l} (8.36 \times .159) + (6.51 \times .339) + (10.3 \times .107) \\ + (6.92 \times .162) + (9.03 \times .181) + (12 \times .05) \end{array} \right] = 7.993W/m \quad (16.674)$$

where \bar{q}_1 is the first hourly load (W/m).

The algorithm keeps track of enough of these past hourly loads to calculate the monthly load. As each month or user defined time passes, hourly loads over the entire month or user defined time “blocks” are averaged and stored in arrays for the respective monthly user defined block of time.

The borehole temperature for any time step is computed by superposing the monthly (larger time block loads) hourly and sub-hourly loads for each time step. To understand more clearly consider the schematic in Figure 16.76 where the borehole temperature at 2193.733 hour is to be estimated. Here the monthly block time is 730 hrs. We have three monthly aggregated load blocks for 730 hrs, 1460 hrs and 2190 hrs and hourly loads from 2191st hr to 2193rd hour. For the remaining 0.733 hours a sub hourly calculation is done. The three monthly aggregated load blocks when superposed using long time g -functions, yields the borehole temperature at the end of 2190th hour. Then the hourly

Figure 16.76: Schematic Showing the Calculation of Hourly Load from the Sub Hourly Loads.

loads from 2191st to 2193rd hrs are superposed using the corresponding short time step g functions values yielding the borehole temperature at the end of 2193rd hour. The sub-hourly variations for the current hour are obtained, by superposing the sub-hourly loads. From the schematic, we see there are two sub-hourly loads, 1 and 2. Thus the borehole temperature at the end of 2193.733 is expressed as:

$$T_{2193.733} = T_{ground} + \sum_{m=1}^3 \left[\frac{\bar{q}_m - \bar{q}_{m-1}}{2\pi k_{ground}} g \left(\frac{t_{2193.733} - t_{730(m-1)}}{t_s}, \frac{r_b}{H} \right) \right] \quad (16.675)$$

$$+ \sum_{n=2190}^{2193} \left[\frac{\bar{q}_n - \bar{q}_{n-1}}{2\pi \kappa_{ground}} g \left(\frac{t_{2193.733} - t_{n-1}}{t_s}, \frac{r_b}{H} \right) \right] \quad (16.676)$$

$$+ \sum_{p=2193}^{2193.733} \left[\frac{q_p - q_{p-1}}{2\pi \kappa_{ground}} g \left(\frac{t_{2193.733} - t_p}{t_s}, \frac{r_b}{H} \right) \right] \quad (16.677)$$

where:

$\bar{\bar{q}}$ is the average monthly loads

\bar{q} is the average hourly loads

Q is the sub-hourly loads

m is the index for monthly aggregated blocks

p is the array index for sub hourly loads

t is time

t_p is the sub hourly time steps over the history period (here, the increment is not always unity).

Superposing the temperature responses of monthly (larger) blocks over the shorter, namely the hourly and sub hourly, introduces some error in the borehole temperature calculation at the beginning of every month. Yavuzturk and Spitler suggest a method to reduce the error in borehole temperature prediction by using a minimum hourly history period during which only the short time step superposition is carried out. In our model this idea is extended to sub hourly loads as well. Thus a user specified minimum sub-hourly history period is included along with the minimum hourly history period to model the sub-hourly variations. During this period only sub-hourly and hourly superpositions are made. This guarantees that at any given time step the superposition of temperature responses involves a minimum period of short time responses, which ensures a better estimation of borehole temperature. For example, a minimum hourly history period of 96 hrs and a minimum sub hourly history period of 5 hours would result in only 2 monthly aggregation blocks (1" and 2"). The last monthly aggregation does not occur because neither of the minimum hourly history period of 96 hours or sub-hourly history period of five hrs is met. So an hourly superposition of the load is carried out for the third month until the minimum sub-hourly history period after which sub hourly superposition is carried out. The equation becomes

$$T_{2193.733} = T_{ground} + \sum_{m=1}^2 \left[\frac{\bar{\bar{q}}_m - \bar{\bar{q}}_{m-1}}{2\pi k_{ground}} g \left(\frac{t_{2193.733} - t_{730(m-1)}}{t_s}, \frac{r_b}{H} \right) \right] \quad (16.678)$$

$$+ \sum_{n=1460}^{2188} \left[\frac{\bar{q}_n - \bar{q}_{n-1}}{2\pi \kappa_{ground}} g \left(\frac{t_{2193.733} - t_{n-1}}{t_s}, \frac{r_b}{H} \right) \right] \quad (16.679)$$

$$+ \sum_{p=2188}^{2193.733} \left[\frac{q_p - q_{p-1}}{2\pi\kappa_{ground}} g \left(\frac{t_{2193.733} - t_p}{t_s}, \frac{r_b}{H} \right) \right] \quad (16.680)$$

Yavuzturk and Spitler have done a detailed analysis on the effect of minimum hourly history period. They found that a minimum hourly history period of 192 hrs for an annual simulation would reduce the running time by 90%. They also found that for a 20-year simulation, the computation time of the aggregated load scheme is just 1% of the non-aggregated load scheme.

16.8.4.4 Summary of Variable Short Time Step Response Factor Model

The load aggregation scheme developed in line with the above example is summarized eight steps as follows:

1. Define monthly load blocks duration (mb) in hrs (generally 730 hrs) and the minimum hourly history period and minimum sub hourly history period.
2. Read Borehole Geometry Parameters: number of boreholes, borehole length radius thickness of the pipe etc. Read Ground and Fluid thermal properties: Ground conductivity, volumetric specific heat capacity of the ground and heat carrier fluid. Read the short and long time-step g -functions into arrays with their respective non-dimensionalized times.
3. Start Simulation from $p = 1$ to nts . Here “nts” is the number of time steps that have occurred since the start of simulation. (Note that P is not a count of number of hour elapsed in the simulation)
4. Compute the hourly loads as each hour passes. This is done by averaging the sub hourly loads during the past hour. The monthly loads are calculated by averaging the hourly loads during that month. This is done by summing the hourly loads during that monthly period and dividing the sum by 730 hours NumMonths(the number of months used in aggregation calculations) is set to the number of months of simulation (current number of aggregated load blocks)
5. If the simulation time is less than the minimum sub hourly history period the borehole temperature is estimated with no aggregation. Only sub hourly loads are superposed as given by the following equation.

$$T_{nts} = T_{ground} + \sum_{p=1}^{nts} \left[\frac{q_p - q_{p-1}}{2\pi\kappa_{ground}} g \left(\frac{t_{nts} - t_p}{t_s}, \frac{r_b}{H} \right) \right] \quad (16.681)$$

6. If the simulation time is less than sum of minimum hourly history and sub hourly history periods, then decomposed hourly aggregated loads are superposed using their corresponding g function until the sub hourly history required. Then the sub hourly temperature differences are found by superposing the decomposed sub hourly loads with their short time step g functions. Average borehole temperature is found by superposing the hourly and sub hourly temperature differences with the following equation

$$T_{nts} = \sum_{n=1}^{nh-sh} \left[\frac{\bar{q}_n - \bar{q}_{n-1}}{2\pi\kappa_{ground}} g \left(\frac{t_{nts} - t_{n-1}}{t_s}, \frac{r_b}{H} \right) \right] + \sum_{p=nts-sh}^{nts} \left[\frac{q_p - q_{p-1}}{2\pi\kappa_{ground}} g \left(\frac{t_{nts} - t_p}{t_s}, \frac{r_b}{H} \right) \right] \quad (16.682)$$

7. If the simulation time is greater than the sum of a monthly period, sub hourly history and the hourly history period. Then monthly load aggregation is performed. Here if the difference between the simulation time and product of a monthly block period and the current number of monthly blocks is greater than the sum of the minimum hourly history and sub hourly history periods then the average borehole temperature is found by the following equation.

$$\begin{aligned} T_{nts} = & T_{ground} + \sum_{m=1}^{calb} \left[\frac{\bar{q}_m - \bar{q}_{m-1}}{2\pi\kappa_{ground}} g \left(\frac{t_{nts} - t_{mb[m-1]}}{t_s}, \frac{r_b}{H} \right) \right] \\ & + \sum_{n=nh-[calb(mb)+sh]}^{nh-sh} \left[\frac{\bar{q}_n - \bar{q}_{n-1}}{2\pi\kappa_{ground}} g \left(\frac{t_{nts} - t_{n-1}}{t_s}, \frac{r_b}{H} \right) \right] \\ & + \sum_{p=nts-sh}^{nts} \left[\frac{q_p - q_{p-1}}{2\pi\kappa_{ground}} g \left(\frac{t_{nts} - t_p}{t_s}, \frac{r_b}{H} \right) \right] \end{aligned} \quad (16.683)$$

8. If the difference between the simulation time and product of a monthly block period and the current number of monthly blocks is less than the sum of the minimum hourly history and sub hourly history periods, then NumMonths is set to one month less than the actual number of months of simulation completed. The average borehole temperature is calculated by superposing the long and time step temperature differences using the following equation.

$$\begin{aligned} T_{nts} = & T_{ground} + \sum_{m=1}^{calb-1} \left[\frac{\bar{q}_m - \bar{q}_{m-1}}{2\pi\kappa_{ground}} g \left(\frac{t_{nts} - t_{mb[m-1]}}{t_s}, \frac{r_b}{H} \right) \right] \\ & + \sum_{n=nh-[(calb-1)(mb)+sh]}^{nh-sh} \left[\frac{\bar{q}_n - \bar{q}_{n-1}}{2\pi\kappa_{ground}} g \left(\frac{t_{nts} - t_{n-1}}{t_s}, \frac{r_b}{H} \right) \right] \\ & + \sum_{p=nts-sh}^{nts} \left[\frac{q_p - q_{p-1}}{2\pi\kappa_{ground}} g \left(\frac{t_{nts} - t_p}{t_s}, \frac{r_b}{H} \right) \right] \end{aligned} \quad (16.684)$$

The following is a summary of the above eight steps:

Define Monthly block duration, minimum hourly history period and minimum sub hourly history period (**Step 1**)

Read Borehole Geometry parameters, Ground and carrier fluid properties and read short and long time-step g functions (**Step 2**)

Do until $p = 1$ to number of time-steps (nts) (**Step 3**)

Compute the Ground Load for the current time step using Entering Fluid temperature (For the first time-step $T_{FarField}$ may be used)

Compute the hourly loads as each hour and monthly loads as each month passes. Calculate the number of monthly blocks (NumMonths)(**Step 4**)

If (Current time less than minimum sub hourly history) (**Step 5**)

use Equation 16.681

Else If (Current Simulation Time less than sum of minimum hourly history and minimum sub hourly history) (**step 6**)

use Equation 16.682

Else

If (Difference between current simulation time and duration of the total number months is Greater than sum of minimum hourly and sub hourly histories) (**step 7**)

use Equation 16.683

Else (step 8)

use Equation 16.684

End if

End if

End do

16.8.5 GroundHeatExchanger:Slinky

This model reuses much of the same code including the load aggregation and temperature response calculations which are described above in the GroundHeatExchanger:Vertical model. As a result, that section can also be used as reference material. This model is unique in that it generates its own temperature response factor g-functions, rather than relying on the other software or data to generate the g-functions. These are generated based on the work by Xiong et al. 2015.

16.8.5.1 Horizontal Slinky Temperature Response Functions

Equation used for calculating the g-function temperature response factors for the horizontal Slinky HX are seen below.

$$g_s(t) = \sum_{i=1}^{N_{ring}} \sum_{j=1}^{N_{ring}} \frac{R}{4\pi N_{ring}} \int_0^{2\pi} \int_0^{2\pi} \left[\frac{\operatorname{erfc}(d(P_j, P_i)/2\sqrt{\alpha t})}{d(P_j, P_i)} - \frac{\operatorname{erfc}\left(\sqrt{d(P_j, P_i)^2 + 4h^2}/(2\sqrt{\alpha t})\right)}{\sqrt{d(P_j, P_i)^2 + 4h^2}} \right] d\omega d\varphi \quad (16.685)$$

where:

$$d(P_j, P_i) = \frac{d(P_{ii}, P_j) + d(P_{io}, P_j)}{2} \quad (16.686)$$

$$d(P_{ii}, P_j) = \sqrt{[x_{0i} + (R - r) \cos \varphi - x_{0j} - R \cos \omega]^2 + [y_{0i} + (R - r) \sin \varphi - y_{0j} - R \sin \omega]^2} \quad (16.687)$$

$$d(P_{io}, P_j) = \sqrt{[x_{0i} + (R - r) \cos \varphi - x_{0j} - R \cos \omega]^2 + [y_{0i} + (R + r) \sin \varphi - y_{0j} - R \sin \omega]^2} \quad (16.688)$$

16.8.5.2 Vertical Slinky Temperature Response Functions

Equations used for calculating the g-function temperature response factors for the vertical Slinky HX are seen below.

$$g_s(t) = \sum_{i=1}^{N_{ring}} \sum_{j=1}^{N_{ring}} \frac{R}{4\pi N_{ring}} \int_0^{2\pi} \int_0^{2\pi} \left[\frac{\operatorname{erfc}(d(P_j, P_i)/2\sqrt{\alpha t})}{d(P_j, P_i)} - \frac{\operatorname{erfc}(d(P_{j'}, P_i)/2\sqrt{\alpha t})}{d(P_{j'}, P_i)} \right] d\omega d\varphi \quad (16.689)$$

where:

$$d(P_j, P_i) = \frac{d(P_{ii}, P_j) + d(P_{io}, P_j)}{2} \quad (16.690)$$

$$d(P_{j'}, P_i) = \frac{d(P_{ii}, P_{j'}) + d(P_{io}, P_{j'})}{2} \quad (16.691)$$

$$d(P_{ii}, P_j) = \sqrt{[x_{0i} + (R - r) \cos \varphi - x_{0j} - R \cos \omega]^2 + [y_{0i} - y_{0j}]^2 + [z_{0i} + (R - r) \sin \varphi - z_{0j} - R \sin \omega]^2} \quad (16.692)$$

$$d(P_{io}, P_j) = \sqrt{[x_{0i} + (R + r) \cos \varphi - x_{0j} - R \cos \omega]^2 + [y_{0i} - y_{0j}]^2 + [z_{0i} + (R + r) \sin \varphi - z_{0j} - R \sin \omega]^2} \quad (16.693)$$

$$d(P_{ii}, P_{j'}) = \sqrt{[x_{0i} + (R - r) \cos \varphi - x_{0j} - R \cos \omega]^2 + [y_{0i} - y_{0j}]^2 + [z_{0i} + (R - r) \sin \varphi - z_{0j} - 2h - R \sin \omega]^2} \quad (16.694)$$

$$d(P_{io}, P_{j'}) = \sqrt{[x_{0i} + (R + r) \cos \varphi - x_{0j} - R \cos \omega]^2 + [y_{0i} - y_{0j}]^2 + [z_{0i} + (R + r) \sin \varphi - z_{0j} - 2h - R \sin \omega]^2} \quad (16.695)$$

16.8.5.3 Model Simplifications for Computational Efficiency

Several simplifications were used to ensure the g-function temperature response factors are computationally efficient. The first simplification is achieved by taking advantage of symmetry. In the Figure 16.77 below, we can see that by taking advantage of symmetry the temperature response for only one quarter of the rings needs be calculated.

The second simplification occurs by realizing that the effect between two rings decreases exponentially as the distance between the rings increases. Near-field rings are defined as rings whose centers are within $2.5m + D$ distance from the center of ring i as is seen in Figure 16.77. Far-field rings are defined as rings whose centers are beyond $10m + D$, with middle-field rings occupying the space in between the near-field and far-field rings. Near-field ring temperature response factors are determined as indicated above for horizontal or vertical slinkys. Middle-field rings are considerably simplified – the interaction between ring is approximated as that of two point sources at their centers. Thermal effect of far-field rings are ignored.

The third and final simplification takes advantage of geometric similarity that ring share. Ring pairs that are geometrically similar do not require recalculation of distances or response factors. Thus the calculations for geometrically similar ring pairs can be reused.

16.8.6 Plant Loop Pond-To-Water Heat Exchanger

The pond model (Object: GroundHeatExchanger:Pond) is a ‘lumped parameter’ model where the pond is represented by a single node with thermal mass. The pond surface temperature is the same as the temperature at this node, i.e. the surface temperature is the same as the bulk temperature.

a) First improvement to the algorithm: use of symmetry

b) Second improvement to the algorithm: dividing surrounding rings into three categories

Figure 16.77: Schematic of first and second improvements to the algorithm for computational efficiency

Figure 16.78: Heat Transfer Mechanisms in a Pond (Chiasson 1999)

A first order differential equation is solved in the model to calculate the pond temperature at each time step. This type of heat rejecter is modeled as several circuits connected in parallel.

Rees (2002) implemented the model developed by Chiasson (1999) for the shallow ponds. The model is based on the assumption that thermal gradients in shallow ponds are negligible, especially during times of heat rejection. Using the lumped parameter approach, an overall energy balance for the pond may be devised as:

$$q_{in} - q_{out} = V \rho C_p \frac{dT}{dt} \quad (16.696)$$

where:

q_{in} is the heat transfer to the pond

q_{out} is the heat transfer from the pond

V is the pond volume

ρ is the density of pond water

q_{in} is the heat transfer to the pond

C_p is the specific heat capacity of pond water

$\frac{dT}{dt}$ is the rate of change of temperature of the pond water.

The rate of change in average pond temperature is given as:

$$\frac{dT}{dt} = \frac{q_{solar} + q_{thermal} + q_{convection} + q_{groundwater} + q_{evaporation} + q_{fluid}}{V \rho C_p} \quad (16.697)$$

where:

q_{solar} is the solar radiation heat gain to the pond

$q_{thermal}$ is the thermal radiation heat transfer at the pond surface.

$q_{convection}$ is the convection heat transfer at the pond surface

q_{ground} is the heat transfer to/from ground to the pond
 $q_{groundwater}$ is the heat transfer due to ground water inflow/outflow
 $q_{evaporation}$ is the heat transfer due to evaporation at the pond surface
 q_{fluid} is the total heat transfer to/from the heat exchanging fluid flowing in all spools or coils in the pond.

A heat balance is calculated at a single node that represents the pond. Heat transfer takes place by surface convection, long-wave radiation to the sky, absorption of solar energy, ground heat transfer and heat exchange with the fluid. A heat exchanger analogy is used to calculate the heat transfer between the heat transfer fluid and the pond. The differential equation defined by the heat balance is solved using a fourth order Runge-Kutta numerical integration method. The implementation along with the model equations are summarized in the figure below.

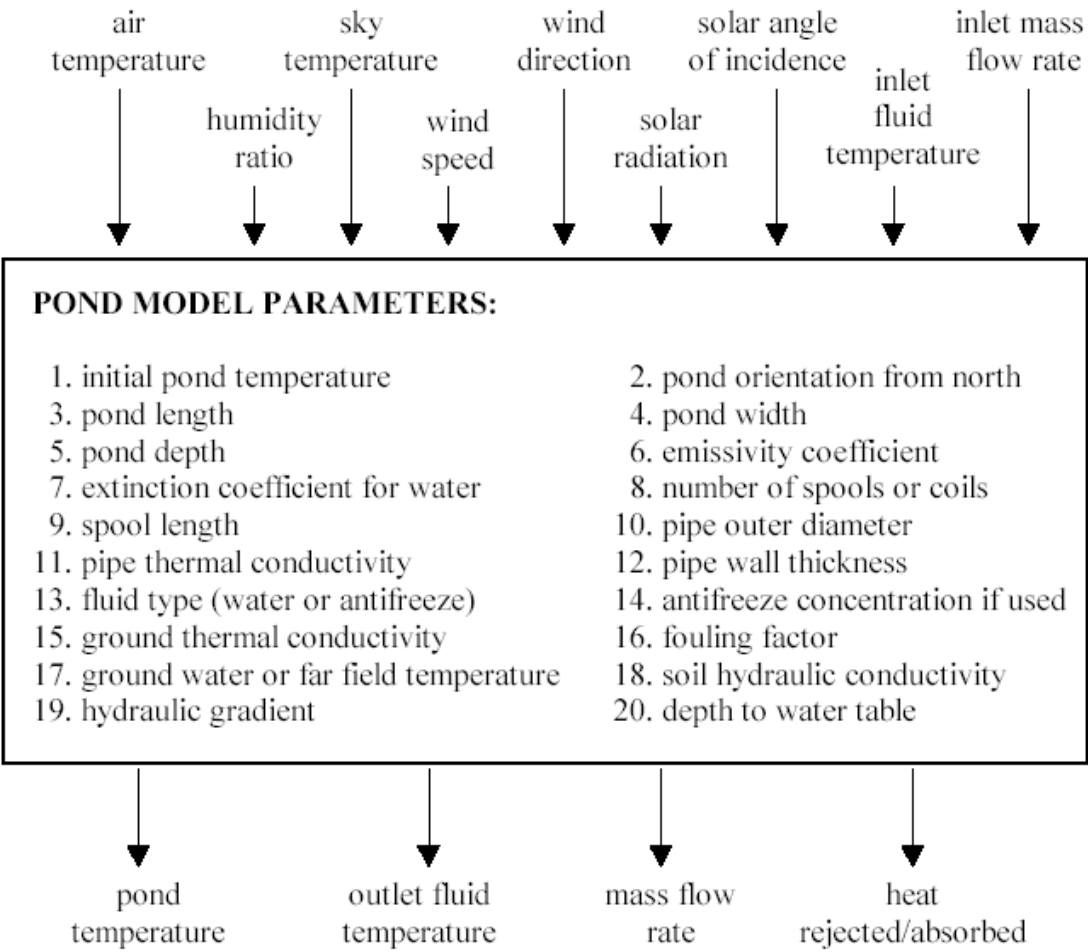

Figure 16.79: Pond Model Component Configuration (Chiasson 1999)

The model overall pond model consists in a number of sub-models which are enumerated below.

16.8.6.1 Solar radiation heat gain to the pond

$$\rho' = \tau_a - \tau \tag{16.698}$$

where:

ρ' is the reflectance

τ is the transmittance of solar radiation by the pond surface and the subscript 'a' refers to the absorbed component.

$$\tau_a = e^{\frac{-\mu' d}{\cos \theta_r}} \quad (16.699)$$

and

$$\tau = \frac{1}{2} \left(\frac{1 - r_{par}}{1 + r_{par}} + \frac{1 - r_{\perp}}{1 + r_{\perp}} \right) e^{\frac{-\mu' d}{\cos \theta_r}} \quad (16.700)$$

where:

μ' is the extinction coefficient for water

d is the pond depth

r_{par} represents the parallel component of unpolarized radiation and r_{\perp} represents the perpendicular component of unpolarized radiation which are computed by Duffie and Beckman (1991) as:

$$r_{par} = \frac{\tan^2 (\theta_r - \theta)}{\tan^2 (\theta_r + \theta)} \quad (16.701)$$

$$r_{\perp} = \frac{\sin^2 (\theta_r - \theta)}{\sin^2 (\theta_r + \theta)} \quad (16.702)$$

Finally, the amount of solar radiation absorbed by the pond (q_{solar}) is expressed as:

$$q_{solar} = I (1 - \rho') A_{pond} \quad (16.703)$$

where:

I is the solar radiation flux incident on the pond surface (here, the total reflectance is approximated by the beam reflectance)

A_{pond} is the area of the pond surface.

The model also accepts solar radiation in the form of beam (I_b) and diffuse (I_d) components, in which case I is computed from:

$$I = I_b \cos \theta + I_d \quad (16.704)$$

16.8.6.2 Thermal radiation heat transfer at the pond surface

$$q_{thermal} = \sigma \alpha (T_{surface}^4 - T_{sky}^4) \quad (16.705)$$

where:

α is the thermal absorptivity

σ is the Stefan Boltzman constant.

16.8.6.3 Convection heat transfer at the pond surface

$$q_{convection} = h_c(T_{pond} - T_{db}) \quad (16.706)$$

ASHRAE simple convection coefficient model is used to obtain the convection coefficient for external surfaces. Initializing of pond temps to mean of dry-bulb temperature T_{db} and ground temperatures is useful because repeated warm up days tend to drive the initial pond temperature toward the dry-bulb temperature. Hence, for each environment the simulation starts the pond temperature T_{pond} midway between the dry-bulb and ground temperature.

16.8.6.4 Heat transfer to/from ground to the pond

Hull et al (1984) expressed the following equation for ground heat losses from any pond. The equations are also based on the assumption that, for all practical purposes, the constant temperature sink is the ground water table (Kishore and Joshi 1984):

$$q_{ground} = U_{ground} A_{ground} (T_{groundwater} - T_{pond}) \quad (16.707)$$

$$U_{ground} = 0.999 \left(\frac{k_{ground}}{d_{groundwater} - d_{pond}} \right) + 1.37 \left(\frac{k_{ground} P_{pond}}{A_{pond}} \right) \quad (16.708)$$

where:

k_{ground} is the thermal conductivity of the ground

$d_{groundwater}$ is the depth of water table

d_{pond} is the pond depth

P_{pond} is the pond perimeter.

16.8.6.5 Heat transfer due to evaporation at the pond surface

Evaporation is calculated assuming a fixed Lewis number unlike the Chaisson model.

$$q_{evaporation} = \left(\frac{Pr}{Sc} \right)^{2/3} \left(\frac{h_c}{C_{p,air}} \right) (HR_f - HR_a) (q_l) \quad (16.709)$$

where:

Pr is the Prandtl number for air

Sc is the Schmidt number for air

h_c is the convection coefficient

HR_f is the humidity ratio at pond surface/film temperature

HR_a is the humidity ratio of air

q_l is the latent heat of air.

Air properties are obtained by applying the existing the psychrometric functions of EnergyPlus.

16.8.6.6 Total heat transfer to/from the heat exchanging fluid flowing in all spools or coils in the pond

$$q_{fluid} = U A_{pipe} (T_{fluid} - T_{pond}) N_{circuit} \quad (16.710)$$

where:

$U A_{pipe}$ is the overall heat transfer coefficient expressed in terms of inside pipe area

$N_{circuit}$ is the number of spools installed in the pond.

The fluid temperature T_{fluid} is computed as the average fluid temperatures of the inlet and the outlet node at a given temperature.

$$UA_{pipe} = \frac{2\pi r_i \cdot L_{spool}}{\sum r_t} \quad (16.711)$$

where:

r_i is the inner pipe radius

L_{spool} is the length of one spool

$\sum r_t$ is the composite thermal resistance defined as the resistance due to fluid flow in the pipe plus the external pipe thermal resistance plus the fouling factor.

16.8.7 Plant Loop Surface-Ground-To-Water Heat Exchanger

This model (Object: GroundHeatExchanger:Surface) is based on the QTF formulation of heat transfer through building elements with embedded heat sources/sinks. The model uses a heat exchanger analogy to relate the inlet fluid temperature to the net heat transfer rate and consequently outlet temperature. The model is entirely passive, i.e. it does not set any flow rates or incorporate any controls. In order to deal with the non-linear boundary conditions at the top surface due to the presence of ice/snow fluxes have to be calculated by the QTF model and temperature calculated from the surface heat balance. This requires some iteration. Note, top surface variables correspond to 'outside' variables in standard CTF/QTF definition. Bottom surface variables correspond to 'inside' variables.

For given current surface temperatures the terms of the QTF equations can be grouped into constant terms, and those depending on the current source flux. The surface heat balance may be given by the following equation (Strand, 1997):

$$QS = \sum_{m=1}^M X_{k,m} T_{i,t-m+1} - \sum_{m=1}^M Y_{k,m} T_{o,t-m+1} + \sum_{m=1}^k F_m q_{i,t-m} + \sum_{m=1}^M W_m q''_{source,t-m+1} \quad (16.712)$$

$$T_S = \sum_{m=1}^M X_{k,m} T_{i,t-m+1} - \sum_{m=1}^M Y_{k,m} T_{o,t-m+1} + \sum_{m=1}^k F_m q_{i,t-m} + \sum_{m=1}^M W_m q''_{source,t-m+1} \quad (16.713)$$

where:

T_s is the temperature of the node where the heat source or sink is present

QS is the surface heat balance

q''_{source} is the heat flux at the location of the heat source or sink

T is the temperature

i is the inside of the building element

o is the outside of the building element

t is the current time step

X, Y, F, W are conduction transfer functions.

The surface balance equation includes terms for incident solar energy, radiation heat transfer from internal sources, linearized radiation between surfaces using the mean radiation temperature concept and convection to the surrounding air.

The heat balance on the water loop is given by:

$$q = \dot{m}c_p(T_{wi} - T_{wo}) \quad (16.714)$$

where:

q is the heat transferred between the water loop and the building elements

\dot{m} is the mass flow rate of water

T_{wi} is the inlet water temperature

T_{wo} is the outlet water temperature.

From the second law of thermodynamics the maximum amount of heat transfer is:

$$q_{\max} = (\dot{m}c_p)_{water}(T_{wi} - T_s) \quad (16.715)$$

where T_s = temperature at the source location

The effectiveness of the heat exchanger is given by:

$$\varepsilon = 1 - e^{-NTU} \quad (16.716)$$

where NTU is defined by:

$$NTU = \frac{UA}{(\dot{m}C_p)_{water}} \quad (16.717)$$

and

$$UA = h\pi DL \quad (16.718)$$

where h is the convection coefficient, D is the interior tube diameter, and L is the total length of the tube.

The Colburn equation is used to define the Nusselt number Nu :

$$Nu = \frac{hD}{k} = 0.023Re_D^{4/5}Pr^{1/3} \quad (16.719)$$

where Pr is the Prandtl number, Re is the Reynolds number and k is the thermal conductivity of the fluid.

$$Re_D = \frac{4\dot{m}}{\pi\mu D} \quad (16.720)$$

where μ is the absolute viscosity of water.

16.8.8 Plant Loop Fluid-to-Fluid Heat Exchanger

This component (Object: HeatExchanger:FluidToFluid) is a simple hydronic heat exchanger that can be used to couple two (hydronic) plant or condenser loops. Sizing and nominal capacity calculations are discussed elsewhere in this document, see the section called Plant Heat Exchanger Sizing. This section first discusses the heat transfer modeling and the control issues.

Heat exchanger performance modeling uses classic effectiveness-NTU correlations. The heat exchanger model can be specified as one of seven types: cross flow both fluid streams unmixed, cross flow both fluid streams mixed, cross flow Loop Supply Side mixed and Loop Demand Side unmixed, cross flow Loop Supply Side unmixed and Loop Demand Side mixed, counter flow, parallel flow, or ideal. The model correlations determine a heat transfer effectiveness value, ε , which is a function of heat exchanger UA, the mass flow rates through both sides, and the specific heat of the fluids in the streams. The effectiveness of an ideal heat exchanger is set to 1.0 and no correlation is needed.

Because the heat exchanger is intended to be generic, its two sides are distinguished by the nature of loop side being connected. One side is called “Loop Supply Side” to indicate the heat exchanger is situated on the supply side of a loop. The other side is called “Loop Demand Side” to indicate it is on the demand side of a loop. The heat exchanger is intended to act as a supply component for the loop connected to it as the “Loop Supply Side” and as a demand component for the loop connected to it as the “Loop Demand Side.” From the point of view of the heat exchanger component itself, the Loop Demand Side acts like a supply source/sink for the Loop Supply Side which acts like a demand to the component.

The mass flow rates and specific heat capacity are multiplied together to evaluate flow thermal capacity for each side and the minimum, maximum, and capacity ratio, R_C , are determined.

$$(\dot{m}c_p)_{SupLoop} = \dot{m}_{SupLoop} * c_{pSupLoop} \quad (16.721)$$

$$(\dot{m}c_p)_{DmdLoop} = \dot{m}_{DmdLoop} * c_{pDmdLoop} \quad (16.722)$$

$$(\dot{m}c_p)_{Min} = MIN \left((\dot{m}c_p)_{SupLoop}, (\dot{m}c_p)_{DmdLoop} \right) \quad (16.723)$$

$$(\dot{m}c_p)_{Max} = MAX \left((\dot{m}c_p)_{SupLoop}, (\dot{m}c_p)_{DmdLoop} \right) \quad (16.724)$$

$$R_C = \frac{(\dot{m}c_p)_{Min}}{(\dot{m}c_p)_{Max}} \quad (16.725)$$

NTU, or Number of Transfer Units, is calculated using:

$$NTU = \frac{UA}{(\dot{m}c_p)_{Min}} \quad (16.726)$$

For a counter flow heat exchanger, effectiveness is calculated using:

$$\varepsilon = \frac{1 - \exp[-NTU(1 - R_C)]}{1 - R_C \exp[-NTU(1 - R_C)]} \quad (16.727)$$

For a parallel flow heat exchanger, effectiveness is calculated using:

$$\varepsilon = \frac{1 - \exp[-NTU(1 + R_C)]}{(1 + R_C)} \quad (16.728)$$

For a cross flow heat exchanger with both streams unmixed, effectiveness is calculated using:

$$\varepsilon = 1 - \exp\left\{\frac{NTU^{0.22}}{R_C} [\exp(-R_C NTU^{0.78}) - 1]\right\} \quad (16.729)$$

For a cross flow heat exchanger with both streams mixed, the effectiveness is calculated using:

$$\varepsilon = \left[\frac{1}{1 - \exp(-NTU)} + \frac{R_C}{1 - \exp(-R_C NTU)} - \frac{1}{NTU} \right]^{-1} \quad (16.730)$$

For a cross flow heat exchanger with the stream with the higher capacity mixed and the stream with the lower capacity unmixed, the effectiveness is calculated using:

$$\varepsilon = \frac{1}{R_C} \{1 - \exp[R_C (\exp(-NTU) - 1)]\} \quad (16.731)$$

For a cross flow heat exchanger with the stream with higher capacity unmixed and the stream with lower capacity mixed, the effectiveness is calculated using:

$$\varepsilon = 1 - \exp\left\{-\frac{1}{R_C} [1 - \exp(-R_C NTU)]\right\} \quad (16.732)$$

Effectiveness values are always limited to be no higher than 1.0. The program code protects from evaluating the exponential with operands that are too large or too small. Once the effectiveness value is determined, the heat transfer rate is calculated using:

$$\dot{Q} = \varepsilon(\dot{m}c_p)_{Min} (T_{SupLoop,In} - T_{DmdLoop,In}) \quad (16.733)$$

Lastly, the fluid temperatures leaving the heat exchanger are calculated using:

$$T_{SupLoop,Out} = T_{SupLoop,In} - \frac{\dot{Q}}{(\dot{m}c_p)_{SupLoop}} \quad (16.734)$$

$$T_{DmdLoop,Out} = T_{DmdLoop,In} + \frac{\dot{Q}}{(\dot{m}c_p)_{DmdLoop}} \quad (16.735)$$

The plant heat exchanger offers a number of control options for a wide variety of applications. This section documents the control decision logic. The general goal of the control is to provide appropriate conditioning of the fluid at the Loop Supply Side connection. The basic control action is to request the appropriate flow rates for each side of the heat exchanger. For all of the control modes, there is also an availability schedule that provides a level of supervisory control to determine if the heat exchange is available to run at all. If the device is scheduled off, then zero flow is requested for both connections. All the control modes can also use minimum and maximum temperature limits. If the limits are used and either of the two inlet temperatures exceeds the limit, the zero flow is requested for both connections.

UncontrolledOn. This control type is very simple. If scheduled on it requests the full design flow rate on the Loop Supply Side connection. If the Loop Supply Side flow rate exceeds a small tolerance, then the full design flow rate is requested for the Loop Demand Side connection.

OperationSchemeModulated. This control type uses the plant operation schemes. Any of the various plant (or condenser) operation schemes (e.g. `PlantEquipmentOperation:CoolingLoad` or `PlantEquipmentOperation:HeatingLoad`). When the heat exchanger is called, the operation scheme will pass a value for the load to be met. If the absolute value of the load is less than a small tolerance (1 W), then zero flow is requested for both connections. If load is significant and negative, then the heat exchanger will attempt to provide cooling. If the load is significant and positive, then it will attempt to provide heating. The two inlet fluid temperatures are compared and if their difference exceeds the minimum temperature difference and has the correct sign for heating or cooling as needed, then the heat exchanger is turned “on.” The model requests the full design flow rate on the Loop Supply Side connection. If the Loop Supply Side flow rate exceeds a small tolerance, then a flow rate for the Loop Demand Side is found to attempt to meet the load. The load value is converted to a target temperature for the fluid leaving the Loop Supply Side connection. The target temperature is then used with the numerical method root solver to solve for the flow rate.

OperationSchemeOnOff. This control type uses the plant operation schemes. Any of the various plant (or condenser) operation schemes (e.g. `PlantEquipmentOperation:CoolingLoad` or `PlantEquipmentOperation:HeatingLoad`). When the heat exchanger is called, the operation scheme will pass a value for the load to be met. If the absolute value of the load is less than a small tolerance (1 W), then zero flow is requested for both connections. If load is significant and negative, then the heat exchanger will attempt to provide cooling. If the load is significant and positive, then it will attempt to provide heating. The two inlet fluid temperatures are compared and if their difference exceeds the minimum temperature difference and has the correct sign for heating or cooling as is needed, then the heat exchanger is turned “on.” The model requests the full design flow rate on the Loop Supply Side connection. If the Loop Supply Side flow rate exceeds a small tolerance, then the full design flow rate is requested for the Loop Demand Side connection.

HeatingSetpointModulated. This control scheme uses a node setpoint. The two inlet fluid temperatures are compared to see if their difference exceeds the minimum temperature difference and has the correct sign for heating to be possible. The temperature setpoint on the reference node is compared to the inlet temperature for the Loop Supply Side to see if heating is desired. If heating is both desired and possible, then the heat exchanger is turned “on.” The model requests the full design flow rate on the Loop Supply Side connection. If the Loop Supply Side flow rate exceeds a small tolerance, then a flow rate for the Loop Demand Side is found to attempt to meet the setpoint. The setpoint temperature is then used with the numerical method root solver to solve for the flow rate.

HeatingSetpointOnOff. This control scheme uses a node setpoint. The two inlet fluid temperatures are compared to see if their difference exceeds the minimum temperature difference and has the correct sign for heating to be possible. The temperature setpoint on the reference node is compared to the inlet temperature for the Loop Supply Side to see if heating is desired. If heating is both desired and possible, then the heat exchanger is turned “on.” The model requests the full design flow rate on the Loop Supply Side connection. If the Loop Supply Side flow rate exceeds a small tolerance, then the full design flow rate is requested for the Loop Demand Side connection.

CoolingSetpointModulated. This control scheme uses a node setpoint. The two inlet fluid

temperatures are compared to see if their difference exceeds the minimum temperature difference and has the correct sign for cooling to be possible. The temperature setpoint on the reference node is compared to the inlet temperature for the Loop Supply Side to see if cooling is desired. If cooling is both desired and possible, then the heat exchanger is turned “on.” The model requests the full design flow rate on the Loop Supply Side connection. If the Loop Supply Side flow rate exceeds a small tolerance, then a flow rate for the Loop Demand Side is found to attempt to meet the setpoint. The setpoint temperature is then used with the numerical method root solver to solve for the flow rate.

CoolingSetpointOnOff. This control scheme uses a node setpoint. The two inlet fluid temperatures are compared to see if their difference exceeds the minimum temperature difference and has the correct sign for cooling to be possible. The temperature setpoint on the reference node is compared to the inlet temperature for the Loop Supply Side to see if cooling is desired. If cooling is both desired and possible, then the heat exchanger is turned “on.” The model requests the full design flow rate on the Loop Supply Side connection. If the Loop Supply Side flow rate exceeds a small tolerance, then the full design flow rate is requested for the Loop Demand Side connection.

CoolingSetpointOnOffWithComponentOverride. This control scheme uses one of three different control signals, a node setpoint, outdoor air drybulb temperature, or outdoor air wetbulb temperature. The two inlet fluid temperatures are compared to see if their difference exceeds the minimum temperature difference and has the correct sign for cooling to be possible. The control signal is compared to the inlet temperature for the Loop Supply Side to see if cooling is desired. If cooling is both desired and possible, then the heat exchanger is turned “on.” When the heat exchanger is on, the remote chiller component is turned off. The model requests the full design flow rate on the Loop Supply Side connection. If the Loop Supply Side flow rate exceeds a small tolerance, then the full design flow rate is requested for the Loop Demand Side connection.

CoolingDifferentialOnOff. This control scheme is based on a simple temperature difference. The two inlet fluid temperatures are compared to see if their difference exceeds the minimum temperature difference and has the correct sign for cooling to be possible. If cooling is possible then it is assumed to be desired and the heat exchanger is turned “on.” The model requests the full design flow rate on the Loop Supply Side connection. If the Loop Supply Side flow rate exceeds a small tolerance, then the full design flow rate is requested for the Loop Demand Side connection.

DualDeadbandSetpointModulated. This control scheme uses dual setpoints on a node. The basic idea is that the heat exchanger will condition the Loop Supply Side connection to drive its temperature into the deadband whenever its inlet temperature is outside the deadband. The model expects dual temperature setpoints to be placed on the setpoint, for example using the object `SetpointManager:Scheduled:DualSetpoint`.

The heat exchanger will operate to cool the Loop Supply Side fluid when the following three conditions are all met:

- 1) the two inlet fluid temperatures are compared to see if their difference exceeds the minimum temperature difference and has the correct sign for cooling to be possible,
- 2) the higher temperature setpoint on the reference node is compared to the inlet temperature for the Loop Supply Side to see if their difference exceeds the minimum temperature difference and has the correct sign for cooling to be possible, and
- 3) the higher temperature setpoint on the reference node is compared to the inlet temperature for the Loop Demand Side to see if their difference exceeds the minimum temperature difference and has the correct sign for cooling to be possible.

The heat exchanger will operate to heat the Loop Supply Side fluid when the following three conditions are all met:

- 1) the two inlet fluid temperatures are compared to see if their difference exceeds the minimum temperature difference and has the correct sign for heating to be possible,
- 2) the lower temperature setpoint on the reference node is compared to the inlet temperature for the Loop Supply Side to see if their difference exceeds the minimum temperature difference and has the correct sign for heating to be possible, and
- 3) the lower temperature setpoint on the reference node is compared to the inlet temperature for the Loop Demand Side to see if their difference exceeds the minimum temperature difference and has the correct sign for heating to be possible.

When the heat exchanger is turned “on,” the model requests the full design flow rate on the Loop Supply Side connection. If the Loop Supply Side flow rate exceeds a small tolerance, then a flow rate for the Loop Demand Side is found to attempt to meet the setpoint. The setpoint temperature is then used with the numerical method root solver to solve for the flow rate.

DualDeadbandSetpointOnOff. This control scheme uses dual setpoints on a node. The basic idea is that the heat exchanger will condition the Loop Supply Side connection to drive its temperature into the deadband whenever its inlet temperature is outside the deadband. The model expects dual temperature setpoints to be placed on the setpoint, for example using the object `SetpointManager:Scheduled:DualSetpoint`.

The heat exchanger will operate to cool the Loop Supply Side fluid when the following three conditions are all met:

- 1) the two inlet fluid temperatures are compared to see if their difference exceeds the minimum temperature difference and has the correct sign for cooling to be possible,
- 2) the higher temperature setpoint on the reference node is compared to the inlet temperature for the Loop Supply Side to see if their difference exceeds the minimum temperature difference and has the correct sign for cooling to be possible, and
- 3) the higher temperature setpoint on the reference node is compared to the inlet temperature for the Loop Demand Side to see if their difference exceeds the minimum temperature difference and has the correct sign for cooling to be possible.

The heat exchanger will operate to heat the Loop Supply Side fluid when the following three conditions are all met:

- 1) the two inlet fluid temperatures are compared to see if their difference exceeds the minimum temperature difference and has the correct sign for heating to be possible,
- 2) the lower temperature setpoint on the reference node is compared to the inlet temperature for the Loop Supply Side to see if their difference exceeds the minimum temperature difference and has the correct sign for heating to be possible, and
- 3) the lower temperature setpoint on the reference node is compared to the inlet temperature for the Loop Demand Side to see if their difference exceeds the minimum temperature difference and has the correct sign for heating to be possible.

When the heat exchanger is turned “on,” the model requests the full design flow rate on the Loop Supply Side connection. If the Loop Supply Side flow rate exceeds a small tolerance, then the full design flow rate is requested for the Loop Demand Side connection.

16.9 Air System Humidifiers

16.9.1 Overview

Air system humidifiers are components that add moisture to the supply air stream. They fall into 2 broad categories: spray type humidifiers which act like direct evaporative coolers, cooling the supply air as well as humidifying it; and dry steam humidifiers, which humidify the supply air stream while causing almost no change to the supply air stream temperature. The EnergyPlus electric and gas fired steam humidifier uses electrical energy and thermal energy, respectively, to convert ordinary tap water to steam which it then injects into the supply air stream by means of a blower fan. The actual electric dry steam unit might be an electrode-type humidifier or a resistance-type humidifier.

16.9.2 Electric and Gas Steam Humidifier

The electric and gas steam humidifier models (object names: Humidifier:Steam:Electric and Humidifier:Steam:Gas) are based on moisture and enthalpy balance equations plus standard psychrometric relationships. The approach is similar to that taken in the ASHRAE HVAC 2 Toolkit, page 4-112 (ASHRAE 1993). EnergyPlus contains its own module of psychrometric routines; the psychrometric theory and relations are given in the 2001 edition of ASHRAE Fundamentals, Chapter 6 (ASHRAE 2001). The model contains both an ideal controller and the component. The control model assumes that there is a minimum humidity setpoint on the component air outlet node. This setpoint is established by a setpoint manager described elsewhere.

16.9.2.1 Model

The component model is a forward model: its inputs are its inlet conditions; its outputs are its outlet conditions and its energy consumption. The inputs are the temperature, humidity ratio, and mass flow rate of the inlet air stream, which are known; and the water addition rate (kg/s) which is determined by the controller. The moisture mass balance and psychrometric calculations are identical for both gas and electric dry steam humidifiers. The only difference is how a heat source (electric or gas) is used to generate the steam.

16.9.2.2 Controller

The controller first decides whether the humidifier is on or off. For the humidifier to be on:

- the humidifier schedule value must be nonzero;

- the inlet air mass flow must be greater than zero;
- the inlet air humidity ratio must be less than the minimum humidity ratio setpoint.

If the humidifier is off, the water addition rate is set to zero. If the humidifier is on, the water addition rate needed to meet the humidity setpoint is calculated.

$$\dot{m}_a \cdot w_{in} + \dot{m}_{w,add,needed} = \dot{m}_a \cdot w_{set} \quad (16.736)$$

where:

\dot{m}_a is the the air mass flow rate (kg/s)

w_{in} is the inlet air humidity ratio (kg/kg)

$\dot{m}_{w,add,needed}$ is the water addition rate needed to meet the setpoint (kg/s)

w_{set} is the humidity ratio setpoint (kg/kg).

Equation 16.736 is the moisture balance equation for the component. It is solved for $\dot{m}_{w,add,needed}$ (the other variables are known) which is passed to the humidifier component model as its desired inlet water addition rate.

16.9.2.3 Component

The inputs to the component model are the air inlet conditions and mass flow rate and the water addition rate set by the controller. The outputs are the air outlet conditions. First the desired water addition rate is checked against component capacity.

$$\dot{m}_{w,add,needed,max} = Min(\dot{m}_{w,add}, Cap_{nom}) \quad (16.737)$$

where Cap_{nom} is the humidifier nominal capacity (kg/s), a user input.

If $\dot{m}_{w,add,needed,max}$ is zero, the outlet conditions are set to the inlet conditions and the water addition rate is set to zero. If the humidifier is scheduled on the component power consumption is set to the standby power consumption: $W_{hum} = W_{stby}$. Otherwise $W_{hum} = 0$.

If $\dot{m}_{w,add,needed,max} > 0$, then the moisture and enthalpy balance equations are:

$$\dot{m}_a \cdot w_{in} + \dot{m}_w = \dot{m}_a \cdot w_{out} \quad (16.738)$$

$$\dot{m}_a \cdot h_{in} + \dot{m}_w \cdot h_w = \dot{m}_a \cdot h_{out} \quad (16.739)$$

where:

\dot{m}_w is set equal to $\dot{m}_{w,add,needed,max}$ and then the above equations are solved for w_{out} and h_{out}

\dot{m}_a is the air mass flow rate (kg/s)

w_{in} is the inlet air humidity ratio (kg/kg)

\dot{m}_w is the inlet water addition rate (kg/s)

w_{out} is the outlet air humidity ratio (kg/kg)

h_{in} is the inlet air specific enthalpy (J/kg)

h_w is the steam specific enthalpy = 2676125 J/kg at 100°C

h_{out} is the outlet air specific enthalpy (J/kg).

The outlet temperature is obtained from:

$$T_{out} = PsyHFnTdbW(h_{out}, w_{out}) \quad (16.740)$$

where:

T_{out} is the outlet air temperature (°C)

$PsyHFnTdbW$ is an EnergyPlus psychrometric function.

The humidity ratio at saturation at the outlet temperature is:

$$w_{out,sat} = PsyWFnTdbRhPb(T_{out}, 1.0, P_{atmo}) \quad (16.741)$$

where:

P_{atmo} is the barometric pressure (Pa)

1.0 is the relative humidity at saturation

$PsyWFnTdbRhPb$ is an EnergyPlus psychrometric function.

If $w_{out} \leq w_{out,sat}$, then the outlet condition is below the saturation curve and the desired moisture addition rate can be met. $\dot{m}_{w,add}$ is set to $\dot{m}_{w,add,needed,max}$ and the calculation of outlet conditions is done. But if $w_{out} > w_{out,sat}$ then it is assumed that this condition will be detected and the steam addition rate throttled back to bring the outlet conditions back to the saturation condition. We need to find the point where the line drawn between state 1 (inlet) and state 2 (our desired outlet) crosses the saturation curve. This will be the new outlet condition. Rather than iterate to obtain this point, we find it approximately by solving for the point where 2 lines cross: the first drawn from state 1 to state 2, the second from $T_1, w_{1,sat}$ to $T_2, w_{2,sat}$; where:

T_1 is the inlet temperature (°C)

$w_{2,sat}$ is the humidity ratio at saturation at temperature T_1 (kg/kg)

T_2 is the desired outlet temperature (°C)

$w_{1,sat}$ is the humidity ratio at saturation at temperature T_2 (kg/kg).

The 2 lines are given by the equations:

$$w = w_1 + ((w_2 - w_1)/(T_2 - T_1)) \cdot (T - T_1) \quad (16.742)$$

$$w = w_{1,sat} + ((w_{2,sat} - w_{1,sat})/(T_2 - T_1)) \cdot (T - T_1) \quad (16.743)$$

Solving for the point (state 3) where the lines cross:

$$w_3 = w_1 + ((w_2 - w_1) \cdot (w_{1,sat} - w_1))/(w_2 - w_{2,sat} + w_{1,sat} - w_1) \quad (16.744)$$

$$T_3 = T_1 + (w_3 - w_1) \cdot ((T_2 - T_1)/(w_2 - w_1)) \quad (16.745)$$

This point isn't quite on the saturation curve since we made a linear approximation of the curve, but the temperature should be very close to the correct outlet temperature. We will use this temperature as the outlet temperature and move to the saturation curve for the outlet humidity and enthalpy. Thus, we set $T_{out} = T_3$ and:

$$w_{out} = PsyWFnTdbRhPb(T_{out}, 1.0, P_{atmo}) \quad (16.746)$$

$$h_{out} = PsyHFnTdbW(T_{out}, w_{out}) \quad (16.747)$$

where $PsyHFnTdbW$ is an EnergyPlus psychrometric function. The water addition rate is set to:

$$\dot{m}_{w,add} = \dot{m}_a \cdot (w_{out} - w_{in}) \quad (16.748)$$

We now have the outlet conditions and the adjusted steam addition rate for the case where the desired outlet humidity results in an outlet state above the saturation curve. The energy consumption of the electric and gas steam humidifiers is calculated separately.

The electric steam humidifier electric consumption is given by:

$$W_{hum} = (\dot{m}_{w,add}/Cap_{nom}) \cdot W_{nom} + W_{fan} + W_{stby} \quad (16.749)$$

where:

W_{fan} is the nominal fan power (W), a user input

W_{stby} is the standby power (W), a user input.

The gas steam humidifier performance calculation is done for fixed and variable entering water temperature. The calculation procedure for fixed and variable entering water temperature are as follows.

16.9.2.4 Fixed Inlet WaterTemperature:

The gas steam humidifier gas consumption rate for fixed entering water temperature is given by:

$$\dot{Q}_{NG} = \frac{\dot{m}_{w,add}}{\dot{m}_{cap,nom}} Q_{NG,nom} \quad (16.750)$$

The actual gas use rate accounting for gas fired humidifier thermal efficiency variation with part load ratio is given by:

$$Q_{NG} = \dot{Q}_{NG} \frac{\eta_{rated}}{\eta_{actual}} \quad (16.751)$$

$$\eta_{actual} = \eta_{rated} \times \text{EffModCurveValue}(\text{PLR}) \quad (16.752)$$

$$\text{PLR} = \frac{Q_{NG}}{Q_{NG,nom}} \quad (16.753)$$

where:

EffModCurveValue is the thermal efficiency modifier curve value as function of part load ratio. This curve is generated from manufacturer's part load performance data

PLR is the part load ratio

$Q_{NG,nom}$ is the nominal or rated gas use rate, (Watts)

Q_{NG} is the actual gas use rate, (Watts)

η_{rated} is the nominal or rated thermal efficiency of gas fired steam humidifier

η_{actual} is the actual thermal efficiency of gas fired steam humidifier accounting for part load performance.

16.9.2.5 Variable Inlet Water Temperature:

The gas use rate is determined from the theoretical gas input rate and actual thermal efficiency. The actual thermal efficiency is the rated thermal efficiency corrected for part load ratio operation. At steady state the gas use rate is given by:

$$Q_{NG} = \frac{\dot{m}_w (h_{fg} + c_{p,w} (100 - T_{w,inlet}))}{\eta_{rated}} \quad (16.754)$$

$$PLR = \frac{Q_{NG}}{Q_{NG,nom}} \quad (16.755)$$

$$\eta_{actual} = \eta_{rated} \times \text{EffModCurveValue}(PLR) \quad (16.756)$$

$$Q_{NG} = \dot{Q}_{NG} \frac{\eta_{rated}}{\eta_{actual}} \quad (16.757)$$

where $T_{w,inlet}$ is the temperature of water entering the gas steam humidifier(°C). This value depends on the water source.

If the rated gas use rate input field is not autosized, then user specified thermal efficiency will be overridden with a value calculated from user specified rated gas use rate, nominal capacity (m³/s) and design conditions as follows:

$$\eta_{rated} = \frac{\dot{V}_{cap,nom} \rho_w (h_{fg} + c_{p,w} \Delta T_w)}{Q_{NG,nom}} \quad (16.758)$$

The gas steam humidifier requires electric power input to the blower fan and associated control units. The auxiliary electric power input rate of the gas steam humidifier is given by:

$$W_{aux} = W_{fan} + W_{controls} \quad (16.759)$$

where:

W_{fan} is the nominal fan power (W), a user input

$W_{controls}$ is the control electric power (W), a user input.

The water consumption rate, in m³/s, for electric and steam humidifier at a reference temperature of 5.05°C is given by:

$$\dot{V}_{cons} = \dot{m}_{w,add} / \rho_w \quad (16.760)$$

where:

\dot{V}_{cons} is the water consumption rate (m³)

ρ_w is the density of water (998.2 kg/m³).

Simulation Models – Encyclopedic Reference

The following descriptions are grouped alphabetically (as much as possible) with some also having additional tags of “Heat Balance”, “HVAC”, and “Plant”. With the integrated solution, these designations signify where the effects of these models have their first impacts.

Main Sections:

- Zone Internal Gains
- Indoor Swimming Pool
- Pipes
- Pumps
- Ideal Loads Air System
- District Cooling
- District Heating
- CentralHeatPumpSystem
- ChillerHeater
- Plant Temperature Source Component

17.1 Zone Internal Gains

17.1.1 Sources and Types of Gains

Internal heat gains from lights, people, and equipment of various types are often significant elements in the zone thermal balance. EnergyPlus allows the user to specify heat gains for several equipment types including people, lights, gas/electric equipment, and several other types. The total heat gain is comprised of convective, radiant and latent gains in various proportions from these sources. Convective gains are instantaneous additions of heat to the zone air. Radiant gains are distributed on the surfaces of the zone, where they are first absorbed and then released back into the room (with some fraction conducted through the surface) according to the surface heat balances. {See Surface Heat Balance Manager / Processes in this document}. Latent gains must be handled by ventilation or air conditioning equipment. Recommended heat gains are given in the ASHRAE Handbook of Fundamentals. These recommendations include the sensible (convective plus radiative) and latent proportions. Sensible gains from equipment are primarily radiant. The

user can specify the heat gains and proportions for any type of equipment. Determining the gains from lights, people and baseboard heat are slightly more complicated.

17.1.2 Heat Gain from Lights

The input object Lights provides a model for internal gains from lights. Radiant gains from lights must be handled differently from other radiant gains for reasons described here (long wavelength description). The total radiant gains from lights must be divided into visible and thermal portions. For example, the total electric input to typical incandescent lights is converted to 10% visible radiation, 80% thermal radiation, and 10% convective gain. In contrast, the electric input to typical fluorescent lights is converted to 20% visible radiation, 20% thermal radiation, and 60% convective gain (see Carrier 1965). These percentage splits are under user control with the Lights input object.

When the value of Return Air Fraction is greater than 0 and the return air flow rate is greater than 0, the portion of light heat will be added to the return air node. The added heat will make the node temperature rise. The temperature difference is calculated in the CalcZoneLeavingConditions function of the ZoneEquipmentManager module:

$$TempRetRise = \frac{QRetAir}{MassFlowRA * CpAir} \quad (17.1)$$

where:

$TempRetRise$ is the temperature rise due to added light heat gain (C)

$QRetAir$ is the added heat gain from return air fraction (W)

$MassFlowRA$ is the mass flow rate at the return node (kg/s)

$CpAir$ is the specific heat (J/kg)

When both node names of return air and exhaust air are entered in the Lights object, the return heat is shared by both nodes. Both nodes will have the same temperature due to added return heat:

$$TempRetRise = \frac{QRetAir}{(MassFlowRA + MassFlowEx) * CpAir} \quad (17.2)$$

where:

$TempRetRise$ is the temperature rise due to added light heat gain (C)

$QRetAir$ is the added heat gain from return air fraction (W)

$MassFlowRA$ is the mass flow rate at the return node (kg/s)

$MassFlowEx$ is the mass flow rate at the exhaust node (kg/s)

$CpAir$ is the specific heat (J/kg)

Although a single Lights object allows a return node and an exhaust node, it is possible to have multiple Lights objects with different return nodes and referred to the same exhaust node. Therefore, the exhaust node will share return heat from different return nodes. The temperature rise at i-th return node is given below:

$$TempRetRise_i = \frac{QRetAir_i}{(MassFlowRA_i + MassFlowEx) * CpAir} \quad (17.3)$$

$TempRetRise_i$ is the temperature rise at i-th return node due to added light heat gain (C)

$QRetAir_i$ is the added heat gain from return air fraction at i-th return node (W)

$MassFlowRA_i$ is the mass flow rate at i-th return node (kg/s)

$MassFlowEx$ is the mass flow rate at the exhaust node (kg/s)

$CpAir$ is the specific heat (J/kg)

The temperature arise at the exhaust node is a sum of all return node temperature rise:

$$TempRetRise = \sum_{i=1}^n \frac{QRetAir_i}{(MassFlowRA_i + MassFlowEx) * CpAir} \quad (17.4)$$

where:

$TempRetRise$ is the temperature rise at the exhaust node due to added light heat gain (C)

$QRetAir_i$ is the added heat gain from return air fraction (W)

$MassFlowRA_i$ is the mass flow rate at the return node (kg/s)

$MassFlowEx$ is the mass flow rate at the exhaust node (kg/s)

$CpAir$ is the specific heat (J/kg)

n is the number of Lights objects with the same exhaust node

17.1.3 Heat Gain from People

The input object People provides a model for internal gains from occupants. Heat is generated in the human body by oxidation at a rate called the metabolic rate (see Thermal Comfort discussion for more details). This heat is dissipated from the body surface and respiratory tract by a combination of radiation, convection, and evaporation. The relative proportions of sensible (radiation plus convection) and latent (evaporation) heat from people is a complex function of the metabolic rate and the environmental conditions. EnergyPlus uses a polynomial function to divide the total metabolic heat gain into sensible and latent portions. That function is based on a fit to data [3] at average adjusted metabolic rates of 350, 400, 450, 500, 750, 850, 1000 and 1450 Btu/h each at temperatures of 70, 75, 78, 80, 82°Fahrenheit. Sensible gains of 0 at 96°F and sensible gains equal to the metabolic rate at 30°F were assumed in order to give reasonable values beyond the reported temperature range.

Average adjusted metabolic rate (Carrier 1965b) is the metabolic rate to be applied to a mixed group of people with a typical percent composition based on the following factors:

- Metabolic rate, adult female = Metabolic rate, adult male X 0.85
- Metabolic rate, children = Metabolic rate, adult male X 0.75

The original data was in I-P (Inch-Pound) units, but the following correlation is in SI (Systems-International) units.

$$S = 6.461927 + .946892M + .0000255737M^2 + 7.139322T - .0627909TM + .0000589172TM^2 - .198550T^2 + .000940018T^2M - .00000149532T^2M^2 \quad (17.5)$$

where:

M is the metabolic rate (W)

T is the air temperature (C)

S is the sensible gain (W).

Latent Gain is simply the total gain (metabolic rate) – sensible gain:

$$\text{LatentGain} = \text{MetabolicRate} - \text{SensibleGain} \quad (17.6)$$

Figure 17.1: Sensible Heat Gain from People Correlation

The function for sensible gain calculation is compared to the original data points in the following figure. The radiant fraction of the sensible gain is a user input on the People object.

17.1.4 Heat Gain from IT Equipment

The input object ElectricEquipment:ITE:AirCooled describes air-cooled electric information technology equipment (ITE) which has variable power consumption as a function of loading and temperature. The calculations are described below.

17.1.4.1 Variable Definitions – User Inputs:

- PDesign is the design power input when fully loaded and entering air temperature is at the user-specified design inlet temperature (W)
- PFanFracDesign is the design fan power input fraction of total power input when fully loaded and entering air temperature is at the user-specified design inlet temperature
- SchDesignLevel is the scheduled fraction of this equipment which is powered up
- SchCPULoading is the scheduled fraction of CPU loading
- TAirInDesign is the air inlet temperature at design condition (°C)

- VAirDesign is the air volume flow rate at design condition (m^3/s)
- VAirfLoadTAir is the air volume flow rate modifier function of TAirIn and SchCPULoading
- PCPUfLoadTAir is the CPU power input modifier function of TAirIn and SchCPULoading
- PFanFlowFrac is the fan power input modifier function of air flow fraction
- RecircFracDesign is the recirculation fraction at design condition ($^{\circ}\text{C}$)
- RecircfLoadTAir is the recirculation fraction modifier function of TAirSupply and SchCPU-Loading
- UPSEffDesign is the design electric power supply efficiency
- UPSEffPLR is the electric power supply efficiency function of part load ratio
- UPSLossFracToZone is the fraction of electric power supply losses to zone

17.1.4.2 Variable Definitions – Simulation Inputs:

- TAirIn is the air inlet temperature at current conditions ($^{\circ}\text{C}$)
- TAirSupply is the supply air node temperature at current conditions ($^{\circ}\text{C}$)
- TZone is the zone air temperature at current conditions ($^{\circ}\text{C}$)
- TRoomAirNodeIn is the room air model inlet node air temperature at current conditions ($^{\circ}\text{C}$)
- RhoAir is the air density (kg/m^3)
- CpAir is the air specific heat ($\text{J}/\text{kg}\cdot\text{K}$)

17.1.4.3 Variable Definitions – Intermediate Calculations:

- PCPUDesign is the design CPU power input when fully loaded and entering air temperature is at the user-specified design inlet temperature (W)
- PFanDesign is the design fan power input when fully loaded and entering air temperature is at the user-specified design inlet temperature (W)
- UPSPLR is the electric power supply part load ratio (can be greater than 1.0)

17.1.4.4 Variable Definitions – Outputs:

- PCPU is the CPU power input (W)
- PFan is the fan power input (W)
- PUPS is the electric power supply net power input (W)
- TAirOut is the air outlet temperature ($^{\circ}\text{C}$)
- VAir is the air volume flow rate (m^3/s)
- FlowFrac is the air volume flow rate fraction of design flow rate
- RecircFrac is the recirculation fraction
- QAir is the air cooling rate (W)
- QUPS is the electric power supply heat loss rate to zone (W)
- QConv is the convective heat gain rate to zone heat balance (W)
- SHI is the supply heat index
- SHIZone is the zone average supply heat index

17.1.4.5 Calculations

The design power input is first split into portions for the CPU (everything in the equipment except the cooling fans) and the fan(s).

$$PCPU_{Design} = P_{Design} * (1 - PFanFrac_{Design}) \quad (17.7)$$

$$PFan_{Design} = P_{Design} * PFanFrac_{Design} \quad (17.8)$$

For each time step, the air inlet and outlet temperature is calculated depending on the type of air flow calculation method. Considering data centers are different from normal well-mixed zones due to the uneven air distribution, two methods are implemented to calculate the IT inlet temperature and zone return air temperature, **FlowFromSystem** and **FlowControlWithApproachTemperatures**. Specifically, the IT inlet temperature differs from AHU supply air temperature, and the actual AHU return air temperature differs from the regular return air temperature when the zone is well mixed.

When using **FlowFromSystem**, the zone is assumed to be well-mixed. The air inlet temperature is calculated depending on the type of air node connection.

TAirIn:

- If Air Node Connection Type = AdjustedSupply

$$RecircFrac = RecircFrac_{Design} * RecircfLoadTAir(SchCPULoading, TAirSupply) \quad (17.9)$$

$$TAirIn = TAirSupply * (1 - RecircFrac) + TAirZone * RecircFrac \quad (17.10)$$

- If Air Node Connection Type = ZoneAirNode

$$TAirIn = TAirZone \quad (17.11)$$

- If Air Node Connection Type = RoomAirModel

$$TAirIn = TRoomAirNodeIn \quad (17.12)$$

Using the air inlet temperature, the CPU power consumption, air flow rate, fan power consumption, and power supply power consumption are calculated.

$$PCPU = PCPU_{Design} * SchDesignLevel * PfLoadTAir(SchCPULoading, TAirIn) \quad (17.13)$$

$$FlowFrac = VAirfLoadTAir(SchCPULoading, TAirIn) \quad (17.14)$$

$$VAir = VAir_{Design} * FlowFrac \quad (17.15)$$

$$PFan = PFan_{Design} * SchDesignLevel * PFanfFlowFrac(FlowFrac) \quad (17.16)$$

$$UPSPLR = (PCPU + PFan) / (PCPU_{Design} + PFan_{Design}) \quad (17.17)$$

$$PUPS = (PCPU + PFan) * (1 - UPSEffficDesign * UPSEffficPLR(UPSPLR)) \quad (17.18)$$

The convective heat gain to the zone and the air outlet temperature are then calculated. The user specified fraction of power supply losses are always added to the general zone heat balance convective heat gain. For air node connection types `AdjustedSupply` and `ZoneAirNode`, the CPU and fan power consumption are also added to the zone convective heat gain. For air connection type `RoomAirModel`, the gains from the CPU and fan power consumption are added to the outlet room air model node.

$$Q_{Air} = P_{CPU} + P_{Fan} \quad (17.19)$$

$$Q_{UPS} = P_{UPS} * UPS_{LossFracToZone} \quad (17.20)$$

Q_{Conv} :

- If Air Node Connection Type = `AdjustedSupply` OR `ZoneAirNode`

$$Q_{Conv} = Q_{Air} + Q_{UPS} \quad (17.21)$$

- If Air Node Connection Type = `RoomAirModel`

$$Q_{Conv} = Q_{UPS} \quad (17.22)$$

$$T_{AirOut} = T_{AirIn} + Q_{Air} / (V_{Air} * \rho_{Air} * C_{pAir}) \quad (17.23)$$

The individual ITE supply heat index is calculated as shown below.

$$SHI = (T_{AirIn} - T_{AirSupply}) / (T_{AirOut} - T_{AirSupply}) \quad (17.24)$$

The zone average ITE supply heat index is weighted by the air flow rate of each ITE object.

$$SHI_{Zone} = \Sigma[V_{Air} * (T_{AirIn} - T_{AirSupply})] / \Sigma[V_{Air} * (T_{AirOut} - T_{AirSupply})] \quad (17.25)$$

If **FlowControlWithApproachTemperatures** is chosen, Two indices are introduced to represent the deviation: (1) Supply approach temperature (δT_{supply}) and (2) Return approach temperature (δT_{return}). The two temperature differences indicate to what degree the air flow management of data centers affects the air distribution, and how much they deviate from the regular well-mixed zone scenario.

$$\delta T_{supply} = T_{in} - T_{supply} \quad (17.26)$$

$$\delta T_{return} = T_{return} - T_{out} \quad (17.27)$$

where:

T_{in} is the IT equipment inlet temperature

T_{supply} is the AHU supply air temperature

T_{return} is the actual AHU return air temperature

T_{out} is the IT equipment outlet temperature.

The two approach temperatures can be calculated by CFD tools for typical IT load levels and air flow management of data centers, or provided by measurement data or lookup tables.

It should be noted that, when **FlowControlWithApproachTemperatures** is chosen,

- The inputs of Air Inlet Connection Type, Design Recirculation Fraction and Recirculation Function of Loading and Supply Temperature Curve Name are ignored.
- For multiple ITE objects defined for one zone, the same calculation method should apply. The return air temperature of this zone would be set as the weighted average return temperature of all ITE objects in this zone.
- Other return air heat gains from window or lights are not allowed.
- Apart from a single VAV terminal unit, other HVAC systems do not apply this method in the ITE zone.

When **FlowControlWithApproachTemperatures** method is applied, during sizing and simulation, as the zone is assumed to be unevenly distributed, the supply air flow rate of the AHU is calculated as:

$$\dot{m}_{sys} = Q_{sys} / (C_{p,air} \cdot (T_{return} - T_{supply})) \quad (17.28)$$

where T_{return} is the weighted return air temperature from all ITE objects in the zone, and T_{supply} is the designed supply air temperature to the ITE objects.

Another modified assumption for this case is, in zones with ITE objects, to make sure the zone heat balance converge, unlike the original thermostat setpoint control logic, the well-mixed zone temperature is not controlled. The actual controlled object is the supply air temperature. So when using this method, the user input of zone cooling setpoint is ignored and the unmet hour for cooling does not apply.

17.1.5 Heat Gain from Baseboard Heat

The input object ZoneBaseboard:OutdoorTemperatureControlled provides a model for an outdoor temperature controlled baseboard heater that adds energy to the zone according a control profile as shown in the following figure. At $T_A = T_2$, the baseboard heat gain is Q_2 . For $T_A > T_2$, there is no heat gain. For $T_A < T_1$, a maximum amount of energy, Q_1 , is added to the zone. There is proportional control between those two temperatures:

$$Q = Q_2 - \frac{(Q_2 - Q_1) \cdot (T_2 - T_A)}{(T_2 - T_1)} \quad (17.29)$$

These temperature and capacity fields can be autosized based upon envelope, infiltration, and ventilation loads. To autosize these fields, users may set a design zone heating temperature that is assumed to be 20°C if blank.

The capacity at low temperature is the maximum capacity of the unit. It includes external envelope conduction load, infiltration load, and ventilation load in a space where the unit serves. The model first finds the lowest outdoor air temperature throughout design days included in the simulation, and determines the conduction load through external envelope as:

$$q_{Cond} = UA (T_{Htg} - T_L) \quad (17.30)$$

where:

q_{Cond} is the conduction load through external envelope (W)

Figure 17.2: Control of Outdoor Temperature Controlled Baseboard Heat

U is the heat transfer coefficient of external wall (W/m²K)

A is the area of external wall (m²)

T_{Htg} is the baseboard zone heating setpoint temperature (°C)

T_L is the low temperature, (°C).

The capacity at the low temperature that is the maximum capacity of the unit is thus expressed as:

$$Cap_{T_L} = q_{Cond} + q_I + q_V \quad (17.31)$$

where:

Cap_{T_L} is the capacity at low temperature (W)

q_I is the design infiltration sensible load (W)

q_V is the design ventilation sensible load (W).

The capacity at the high temperature is then prorated against the reference low and high temperatures as:

$$Cap_{T_H} = Cap_{T_L} \frac{(T_{Htg} - T_H)}{(T_{Htg} - T_L)} \quad (17.32)$$

where:

Cap_{T_H} is capacity at high temperature (W)

T_H is high temperature (°C).

17.1.6 Distribution of Radiant Gains

It is useful to consider the distribution of short wavelength (including visible) radiant energy separate from long wavelength (thermal) radiant energy because many materials have different optical properties at different wavelengths. An extreme example is glass that is opaque to the long wavelengths and transparent to the short. Properties of materials vary across the entire spectrum of wavelengths. In EnergyPlus, all radiant interactions are represented in terms of only two wavelengths: “short” and “long”. Short wavelength refers to the distribution given by a ~6000K black body source such as the sun. Long wavelengths refer to radiation from ~300K sources such as walls or people. There is negligible overlap between these two distributions. Some sources, such as lights, must be considered as emitting both long and short wavelength radiation in proportions that approximate their actual effects on room surfaces.

Long wavelength radiation from all internal sources, such as people, lights and equipment, is combined and then distributed over surfaces. (see Internal Long-Wave Radiation Exchange).

Some fraction of the beam solar radiation transmitted into the zone is directly absorbed by the interior surfaces according to the solar distribution algorithm (see Solar Distribution) selected by the user. The beam radiation not directly absorbed, plus the diffuse sky and ground-reflected radiation, plus the short wavelength radiation from lights are combined and distributed over the surfaces of the zone according to:

$$QSI_i = QS_n \cdot \alpha_i / \sum_{i=1}^{NS} S_i \cdot (1 - \rho_i) \quad (17.33)$$

If all surfaces in the room are opaque, the radiation is distributed in proportion to the area*absorptance product of each surface. For surfaces which are transparent,

$$\rho_i = 1 - \alpha_i - \tau_i \quad (17.34)$$

That fraction of radiation represented by τ_i is lost from the zone.

The transmittance and absorptance of transparent surfaces (windows or glass doors) are calculated as in section Window Calculation Module based on the optical properties of the window material layers. The total absorptance of the window is computed for the interior shading device, the inside surface, and the outside surface for diffuse solar radiation incident from outside the zone. Those absorptances are used for short wavelength radiation incident from inside the zone. In most cases, this should not cause significant error. When movable insulation covers the window, the radiation that would have been transmitted is absorbed at the outer surface of the window (thermally equal to the inside surface of the insulation).

17.2 Indoor Swimming Pool

The modeling of the indoor swimming pool is integrated into the surface heat balance procedures already in EnergyPlus with special modifications for radiation between the pool water surface and the surrounding of the space, convection to the surrounding air, evaporation of water, conduction to the pool bottom, and solar radiation absorbed in the pool water, the pool heating system, the presence of a cover, etc. Effectively, the pool water mass is “added” to or lumped into the inside face of the surface to which the pool is “linked”. Conduction through the floor uses the standard CTF formulation, however the heat balance is modified to include other terms specific to the pool water.

Some assumptions of the model are given below, followed by more details of individual components of the model.

- The pool water is lumped together at the inside face of a surface and follows the standard EnergyPlus heat balance methodology with some modifications based on the pool model details described in this section.
- The pool itself must reference a surface that is specifically defined as a floor and it covers the entire floor to which it is linked.
- The pool cannot be part of a low temperature radiant system (meaning that the construction of the floor cannot have any embedded pipes for heating or cooling). In addition, the floor/pool cannot be defined with any movable insulation or be defined as a ventilated slab.
- The pool/floor surface must use the standard CTF solution algorithm.
- The pool may be covered and the fraction covered is defined by user input. This value may vary from 0.0 to 1.0.

- The pool cover has an impact on evaporation, convection, short-wavelength radiation, and long-wavelength radiation. Each of these has a separate user input that reduces the heat transfer parameter from the maximum achieved with a cover. While the cover percentage is allowed to vary via a user schedule input, each individual parameter for these four heat transfer modes is a fixed constant. For evaporation and convection, the factors simply reduce the amount of heat transfer proportionally. For the radiation terms, the factors reduce the amount of radiation that impacts the surface (pool) directly. The remaining radiation is assumed to be convected off of the pool cover to the zone air.
- Pool water heating is achieved by defining the pool as a component on the demand side of a plant loop.
- Makeup water replaces any evaporation of water from the pool surface and the user has control over the temperature of the makeup water.
- The pool is controlled to a particular temperature defined by user input.
- Evaporation of water from the pool is added to the zone moisture balance and affects the zone humidity ratio.
- The pool depth is small in comparison to its surface area. Thus, heat transfer through the pool walls is neglected. This is in keeping with the standard assumption of one-dimensional heat transfer through surfaces in EnergyPlus.

17.2.1 Energy Balance of Indoor Swimming Pool

Heat losses from indoor swimming pools occur by a variety of mechanisms. Sensible heat transfer by convection, latent heat loss associated with evaporation, and net radiative heat exchange with the surrounding occur at the pool surface. Conductive heat losses take place through the bottom of the pool. Other heat gains/losses are associated with the pool water heating system, the replacement of evaporated water with makeup water. The energy balance of the indoor swimming pool estimates the heat gains/losses occurring due to:

- convection from the pool water surface
- evaporation from the pool water surface
- radiation from the pool water surface
- conduction to bottom of pool
- fresh pool water supply
- pool water heating by the plant
- changes in the pool water temperature

Detailed methods for estimating these heat losses and gains of the indoor swimming pools are described in the subsections below.

17.2.2 Convection from the pool water surface

The convection between the pool water and the zone are defined using:

$$Q_{conv} = h \cdot A \cdot (T_p - T_a) \quad (17.35)$$

$$h = 0.22 \cdot (T_p - T_a)^{1/3} \quad (17.36)$$

where:

Q_{conv} is the convective heat transfer rate (W/m²)

h is the convection heat transfer coefficient (W/m²-°C)

T_p is the pool water temperature (°C)

T_a is the air temperature over pool (°C).

When a cover is present, the cover and the cover convection factor reduce the heat transfer coefficient proportionally. For example, if the pool is half covered and the pool cover reduces convection by 50%, the convective heat transfer coefficient is reduced by 25% from the value calculated using the above equation.

17.2.3 Evaporation from the pool water surface

There are 5 main variables used to calculate the evaporation rate (Q_{evap}). Note that the units of the equation below are IP units, but this equation is used with conversion factors internally in the EnergyPlus code.

- Pool water surface area
- Pool water temperature
- Room air temperature
- Room air relative humidity
- Pool water agitation and Activity Factor

$$\dot{m}_{evap} = 0.1 \cdot A \cdot AF \cdot (P_w - P_{dp}) \quad (17.37)$$

where:

\dot{m}_{evap} is the evaporation rate of pool water (lb/h)

A is the surface area of pool water (ft²)

AF is the activity factor

P_w is the saturation vapor pressure at surface of pool water (in. Hg)

P_{dp} is the partial vapor pressure at room air dew point (in. Hg).

Table 17.1: Typical Activity Factor (AF)

Type of Pool	Activity Factor (AF)
Recreational	0.5
Physical Therapy	0.65
Competition	0.65
Diving	0.65
Elderly Swimmers	0.5
Hotel	0.8
Whirlpool, Spa	1.0
Condominium	0.65
Fitness Club	0.65

Type of Pool	Activity Factor (AF)
Public, Schools	1.0
Wave Pool, Water Slides	1.5 – 2.0

When a cover is present, the cover and the cover evaporation factor reduce the amount of evaporation proportionally. For example, if the pool is half covered and the pool cover reduces convection by 50%, the convective heat transfer coefficient is reduced by 25% from the value calculated using the above equation. The value is converted to a latent gain (loss) through multiplication of the evaporation rate by the heat of vaporization of water.

The user should be aware of two key assumptions built into the equations for calculating the evaporation from the pool. First, when the activity factor is zero, no evaporation will take place. Thus, activity factor is not the same thing as occupancy and should not be zero when there are no people in the pool as that will completely eliminate evaporation. Second, when the cover evaporation factor is zero, the cover will not reduce evaporation at all. A cover factor of 1.0 means that the cover will completely block evaporation.

17.2.4 Radiation exchange with the pool water surface

This uses the EnergyPlus internal short- and long-wavelength radiation balances already in place. When a cover is present, it acts to reduce the amount of radiation that arrives at the pool water surface in comparison to the no cover case. Any reduction in either type of radiation is accounted for by adding a convective gain/loss to the zone air. So, in effect, the cover absorbs some radiation and then convects it to the zone air.

17.2.5 Conduction through the bottom of the pool

The model ignores 2-d effects of pool walls and assume that pool depth is much less than the pool area. Conduction is calculated using the Conduction Transfer Function (CTF) equation with the outside temperature determined by the outside heat balance and the inside surface temperature calculated using the pool water heat balance that is lumped together with the inside surface heat balance.

17.2.6 Makeup pool water supply

$$Q_{fw} = \dot{m}_{fw} \cdot cw \cdot (T_p - T_{fw}) \quad (17.38)$$

where:

\dot{m}_{fw} is the mass flow rate of fresh water (kg/s)

c_w is the specific heat of water (J/kg-°C)

T_p is the pool water temperature (°C)

T_{fw} is the fresh water supply temperature (°C).

17.2.7 Heat Gain from People

The input for the swimming pool requires that the user enter the maximum number of people in the pool, a schedule modifying the maximum number of people for different pool occupancies,

and a heat gain per person schedule for differing activities. These three parameters allow for the calculation of a total heat gain from people during a given time. It is assumed that all of the heat gain from people is via convection to the pool water.

17.2.8 Heat from auxiliary pool heater

$$Q_{fw} = \dot{m}_{hw} \cdot c_w \cdot (T_p - T_{hw}) \quad (17.39)$$

where:

\dot{m}_{hw} = Mass flow rate (kg/s)

c_w = Specific heat of water (J/kg-°C)

T_p = Pool water temperature (°C)

T_{hw} = Heated water supply temperature (°C).

17.2.9 Pool Heating to Control the Pool Water Temperature

The equation used to determine the flow rate request of hot water from the plant is an extremely simplified version of the pool heat balance. This is because the mass of the pool is so much larger than any of the other heat flows. As a result, for the sake of establishing a heated water flow rate, the following equation is used:

$$\frac{m_w c_p}{\Delta t} (T_{set} - T_{old}) = \dot{m}_p \cdot c_p \cdot (T_{in} - T_{set}) \quad (17.40)$$

where:

m_w is the mass of pool water (kg)

c_p is the specific heat of water (J/kg-°C)

Δt is the time step length (s)

T_{set} is the desired pool water temperature (°C)

T_{old} is the temperature of water at the last time step (°C)

\dot{m}_p is the needed mass flow rate of water from the plant (kg/s)

T_{in} is the inlet water temperature from the plant (°C).

This equation is rearranged to solve for the needed mass flow rate of water from the plant since all of the other terms are known or given based on user input. This establishes a flow request to the plant and is capped at the maximum value defined in input by the user.

17.2.10 Pool/Surface Heat Balance Equation Summary

The following equation is the basis for the pool/surface heat balance. As has been mentioned previously, the pool water is “merged” with the inside surface heat balance which is essentially the same thing as lumping the entire water of the pool in the inside surface heat balance.

$$\frac{m_w \cdot c_p}{\Delta t} (T_{set} - T_{old}) = Q_{cond} + Q_{conv} + Q_{lwrad} + Q_{swrad} + Q_{damp} + Q_{muw} + Q_{heater} + Q_{evap} \quad (17.41)$$

where:

$\frac{m_w \cdot c_p}{\Delta t} (T_{set} - T_{old})$ is the change in energy stored in the pool water

Q_{cond} is the net conduction to/from the pool water to the floor

Q_{conv} is the net convection between the pool water and the zone air

Q_{lwrad} is the net long-wavelength radiation between the pool water/floor and the surrounding surfaces as well as from internal heat gains

Q_{swrad} is the net short-wavelength radiation to the pool water/floor from solar and internal heat gains

Q_{damp} is the standard damping term used in the inside heat balance to avoid large swings in the radiation balance that sometimes cause instability in the solution (see the standard heat balance information for more details)

Q_{muw} is the net gain/loss from replacing water evaporated from the pool with makeup water

Q_{heater} is the net heat added to the pool via the plant loop (controlled to maintain a setpoint temperature as described above)

Q_{evap} is the net heat loss due to evaporation of pool water to the zone air.

Details on each of these terms was either provided in previous parts of this section or in the standard EnergyPlus heat balance discussion elsewhere in the Engineering Reference.

17.2.11 Other additional information

The following subsections are some useful information that those wishing to model a swimming pool in EnergyPlus might find helpful. Further information can be found on-line or in reputable sources such as the ASHRAE Handbooks.

17.2.12 Swimming Pool Flow Rate

The flow rate of the circulating pump is designed to turn over (circulate) the entire volume of water in the pool in 6 to 8 hours, or 3 or 4 times in 24 hours. About 1 or 2 percent of the pumped circulation rate should be provided as continuous makeup water demand to overcome losses from evaporation, bleed-off, and spillage. To fill the pool initially, a separate quick-fill line should be provided to do the job in 8 to 16 hours; however, filling is usually done at off-peak hours. Thus, the demand flow rate need not be considered in the system demand calculations, unless it out-weighs the demand of all other demands even during the off-peak hours.

17.2.13 Comfort and Health

Indoor pools are normally maintained between 50 and 60% RH for two reasons:

- Swimmers leaving the water feel chilly at lower relative humidity due to evaporation off the body
- It is considerably more expensive (and unnecessary) to maintain 40% RH instead of 50% RH

17.2.14 Air Delivery Rates (Indoor Pool)

Most codes require a minimum of 6 ACH, except where mechanical cooling is used. This rate may prove inadequate for some occupancy and use. Where mechanical dehumidification is provided, air delivery rates should be established to maintain appropriate conditions of temperature and humidity. The following rates are typically desired:

- Pools with no spectator areas, 4 ~ 6 ACH

- Spectator areas, 6 ~ 8 ACH
- Therapeutic pools, 4 ~ 6 ACH

Table 17.2: Typical Swimming Pool Design Conditions

Type of Pool	Air Temperature (°C)	Water Temperature (°C)
Recreational	24-30	24-30
Physical Therapy	26-30	30-32
Competition	26-29	24-28
Diving	27-29	27-32
Elderly Swimmers	29-32	29-32
Hotel	28-29	28-30
Whirlpool / Spa	27-29	36-40

17.3 Pipes

17.3.1 Heat Transfer Pipes (Objects: Pipe:Indoor & Pipe:Outdoor)

17.3.1.1 Heat Loss and Time Delay in Pipes

The effects of heat loss and time delay in plant loop pipes exposed to air (Pipe:Indoor and Pipe:Outdoor) can be modeled explicitly in EnergyPlus. Users can select the environment with which the pipe transfers heat. Currently users have three options: ‘OutdoorAir’, ‘Zone’ and ‘Schedule’. Simulation for each of the environments is similar except the way in which the heat transfer between the pipe outer wall and the surrounding environment is calculated. When using the ‘OutdoorAir’ option, the current outdoor dry-bulb temperature and wind velocity from the weather file (or design day input) are used. When the environment is specified as ‘Zone’, the mean air temperature and room air velocity of the corresponding zone are used.

In the case of a pipe in a zone, the heat loss or gain is accounted for in the pipe heat transfer calculation and is also included in the zone air heat balance calculations. When the environment is specified as ‘Schedule’, the user specifies a temperature and velocity schedule which will be used to calculate the heat transfer.

Pipe heat transfer in EnergyPlus is simulated by discretizing the pipe length into a number of nodes (20) and is an implementation of the model by Hanby et al. (2002). A control volume drawn around a node in the pipe is shown in Figure 17.3. Three nodes are defined at each discrete section of the pipe and represent the fluid, pipe wall and external environment. The fluid and pipe have defined thermal capacitance (mass). The insulation around the pipe is currently modeled as steady-state (no thermal mass), and so the effect of this resistance is accounted for within the h_f term in the following description. For the fluid, there is one-dimensional flow from each upstream node.

Figure 17.3: Control Volume drawn around node *i*

The model is formulated from the heat balances on the fluid and wall nodes.

$$M_{f,i} C_{P,f} \frac{dT_{f,i}}{dt} = \dot{m} C_{P,f} (T_{f,i-1} - T_{f,i}) - h_f A_i (T_{f,i} - T_{w,i}) \quad (17.42)$$

$$M_{w,i} C_{P,w} \frac{dT_{w,i}}{dt} = h_f A_i (T_{f,i} - T_{w,i}) - h_e A_i (T_{w,i} - T_e) \quad (17.43)$$

where subscripts w , f and e denote the values for pipe wall, fluid and environment, respectively. The current node is represented by a subscript of i , while the previous node is represented by $i-1$. In the previous two equations, the terms are defined by:

M is the mass

C_p is the specific heat

\dot{m} is the mass flow rate of fluid in pipe

T is the Temperature

A is the heat transfer area

h is the film convective resistance

t is time.

The exterior film convective resistance is calculated based on either wind speed, room air velocity, or a scheduled value based on the type of pipe heat transfer object. However, when the velocity gets too low, natural convection must be modeled. This is handled within the program by having a lower limit on the Nusselt number. For natural convection from a horizontal cylinder, a constant Nusselt number is assumed based on information from Spang (referenced below). This Nusselt number is 0.36. The Nusselt number used in calculating the exterior convection coefficient (Incropera and Dewitt 1996) is the maximum of the Nusselt number from the forced convection coefficient correlation and this natural convection Nusselt number (0.36).

In addition, the exterior resistance from the pipe wall inner surface to the environment will include resistance values for the pipe wall itself and any insulation specified around the pipe. This is treated as steady state value, so the simulation results are not affected by a change in insulation specific heat. However, the resistance is calculated based on thermal conductivity and thickness (using radial coordinate system), so the simulation results will vary with material conductivity changes. Again, this resistance is added in series with the exterior surface film convective resistance such that h_f contains film and insulation resistance.

Approximating the derivatives using backward differencing enables these equations to be represented as simultaneous algebraic equations. For the fluid, at time step n , the heat balance is:

$$\frac{M_{f,i}C_{P,f}}{\Delta t} (T_{f,i}^n - T_{f,i}^{n-1}) = \dot{m}C_{P,f} (T_{f,i-1}^n - T_{f,i}^n) - h_f A_i (T_{f,i}^n - T_{w,i}^n) \quad (17.44)$$

Rearranging gives:

$$T_{f,i}^n [M_{f,i}C_{P,f} + \dot{m}C_{P,f}\Delta t + h_f A_i \Delta t] = \dot{m}C_{P,f}\Delta t T_{f,i-1}^n + h_f A_i \Delta t T_{w,i}^n + M_{f,i}C_{P,f}T_{f,i}^{n-1} \quad (17.45)$$

or:

$$a_1 T_{f,i}^n = a_2 T_{f,i-1}^n + a_3 T_{w,i}^n + a_4 T_{f,i}^{n-1} \quad (17.46)$$

where:

$$\begin{aligned} a_1 &= M_{f,i}C_{P,f} + \dot{m}C_{P,f}\Delta t + h_f A_i \Delta t \\ a_2 &= \dot{m}C_{P,f}\Delta t \\ a_3 &= h_f A_i \Delta t \\ a_4 &= M_{f,i}C_{P,f} \end{aligned} \quad (17.47)$$

Similarly, taking backwards differences for the conduit wall at time step n , the heat balance becomes:

$$\frac{M_{w,i}C_{P,w}}{\Delta t} (T_{w,i}^n - T_{w,i}^{n-1}) = h_f A_i (T_{f,i}^n - T_{w,i}^n) - h_e A_i (T_{w,i}^n - T_e^n) \quad (17.48)$$

Rearranging gives:

$$T_{w,i}^n [M_{w,i}C_{P,w} + h_f A_i \Delta t + h_e A_i \Delta t] = h_f A_i \Delta t T_{f,i}^n + h_e A_i \Delta t T_e^n + M_{w,i}C_{P,w}T_{w,i}^{n-1} \quad (17.49)$$

or:

$$b_1 T_{w,i}^n = b_2 T_{f,i}^n + b_3 T_{e,i}^n + b_4 T_{w,i}^{n-1} \quad (17.50)$$

where:

$$\begin{aligned} b_1 &= M_{w,i} C_{p,w} + h_f A_i \Delta t + h_e A_i \Delta t \\ b_2 &= h_f A_i \Delta t \\ b_3 &= h_e A_o \Delta t \\ b_4 &= M_{w,i} C_{p,w} \end{aligned} \quad (17.51)$$

Substituting Equation 17.50 into Equation 17.46 gives an equation for the current fluid temperature:

$$a_1 T_{f,i}^n = a_2 T_{f,i-1}^n + a_3 (b_2 T_{f,i}^n + b_3 T_{e,i}^n + b_4 T_{w,i}^{n-1}) / b_1 + a_4 T_{f,i}^{n-1} \quad (17.52)$$

$$T_{f,i}^n = \frac{1}{(a_1 - a_3 b_2 / b_1)} [a_2 T_{f,i-1}^n + a_3 (b_3 T_{e,i}^n + b_4 T_{w,i}^{n-1}) / b_1 + a_4 T_{f,i}^{n-1}] \quad (17.53)$$

The conduit is simulated by solving Equation 17.53 followed by Equation 17.46 for each of the twenty cells in the model and incrementing the time step. The fluid temperature of the last node is taken to be the pipe outlet temperature.

17.3.2 Underground Pipe (Object: Pipe:Underground)

17.3.2.1 Description of Model

The buried pipe model in EnergyPlus is similar to the other pipe heat transfer objects (i.e., Pipe:Indoor and Pipe:Outdoor) except for the way in which the pipe boundary condition is developed. For a buried pipe the ground between the pipe and the surface must be modeled. For a shallow buried pipe, the GroundHeatExchanger:Surface object may be used, which uses modified conduction transfer functions to model the ground. However, beyond a certain thickness, the transfer function method fails, and EnergyPlus will respond with a fatal error due to convergence problems. Therefore, when a pipe is buried deeper than about one meter, this new buried pipe model should be used. When the pipe is buried shallower than one meter, either model may be used. Due to the finite difference nature of the Pipe:Underground model, the GroundHeatExchanger:Surface may be slightly faster and therefore more desirable.

The buried model develops a grid around the pipe. The grid was based originally on a model by Piechowski (1999), and still carries the model nomenclature. The grid extends from the ground surface down to a calculated distance below the pipe. The domain extends sideways from the symmetric center of the pipe to a calculated distance from the pipe. The grid stretches along the

full length of the pipe. At each cross section, transient 2D Cartesian finite difference equations are used, updating each node except the node centered on the pipe. Axial heat transfer is not modeled in the soil. The large view of the outer Cartesian grid system is shown in Figure 17.4.

Figure 17.4: Pipe:Underground Outer Finite Difference Grid

When the model encounters the pipe node, the existing model for Pipe:Interior and Pipe:Exterior pipes is used. The finite difference temperatures neighboring the pipe, grid spacing and soil properties are used to create an average boundary temperature for the pipe along with a conductance value. With a boundary temperature available and a conductance value mimicking the convection coefficient, the simulation continues exactly as with the other pipe heat transfer objects. To avoid redundancy, see the Pipe:Indoor or Pipe:Outdoor objects for a detailed description of the pipe model.

17.3.2.2 Boundary Conditions

The boundary conditions for this model include a symmetric vertical boundary centered on the pipe, the ground surface, a 'far-field', and a 'deep ground'. The ground surface boundary uses current simulation outdoor dry-bulb temperature, and the user-entered convection coefficient. The 'far-field' and 'deep ground' temperatures come from the "undisturbed" ground temperature object specified in the input.

Currently, the model is set up to be exposed to open soil above the pipe. If the user intends on simulating this buried pipe under a foundation slab, the effects can be approximating by use of the basement/slab heat transfer preprocessor program. This program takes in general building information, and performs a simulation which generates ground temperatures. Typically these effects are used to generate boundary conditions for the floor zone, but they may also be used in generating the ground surface temperatures for this pipe model. The data from the slab program will be monthly temperatures, so the user can use these as a surface ground temperature object which provides boundary data to the Pipe:Underground model.

17.3.2.3 Geometry

The model develops the pipe depth and ground thickness from the user-entered construction information. The soil, pipe wall, and optional pipe insulation are entered as materials (with inherent thicknesses). The soil is entered as a standalone material, while the pipe insulation (if applicable) and the pipe wall should be given as a construction containing one or two materials. With knowledge of each individual thickness, the pipe geometry is obtained. The pipe length and inside diameter are the only additional geometry inputs.

17.3.2.4 Model Assumptions

- Constant properties throughout domain
- Moisture is not directly involved with the model operation, so careful selection of soil thermal conductivity is a priority
- Negligible axial heat transfer compared to radial heat transfer
- Axisymmetric heat transfer in near pipe region
- Surface convection coefficient is constant throughout simulation (does not vary with wind speed)

17.3.3 PipingSystem:Underground Simulation

In order to simulate diverse underground piping systems, a generalized model has been implemented which allows placement of pipes in a solid medium (soil). The model simulates circuiting effects of multiple pipes by allowing fluid to flow in the pipes in different directions. The model also has the capability of simulating interaction with zone surfaces to account for things such as basement heat transfer in a foundation heat exchanger. Different aspects of the modelling approach are described in this section which can assist the user in determining if this model is appropriate for a particular application, and determining input parameter values.

An alternative interface is implemented which provides a simpler set of inputs for simulating horizontal trench heat exchangers. The key limitations of the simpler inputs include all piping in the domain being on a single circuit, all trenches equidistance apart, and each trench with the same burial depth. If this is satisfactory for an application, the `GroundHeatExchanger:HorizontalTrench` object is a suitable object. The object uses the same underlying simulation algorithms and data structures as the detailed piping system model, but with a simpler set of input parameters. For other cases and more detailed studies, the `PipingSystem:Underground:*` objects provide full flexibility.

A dual-coordinate system finite volume heat transfer model of pipes buried in a conducting medium is employed. The dual-coordinate system consists of a coarse Cartesian system in the conducting region (the soil, for example) with a refined radial system in the near-pipe region. The pipes

are connected as objects on the plant loop and are simulated as needed during loop convergence, while the ground itself is only simulated once per system time step.

17.3.3.1 Approach:

17.3.3.2 General Development and Solution Scheme

A new heat transfer model is implemented to handle a diverse set of buried pipe conditions. The model uses a dual-coordinate system approach to solve a finite volume domain in a computationally efficient manner. The main idea behind the dual coordinate system technique is to focus the computational effort to the region where it is most needed: near the pipe(s). To this end, a coarse grid Cartesian coordinate system is used to solve the slow-moving ground heat transfer. Then, within one of these cells, a radial coordinate system is configured around the pipe/insulation with a specialized interface cell between the systems. Figure 17.5 shows an example of cells surrounding a pipe, including the radial region in the near-pipe cell, while Figure 17.6 shows a zoomed-in view of the near-pipe cell itself.

The ground heat transfer model can be set up in a fully-3D or quasi-3D manner. In either case, there is a three-dimensional grid of Cartesian cells placed in the domain. In fully-3D mode, the axial heat transfer is accounted for; in quasi-3D mode, the axial effects are ignored and the result is essentially a set of 2D slices along the length of the domain. The determination of which method will be utilized in the final model shall be based upon final testing and on a balance between accuracy vs. computation time. This option could be left to the end-user, but this will likely be unnecessary input overhead.

A fully implicit (and thus numerically stable) formulation is used to describe all cells, which means an iteration loop must be implemented. In this solver, an outer iteration loop is used to bring the entire domain to convergence, while an inner iteration loop is used over all the radial cells. This is intended to focus the computational effort even further. The outer region may converge within one or two iterations, while the “near-pipe” cells may take much more iteration. For this reason, it does not make sense to iterate over the entire domain a large number of times.

17.3.3.3 Boundary Conditions

The farfield boundary condition is defined by a Kusuda and Achenbach (1965) correlation, which requires annual ground surface temperature data. As with the current Pipe:Underground model, the user will be able to enter the correlation parameters directly, or information from the monthly ground temperature input object will be used to infer the parameters.

The ground surface boundary condition is defined by an energy balance between the surrounding interior cells and the ground surface, including convection and radiation. As with the Pipe:Underground object, the ground surface sun exposure may be an optional input to allow for a shaded ground surface. In addition to the standard conduction, convection, and both short- and long-wave solar radiation at the surface, the ground surface boundary condition also includes the effects of evapotranspiration in the surface vegetation—the heat loss due to evaporation from soil to plant surface, and transpiration internal to the plant itself. The evapotranspiration rate is calculated as a moisture loss by using the Walter et al. (2005) model, and translated into a heat loss by multiplication with the density and latent heat of evaporation of water. The evapotranspiration rate is dependent on the type of vegetation at the surface; the user can vary the surface vegetation from anywhere between a concrete surface and a fairly tall grass (about 7”).

Figure 17.5: Radial "near-pipe" cell within a Cartesian cell

Figure 17.6: Close-up view of example radial cell

Based on the application, an adiabatic boundary condition will also be implemented and employed on particular surfaces of the domain. For the case where a basement or under-slab region is present, for example, an adiabatic boundary will represent the vertical line of symmetry.

17.3.3.4 “Pipe Cell” Simulation

The ground is discretized into coarse Cartesian cells, some of which will contain a pipe. These “pipe-cells” are further discretized into a radial system with a specialized interface cell to couple these systems. The radial cells consist of a number of ground cells, with an optional insulation cell, then the pipe cell, followed by the fluid itself.

The fluid is modeled as a cylindrical cell interacting with incoming fluid and heat transfer to the pipe. When there is no flow in the system, the cell essentially becomes radially adiabatic so that the fluid temperature will float during off periods. It will not be equal to ground temperatures, unless it is off for a long time and the transient heat is allowed to dissipate. When there is flow in the system, the incoming fluid and heat transfer from the pipe wall balance with the mass of the cell to come up with a new fluid temperature for that cell, to be passed downstream to the next cell.

The fluid within the cells is modeled directionally, so that the flow can be circuited through multiple pipe segments in different directions. The flow direction in each pipe is specified by a choice field input.

17.3.3.5 Basement Interaction

The model can also interact with basement surfaces. The interaction is split into two sections: floor surfaces and wall surfaces. For each of these, the analysis is lumped, i.e., all walls are treated as one average wall surface and all floors are treated as one average floor surface. The distance that the basement impinges within the domain is defined by a simple width and height specification. The domain is then *cutaway* for that region. Note that these distances then refer to the exterior surface of the wall or floor.

The ground heat transfer model does not perform any transient simulation of the basement surfaces. The transient condition through these surfaces are left to the appropriate surface heat balance algorithms. Instead, this model interacts directly at the outer boundary through the use of an *OtherSideConditions* model. The ground heat transfer model will take the current exterior surface heat flux and use that as the boundary for neighboring cells. Once convergence is achieved, the ground model will then effectively apply a constant surface temperature boundary condition by using a very high value of convection coefficient. The surface heat balance algorithms will then pick this up during the next zone time step.

17.3.3.6 Mesh Development

The mesh is developed by using a few simple parameters. There are two distinct categories, the large-scale Cartesian mesh and the near-pipe refined radial mesh.

- X, Y, Z mesh
 - Mesh Layout
 - Cell density

- Radial mesh
 - Radial mesh thickness
 - Cell count

The Cartesian mesh uses a cell density parameter to define the number of cells to use in the simulation. Instead of requiring a detailed specification of all cell regions in the domain, this one parameter is used to specify a mesh density and is applied to all domain regions. The cell density parameter represents the number of cells within any two domain partitions. A domain partition is a basement wall or a pipe placed in the domain. Once these partitions are all laid out and validated, the regions between them are populated with the number of cells specified in the cell density parameter. Although this may lead to a variation of cell size within the domain, it is assumed that this will help focus computational intensity in the domain. Of course, the number of cells (cell density parameter) can be different for each of the X, Y, and Z directions to allow for further fine tuning of the domain.

The Cartesian mesh is laid out in either a uniform or symmetric-geometric fashion. In the former, the cells between any two domain partitions are equally sized. In the latter, the cells are smaller near the partitions to again help fine-tuning computational intensity. If the latter is selected, the amount of non-uniformity is specified by an additional parameter.

The radial coordinate system is always uniform for the soil cells. The two parameters to be specified for this region are the cell count (the number of soil cells to be generated outside of the pipe cell), and the radial mesh thickness (the radial distance from pipe outer wall to the cell boundary). Each soil cell will then have a radial thickness equal to the radial mesh thickness divided by the cell count.

17.3.3.7 Simulation Methodology

The actual simulation of this model is performed in two parts: the ground simulation and the pipe cell simulation.

Since the ground is likely to be slow-moving and easily converging, it is simulated once per system time step. This will simulate all the cells in the domain which do not contain a pipe segment. The boundary conditions for this step are then the current surface conditions and farfield model along with the previous values for pipe cell temperature. This small lag should provide suitable accuracy as the system time step will usually be smaller than the time constant of the pipe cell. This decoupling leverages the core of the model development by again placing computational effort where it is needed most, near the pipes.

The ground simulation is performed once per time step, but the pipe cell simulation is performed at each call to the component. Each pipe will be placed on a plant loop, but not necessarily on the same plant loop or loop side. Thus, at each call to the object, that pipe will use the temperatures of the ground cells near the pipe as boundary conditions to simulate the “near-pipe” radial cells and fluid cell. In this manner, the pipes will simulate numerous times following the convergence flow of the plant loop system.

17.4 Pumps

The water pump is quite simply the component that drives the flow in plant and condenser loops. How it reacts depends on several different conditions. In total, there are three different decision variables, two of which are defined by user input. These three deciding factors are whether the pump is constant or variable speed, whether the pump operation is continuous or intermittent, and whether or not there is a load on the loop. The pump is simulated first on the supply side loop after the demand side loop has determined what the demand on the loop will be. For further reference look at sections Pump Control for Plant and Condenser Loops, Plant/Condenser Supply Side, and Plant/Condenser Demand Side in the Plant Flow Resolver of this document.

17.4.1 Summary of Pump Rules

- Pumps in Plant Loop can be on the supply side or demand side
- A Pump, if present, in the demand side of plant loop must be the first component of the inlet branch.
- Pumps in Condenser loop must be on supply side
- Pumps can operate as constant or variable flow.
- Pumps can run continuously or intermittently.
- Single boiler/chiller with NO bypass, use Pump:ConstantSpeed
 - Boiler/chiller should be constant flow
 - Pump should be intermittent
- Single boiler/chiller with NO bypass, Pump:VariableSpeed
 - Boiler/chiller should be variable flow, regardless of whether pump is intermittent or continuous (runs at the minimum if demand is less than minimum, this includes zero.)
- Single boiler/chiller with bypass, Pump:ConstantSpeed
 - Boiler/chiller can be constant or variable flow
 - Pump may be intermittent or continuous as long as the bypass can handle the entire pump volume when the boiler is not operating

Multiple branches add more complexity, but it is nothing more than continuity. If the pump is putting out flow then it has to have a branch to flow down whether it is a chiller or a bypass. It can be safer to add the bypass for a simulation. If the active machines require the flow the bypass will

be dry. If performing a pressure simulation, and the flow goes through a machine which is off, the pressure drop will be accounted for, but no heat transfer through the machine will be calculated.

If the user designates a pump that is operating continuously, the pump will run regardless of whether or not there is a load. This may have the net effect of adding heat to the loop if no equipment is turned on. If the pump operates intermittently, the pump will run at its capacity if a load is sensed and will shut off if there is no load on the loop. If the pump is scheduled, the schedule modifies the Rated Volumetric Flow Rate of the pump on a time basis. The default is that the pump is ON and runs according to its other operational requirements.

Shown below is pseudo code for the calculation of the total efficiency of the pump and the actual pumping efficiency when the motor efficiency is accounted for either variable or constant volume pumps.

```
! Total Efficiency % = Rated Volume Flow Rate * Rated Pump Head / Rated Power Use
TotalEffic = PumpEquip(PumpNum)%NomVolFlowRate * &
              PumpEquip(PumpNum)%NomPumpHead / &
              PumpEquip(PumpNum)%NomPowerUse
! Calculated Pump Efficiency % = Total Efficiency % / Motor Efficiency %
PumpEquip(PumpNum)%PumpEffic = TotalEffic /
              PumpEquip(PumpNum)%MotorEffic
```

17.4.2 Dynamic Pump Pressure Head

There is an option when performing plant/condenser loop simulations to account for dynamically changing loop pressure drop. For the current implementation, the loop pressure drop is calculated based on pressure drop data on each branch of the loop, then this total pressure drop is set as the pump pressure head. There is no pump curve implemented yet, so it is assumed that the pump can always handle this pressure value. This is a first approximation to actually having the pump ride a curve, and this initial implementation allows the user to enter minimal data, and yet get a more dynamic output for pump power, which is calculated based on current pressure drop and flow rate. The equation for pump power is now:

$$\text{Pump Electric Power} = \text{Pump Volume Flow Rate} * \frac{\text{Pump Head}}{\text{Total Efficiency}} \quad (17.54)$$

Without the pressure simulation, the pump power is based on the rated value entered with the pump object. For further information, see the input-output reference for Branch objects, and PlantLoop/CondenserLoop objects; as well as the Plant/Condenser loop section of this engineering reference.

17.4.3 Variable Speed Pump

A variable speed pump (object name: Pump:VariableSpeed) is defined with maximum and minimum flow rates that are the physical limits of the device. The pump will operate and select a flow somewhere between the minimum and maximum limits. In the case where the pump is running, the pump will try to meet the flow request made by demand side components.

All of the pump rules and efficiency and power calculations are applicable from the introduction in the pump group section. The main difference between the the variable volume pump and the

constant volume pump is the Part Load Performance Curve. The fraction of full load power is determined by the cubic equation:

$$\text{FractionFullLoadPower} = C_1 + C_2 \text{PLR} + C_3 \text{PLR}^2 + C_4 \text{PLR}^3 \quad (17.55)$$

where C_1, C_2, C_3 , and C_4 are Coefficients 1 – 4 and PLR is the Part Load Ratio. In the pseudo code below, the `FracFullLoadPower` modifies the `NomPowerUse` for the total pump “Power” and shows the “ShaftPower” and the “PumpHeattoFluid”.

```
VolFlowRate = PumpMassFlowRate / LoopDensity
PartLoadRatio = VolFlowRate / PumpEquip(PumpNum)%NomVolFlowRate
FracFullLoadPower = PumpEquip(PumpNum)%PartLoadCoef(1) &
                    + PumpEquip(PumpNum)%PartLoadCoef(2) * PartLoadRatio &
                    + PumpEquip(PumpNum)%PartLoadCoef(3) * PartLoadRatio**2 &
                    + PumpEquip(PumpNum)%PartLoadCoef(4) * PartLoadRatio**3
Power = FracFullLoadPower * PumpEquip(PumpNum)%NomPowerUse
ShaftPower = Power * PumpEquip(PumpNum)%MotorEffic
! This adds the pump heat based on User input for the pump
! We assume that all of the heat ends up in the fluid eventually since this is a closed loop
! PumpHeattoFluid = ShaftPower*(1-PumpEquip(PumpNum)%PumpEffic)
PumpHeattoFluid = ShaftPower + (Power - ShaftPower) &
                  *PumpEquip(PumpNum)%FracMotorLossToFluid
Node(OutletNode)%Temp = Node(InletNode)%Temp &
                      + PumpHeattoFluid/(PumpMassFlowRate * LoopCp)
PumpEquip(PumpNum)%Power = Power
```

17.4.4 Pressure-based Flow for Variable Speed Pumps

With the introduction of pressure simulations in plant loops, the variable speed pump object now has the capability to model a more realistic variable speed operation. There are two operation modes which are introduced: differential pressure control is a widely used VFD control method while most VFDs also have a manual control mode in which the user determines the input frequency of the electric motor. The mode can be selected as ‘ManualControl’ or ‘PressureSetpointControl’ in the VFD Control Type input in Pump:VariableSpeed objects.

In manual VFD control mode the specified schedule will determine the current pump rotational speed throughout the simulation. This RPM value will be used to scale the pump curve which is entered by the user in non-dimensional form. Once the pump curve has been fixed then the successive substitution method will use this curve with the system curve to resolve the operating point. VFD manual control mode is implemented in EnergyPlus with the use of the RPM schedule input.

Differential pressure based control will maintain the differential pressure within the specified range. The pressure drop corresponding to the mass flow request will be calculated using the effective pressure constant of the system. This pressure drop will be checked against the pressure set point range. If the pressure drop is within the user specified range, then the mass flow rate will be checked against mass flow rates of operating points corresponding to maximum and minimum rotational speeds. Maximum and minimum differential pressure and rotational speeds are schedule inputs and can be entered as constant schedule.

The allowable mass flow rate range for the Differential pressure control is explained in the Figure 17.7.

Figure 17.7: Allowable mass flow rate range for the Differential pressure control

17.4.5 Constant Speed Pump

The operation of a constant speed pump (object name: Pump:ConstantSpeed) is fairly straightforward. The user designates a maximum flow rate and when this pump operates it will run at that capacity. The main difference between the constant speed pump and the variable speed pump is that the fraction of full load power is always = 1. In the pseudo code below, the `FracFullLoadPower` is = 1.0, therefore the Power is always the full power.

```
VolFlowRate = PumpMassFlowRate / LoopDensity
PartLoadRatio = VolFlowRate / PumpEquip(PumpNum)%NomVolFlowRate
FracFullLoadPower = 1.0
Power = FracFullLoadPower * PumpEquip(PumpNum)%NomPowerUse
ShaftPower = Power * PumpEquip(PumpNum)%MotorEffic
```

```

! This adds the pump heat based on User input for the pump
! We assume that all of the heat ends up in the fluid eventually since this is a closed loop
! PumpHeatToFluid = ShaftPower*(1-PumpEquip(PumpNum)%PumpEffic) &
PumpHeatToFluid = ShaftPower + (Power - ShaftPower) &
                    * PumpEquip(PumpNum)%FracMotorLossToFluid
Node(OutletNode)%Temp = Node(InletNode)%Temp &
                    + PumpHeatToFluid/(PumpMassFlowRate * LoopCp)
PumpEquip(PumpNum)%Power = Power

```

17.4.6 Pressure-based Flow for Constant Speed Pumps

The constant speed pump can flow can also be overridden dynamically based on a response to the plant loop pressure drop. In “single-loop-pump” simulations (no branch pumps, no common pipe), the user can enter a dimensionless pump curve on the Pump:ConstantSpeed (see I/O ref) object which represents the single speed pressure-flow relationship of the pump. In the process of determining the operating flow rate for the pump, the pump will check to see if a valid pressure simulation is being performed. If it is, a flow will be prescribed based on a resolution between system pressure characteristics and the pump pressure curve. This will cause the pump flow to be “unpredictable,” meaning that it will not always be a constant, expected value, which is basically what the constant speed pump gives you without the pressure simulation. There is more detail on the pressure based simulation in the Plant/Condenser loop sections of this documentation.

17.4.7 Pump Heat Addition to the Loop

Due to the fact that a pump is a mechanical device that acts on the fluid it is circulating, it causes the fluid to increase in temperature. The EnergyPlus model assumes that all pressure increase caused by the pump will eventually be lost due to friction, and that friction will be added as heat to the fluid. Since the plant and condenser loops are not yet true pressure-based models, EnergyPlus assumes that all of the heat resulting from the pump itself and from friction throughout the loop. Therefore, as of version 7, the pump heat is added to the plant loop interface by injecting the heat into the mixed tanks used to model loop thermal capacitance (previously it was added at the outlet node of the pump). The amount of heat added to the fluid is calculated using the following two equations:

$$ShaftPower = PumpPower * PumpMotorEfficiency \quad (17.56)$$

$$PumpHeatToFluid = ShaftPower + (PumpPower - ShaftPower) * FracMotorLossToFluid \quad (17.57)$$

where the pump motor efficiency is defined by the user input and the FracMotorLossToFluid is the amount of heat generated by the pump motor that is added to the fluid loop (as opposed to being lost to the environment where the pump is located). FracMotorLossToFluid is also a user input.

Note that the shaft power relates to the increase in head through the pump. Since all of this head is lost through the piping network due to frictional heat, this represents a heat gain by the fluid throughout the network. For simplicity, this heat is added along with the heat resulting from

the pump motor. The difference between the pump power and the shaft power is the inefficiency of the pump—or the amount of energy input into the pump that the motor converts to heat rather than mechanical energy. Some of this heat is added to the fluid being pumped. These two terms are shown in the PumpHeatToFluid equation shown above. Since EnergyPlus Version 7, this heat is added to the loop capacitance tank(s) rather than at the pump's outlet and so the outlet temperature is equal to the inlet temperature.

17.4.8 Pump Heat Addition to Surrounding Zone

If the user input includes naming a Zone that surrounds the pump, then the pump becomes a source of internal heat gain to that zone. The amount of heat transmitted to the surrounding zone is simply the difference between power input and the rate of heat transferred to the fluid. The user can also input a fraction, f_{rad} , that controls the overall split between thermal radiation and sensible convection. The pump's sensible zone gains are determined using the following equations:

$$TotalZoneGain = PumpPower - PumpHeatToFluid \quad (17.58)$$

$$ConvectiveZoneGain = (1 - f_{rad}) * TotalZoneGain \quad (17.59)$$

$$RadiativeZoneGain = f_{rad} * TotalZoneGain \quad (17.60)$$

17.4.9 Headered Pumps

The input objects HeaderedPumps:ConstantSpeed and HeaderedPumps:VariableSpeed provide models for headered pumps that consist of two or more pumps connected in parallel. The headered pump is simulated as a single component, and it is specified as an integer number of a specific pump. The flow rate provided by the headered pump is determined by the number of pumps in operation and the flow rate of the individual pump. The total flow rate is calculated as

$$FlowProvided = NumPumpsON * IndividualPumpFlowRate \quad (17.61)$$

The simulation starts by turning ON all pumps in the group. The pumps are then turned OFF one at a time until the flow provided is less than the flow requested. Finally the last pump is turned back ON to meet the remaining flow (FlowDifference) requested. The flow rate of the last pump depends on the pump bank type. For constant speed headered pumps, the last pump runs at the nominal flow rate, thereby giving a final headered pump flow which is equal to or greater than the flow requested. In a variable speed headered pump the last pump runs at part load so that the flow provided matches the flow requested. The power of the headered pump is then calculated as

$$Power = (PR_{FL} * N_{FL} + PR_{PL} * N_{PL}) * P_{Nom} \quad (17.62)$$

where:

$Power$ is the power consumed by the pump bank

PR_{FL} is the power ratio at full load (generally equal to 1)

N_{FL} is the number of pumps running at full load

PR_{PL} is the power ratio at part load

N_{PL} is the number of pumps running at part load

P_{Nom} is the nominal power consumption of individual pumps.

For a constant speed headered pump, N_{PL} is zero. For a variable speed headered pump, N_{PL} is equal to one.

17.4.10 Condensate Pumps

The input object Pump:VariableSpeed:Condensate provides a model for steam condensate pumps, see the discussion for steam loops, reference: Condensate Pump.

17.5 Ideal Loads Air System

17.5.1 Overview

The input object ZoneHVAC:IdealLoadsAirSystem provides a model for an ideal HVAC system. It occupies a place in the program hierarchy corresponding to a zone HVAC unit. It is not connected to a central air system – instead each ZoneHVAC:IdealLoadsAirSystem object supplies cooling or heating air to a zone in sufficient quantity to meet the zone load or up to its limits, if specified. The ideal loads air system(s) may be optionally connected to a return plenum. The supply air conditions are controlled based on specifications in the ZoneHVAC:IdealLoadsAirSystem input. The system has options for humidity control, outdoor air, economizer, demand controlled ventilation, and heat recovery.

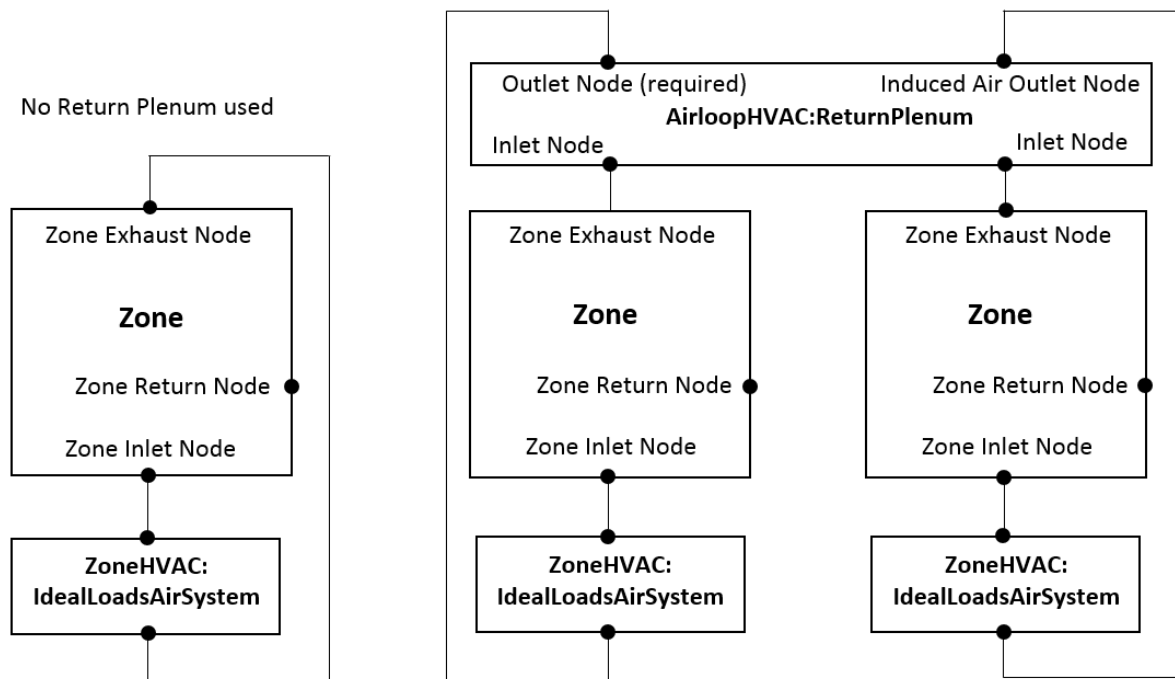

Figure 17.8: Ideal Loads Air System with and without plenum

17.5.2 Model

The ZoneHVAC:IdealLoadsAirSystem object is modeled as an ideal VAV terminal unit with variable supply temperature and humidity. The supply air flow rate is varied between zero and the maximum in order to satisfy the zone heating or cooling load, zone humidity controls, outdoor air requirements, and other constraints, if specified.

17.5.2.1 Inputs and Data

The user specifies some or all of the following data for each ZoneHVAC:IdealLoadsAirSystem object:

- name of unit availability schedule
- name of the zone inlet node
- name of the zone exhaust node
- name of the system inlet node (if plenum is used)
- maximum supply air temperature when in heating mode $T_{max,heating}$ (°C)
- minimum supply air temperature when in cooling mode $T_{min,cooling}$ (°C)
- maximum supply air humidity ratio when in heating mode $W_{max,humid}$ (kg water/kg dry air)
- minimum supply air humidity ratio when in cooling mode $W_{min,dehum}$ (kg water/kg dry air)
- heating limit type flag (*LimitFlowRate*, *LimitCapacity*, *LimitFlowRateAndCapacity* or *No-Limit*) *HeatingLimit*
- maximum heating air flow rate (m³/s)
- maximum sensible heating capacity (W)
- cooling limit type flag (*LimitFlowRate*, *LimitCapacity*, *LimitFlowRateAndCapacity* or *No-Limit*) *CoolingLimit*
- maximum cooling air flow rate (m³/s)
- maximum total cooling capacity (W)
- name of heating availability schedule
- name of cooling availability schedule
- dehumidification control type flag (*ConstantSensibleHeatRatio*, *Humidistat*, *None*, or *ConstantSupplyHumidityRatio*) *DehumidCtrlType*
- cooling sensible heat ratio
- humidification control type flag (*Humidistat*, *None*, or *ConstantSupplyHumidityRatio*) *HumidCtrlType*

- name of a DesignSpecification:OutdoorAir object
- outdoor air inlet node name
- demand controlled ventilation control type flag (*None*, *OccupancySchedule* or *CO2Setpoint*)
- outdoor air economizer type flag (*NoEconomizer*, *DifferentialDryBulb*, or *DifferentialEnthalpy*)
- heat recovery type flag (*None*, *Sensible*, or *Enthalpy*)
- sensible heat recovery effectiveness
- latent heat recovery effectiveness

All input data for the ZoneHVAC:IdealLoadsAirSystem is stored in the array PurchAir. The model and data are encapsulated in the module PurchasedAirManager.

- Set the unit on/off flag *UnitOn*. The unit is off (*UnitOn = False*) if the unit availability schedule value is ≤ 0 ; otherwise the unit is on (*UnitOn = True*). If the unit is on, the calculation proceeds through the remaining steps. If the unit is off, the zone inlet node conditions are set to the zone node condition, the inlet node mass flow rate is set to zero, and the unit outputs are set to zero.
- Calculate the minimum outdoor air mass flow rate based on the specifications in the DesignSpecification:OutdoorAir object, if specified.
- Calculate the sensible and latent impact of the outdoor air flow relative to the zone conditions
- Determine if the unit needs to heat or cool
 - If outdoor air sensible impact is \geq load to zone cooling setpoint and the current thermostat type is not SingleHeatingSetPoint, then unit is in cooling mode
 - If outdoor air sensible impact is $<$ load to zone heating setpoint then unit is in heating mode
 - Else if neither condition is true, then unit is in deadband mode (provides outdoor air but shuts off economizer and heat recovery and all humidity control options except *Humidistat* option)
- If in cooling mode, simulate outdoor air economizer and adjust outdoor air mass flow rate
- Calculate supply air mass flow rate
 - If outdoor air flow rate exceeds applicable maximum flow rate (heating or cooling) then reduce outdoor air mass flow rate, issue warning, and set supply air mass flow rate equal to outdoor air mass flow rate

Else

- Calculate supply air mass flow rate required to meet zone sensible load at the applicable (heating or cooling) supply temperature limit ($T_{max,heating}$ or $T_{min,cooling}$)

$$\dot{m}_s = \dot{Q}_z / (c_{p,air} \cdot (T_s - T_z)) \quad (17.63)$$

- If *DehumidCtrlType* = Humidistat (and other conditions are met, see below), then calculate the supply air mass flow rate required to meet the humidistat dehumidification setpoint at $W_{min,dehum}$
- If *HumidCtrlType* = Humidistat (and other conditions are met, see below), then calculate the supply air mass flow rate required to meet the humidistat humidification setpoint at $W_{max,humid}$
- Set the supply air mass flow rate to the greatest of these, but limit to the applicable (heating or cooling) maximum flow rate
- Calculate the mixed air conditions, modeling heat recovery, if applicable
 - The recirculation air conditions are set equal to the zone return air node conditions; if there is no return air node the recirculation air conditions are set equal to the conditions at the zone node.
 - The unit entering conditions are then:
If $\dot{m}_s > \dot{m}_{oa}$, then:

$$h_{ma} = (\dot{m}_{oa} \cdot h_{oa} + (\dot{m}_s - \dot{m}_{oa}) \cdot h_{recirc}) / \dot{m}_s \quad (17.64)$$

$$W_{ma} = (\dot{m}_{oa} \cdot W_{oa} + (\dot{m}_s - \dot{m}_{oa}) \cdot W_{recirc}) / \dot{m}_s \quad (17.65)$$

$$T_{ma} = \text{PsyHFnTdbW}(h_{ma}, W_{ma}) \quad (17.66)$$

Otherwise the entering air conditions are set equal to the outside air conditions.

- Calculate the supply air temperature required to meet the zone sensible load at the supply air mass flow rate, but limit to the applicable (heating or cooling) supply temperature limit ($T_{max,heating}$ or $T_{min,cooling}$)

$$T_s = T_z + \dot{Q}_z / (c_{p,air} \cdot \dot{m}_s) \quad (17.67)$$

- Calculate the supply humidity ratio based on the specified humidity control types, but limit to the applicable (heating or cooling) supply humidity ratio limit
 - *DehumidCtrlType* = None sets the supply air humidity ratio equal to the mixed air humidity ratio.
 - *DehumidCtrlType* = Humidistat, this will actively dehumidify to the humidistat dehumidification setpoint during cooling and deadband operation, and during heating operation if *HumidCtrlType* = Humidistat

- *DehumidCtrlType = ConstantSensibleHeatRatio* sets the supply air humidity ratio using the cooling sensible heat ratio.
 - *DehumidCtrlType = ConstantSupplyHumidityRatio* sets the supply air humidity ratio = $W_{min,dehum}$.
 - *HumidCtrlType = None* sets the supply air humidity ratio equal to the mixed air humidity ratio.
 - *HumidCtrlType = Humidistat*, this will actively humidify to the humidistat humidifying setpoint during heating and deadband operation, and during cooling operation if *DehumidCtrlType = Humidistat*
 - *HumidCtrlType = ConstantSupplyHumidityRatio* sets the supply air humidity ratio = $W_{max,humid}$.
- Limit supply humidity ratio to saturation at the supply temperature
 - Check the applicable capacity limits (sensible heating and total cooling) and adjust supply air temperature and humidity if needed.
 - Set the zone inlet node conditions to the supply air mass flow rate, temperature, and humidity ratio.
 - Calculate the unit output and load components.
 - If a zone return plenum is used, after all ideal loads systems that are connected to the plenum are simulated, simulate the return plenum.

17.6 District Cooling

When the user is not interested in a plant simulation or there is some centralized source of chilled water, the following model can be used in the input. This allows the user to achieve a simulation without specifying operating parameters or curve fits for chiller models. This model only needs the connections to the loop and the nominal capacity to simulate. See the InputOutput Reference for additional information (Object: DistrictCooling). This model calculates the output capacity necessary from the inlet temperature to the setpoint temperature for that loop with the given mass flow rate in Watts.

17.7 District Heating

When the user is not interested in a plant simulation or there is some centralized source of hot water, the following model can be used in the input. This allows the user to achieve a simulation without specifying operating parameters or curve fits for boiler models. This model only needs the connections to the loop and the nominal capacity to simulate. See the InputOutput Reference for additional information (Object: DistrictHeating). This model calculates the output capacity necessary from the inlet temperature to the setpoint temperature for that loop with the given mass flow rate in Watts.

17.8 CentralHeatPumpSystem

17.8.1 Overview

The CentralHeatPumpSystem object simulates the performance of a central heat pump system containing one or more chiller-heater objects. The main function of the object is to call relevant calculation methods for the chiller-heater objects depending on their operating modes, and to calculate temperatures at the outlet nodes and the total energy transfer. The object can be connected to plant loops and a source loop (see Input-Output Reference document), and the node connections are solely dependent on individual chiller-heaters' operating modes. The central system receives water flows from each plant and source loop and then distributes them to individual chiller-heaters as requested. The conditioned water flows leaving the chiller-heaters are then returned to the system, and in turn flow back to the plant loops and source loop to produce heating and cooling, or exchange heat with the source loop.

17.8.2 Model Description

The model first determines operating modes based on the cooling and heating loads on the system, and then decides which calculation algorithm is called. It calls the cooling calculation subroutine when cooling load is demanded, the heating calculation subroutine when heating load is demanded, and both cooling and heating calculation subroutines when both cooling and heating loads are demanded, i.e., simultaneous cooling-heating mode. It then calculates mass-weighted temperatures and heat transfer energy. Six different operating modes (0 through 5) are possible:

- 0: off
- 1: cooling-only mode
- 2: heating-only mode
- 3: heat recovery mode
- 4: cooling dominant simultaneous cooling-heating mode
- 5: heating dominant simultaneous cooling-heating mode.

The model reads different node information over the operating mode so that outlet water conditions at each node of the system can be appropriately determined.

In cooling-only mode (mode 1), the system is connected to the chilled water loop and source loop. It thus reads the evaporator outlet temperatures and mass flow rates of the chiller-heaters to calculate a mass-weighted chilled water temperature at the system outlet node, and the condenser outlet temperatures and mass flow rates of the chiller-heaters to calculate a mass-weighted source water temperature at the system outlet node. In heating-only mode (mode 2), the system is connected to the hot water loop and source loop. It thus reads the condenser temperatures and mass flow rates of the chiller-heaters to calculate a mass-weighted hot water temperature at the system outlet node, and the evaporator temperatures and mass flow rates of the chiller-heaters to calculate a mass-weighted source temperature at the system outlet node.

In simultaneous cooling-heating mode, three different operating modes (mode 3 through 5) are possible. The model checks which simultaneous cooling-heating mode (3, 4, or 5) each chiller-heater is in, and calculates relevant mass-weighted temperatures. The system may be connected to three loops such as chilled water loop, hot water loop, and source water loop in mode 4 or mode 5.

In heat recovery mode, both evaporator temperatures and condenser temperatures are read and a mass-weighted temperature for both chilled water and hot water is calculated. The chiller-heaters

in mode 3 do not exchange heat with source water. At least one of the chiller-heaters within the system is in heat recovery mode during simultaneous cooling-heating mode. The system may be only connected to both chilled water loop and hot water loop if all operating chiller-heaters are in heat recovery mode.

The following nomenclature is used in the equations for this model shown below:

$\dot{m}_{cw,bypass}$ is the chilled water bypass mass flow rate in the system (kg/s)

$\dot{m}_{hw,bypass}$ is the hot water bypass mass flow rate in the system (kg/s)

$\dot{m}_{src,bypass}$ is the source water bypass mass flow rate in the system (kg/s)

$\dot{m}_{cw,CH}$ is the chilled water mass flow rate of i^{th} chiller-heater's evaporator [kg/s]

$\dot{m}_{hw,CH}$ is the hot water mass flow rate of i^{th} chiller-heater's condenser (kg/s)

$\dot{m}_{src,CH}$ is the source water mass flow rate of i^{th} chiller-heater, which varies with operating modes (kg/s)

$\dot{m}_{cw,sys}$ is the chilled water mass flow rate of the system (kg/s)

$\dot{m}_{hw,sys}$ is the hot water mass flow rate of the system (kg/s)

$\dot{m}_{src,sys}$ is the source water mass flow rate of the system (kg/s)

$T_{cw,sys}$ is the chilled water outlet temperature of the system (°C)

$T_{hw,sys}$ is the hot water outlet temperature of the system (°C)

$T_{src,sys}$ is the source water outlet temperature of the system (°C)

$T_{cw,bypass}$ is the mass-weighted bypass chilled water temperature in the system (°C)

$T_{hw,bypass}$ is the mass-weighted bypass hot water temperature in the system (°C)

$T_{src,bypass}$ is the mass-weighted bypass source water temperature in the system (°C)

$T_{cw,CH}$ is the mass-weighted chilled water outlet temperature from chiller-heaters (°C)

$T_{hw,CH}$ is the mass-weighted hot water outlet temperature from chiller-heaters (°C)

$T_{src,CH}$ is the mass-weighted source water outlet temperature from chiller-heaters (°C)

$T_{cw,i}$ is the chilled water inlet temperature of the system (°C)

$T_{hw,i}$ is the hot water inlet temperature of the system (°C)

$T_{src,i}$ is the source water inlet temperature of the system (°C)

$T_{cw,out}$ is the chilled water outlet temperature of i^{th} chiller-heater (°C)

$T_{hw,out}$ is the hot water outlet temperature of i^{th} chiller-heater (°C)

$T_{src,out}$ is the source water outlet temperature of i^{th} chiller-heater (°C).

The model reads node information and local variables of individual chiller-heaters. The nodes and local variables vary with the operating modes as described above in order to calculate mass-weighted temperatures. In the cooling-only mode, it calculates a mass-weighted chilled water temperature ($T_{cw,CH}$) and a source water temperature ($T_{src,CH}$) as follows:

$$T_{cw,CH} = \sum_{CH=1}^n T_{cw,out} \frac{\dot{m}_{cw,CH}}{\dot{m}_{cw,sys}} \quad (17.68)$$

$$T_{src,CH} = \sum_{CH=1}^n T_{src,out} \frac{\dot{m}_{src,CH}}{\dot{m}_{src,sys}} \quad (17.69)$$

In heating-only mode, it calculates a mass-weighted hot water temperature ($T_{hw,CH}$) and a source water temperature ($T_{src,CH}$) as follows:

$$T_{hw,CH} = \sum_{CH=1}^n T_{hw,out} \frac{\dot{m}_{hw,CH}}{\dot{m}_{hw,sys}} \quad (17.70)$$

$$T_{src,CH} = \sum_{CH=1}^n T_{src,out} \frac{\dot{m}_{src,CH}}{m_{src,sys}} \quad (17.71)$$

When all chiller-heaters are in heat recovery mode, it calculates a mass-weighted chilled water temperature ($T_{cw,CH}$) and hot water temperature ($T_{hw,CH}$) as follows:

$$T_{cw,CH} = \sum_{CH=1}^n T_{cw,out} \frac{\dot{m}_{cw,CH}}{m_{cw,sys}} \quad (17.72)$$

$$T_{hw,CH} = \sum_{CH=1}^n T_{hw,out} \frac{\dot{m}_{hw,CH}}{m_{hw,sys}} \quad (17.73)$$

In cooling or heating dominant simultaneous cooling-heating mode (mode 4 and 5), at least one chiller-heater should be in heat recovery mode, and the other(s) are in either mode 4 or mode 5. The system is connected to three loops such as chilled water loop, hot water loop, and source water loop. The model thus calculates a mass-weighted chilled water temperature ($T_{cw,CH}$), hot water temperature ($T_{hw,CH}$), and source water temperature ($T_{src,CH}$) as follows:

$$T_{cw,CH} = \sum_{CH=1}^n T_{cw,out} \frac{\dot{m}_{cw,CH}}{m_{cw,sys}} \quad (17.74)$$

$$T_{hw,CH} = \sum_{CH=1}^n T_{hw,out} \frac{\dot{m}_{hw,CH}}{m_{hw,sys}} \quad (17.75)$$

$$T_{src,CH} = \sum_{CH=1}^n T_{src,out} \frac{\dot{m}_{src,CH}}{m_{src,sys}} \quad (17.76)$$

The model then calculates a mass-weighted temperature for the by-pass flows remained in the system as follows:

$$T_{cw,bypass} = T_{cw,i} \frac{\dot{m}_{cw,bypass}}{m_{cw,sys}} \quad (17.77)$$

$$T_{hw,bypass} = T_{hw,i} \frac{\dot{m}_{hw,bypass}}{m_{hw,sys}} \quad (17.78)$$

$$T_{src,bypass} = T_{src,i} \frac{\dot{m}_{src,bypass}}{m_{src,sys}} \quad (17.79)$$

The outlet temperatures at each outlet node of the system are then determined as it sums both mass-weighted temperatures up as follows:

$$T_{cw,sys} = T_{cw,CH} + T_{cw,bypass} \quad (17.80)$$

$$T_{hw,sys} = T_{hw,CH} + T_{hw,bypass} \quad (17.81)$$

$$T_{src,sys} = T_{src,CH} + T_{src,bypass} \quad (17.82)$$

The total heat transfer energy of the system is also calculated in the same manner as the temperature calculations. The model simply sums all heat transfer energy of the chiller-heaters depending on their operating modes.

17.9 ChillerHeaterPerformance:Electric:EIR

17.9.1 Overview

The object simulates the performance of a chiller-heater which can receive pre-cooled or pre-heated water from the source loop, and provide cooling, heating, or simultaneous cooling-heating. The object needs to work with the Central Heat Pump System object to be controlled properly. This model does not simulate the thermal performance or the power consumption of associated pumps or cooling towers. The Central Heat Pump System object holds the input/output nodes connection of the chiller-heater and its control scheme, once the chiller-heater is properly referred.

17.9.2 Model Description

The model uses user-input performance information at design conditions along with three performance curves (curve objects) for cooling capacity and efficiency to determine chiller operation at off-design conditions. Three additional performance curves for heating capacity and efficiency are used when the chiller is operating in a heating-only mode or simultaneous cooling-heating mode.

17.9.2.1 Cooling-only mode

The following nomenclature is used in the cooling equations:

$CompMotorEffic$ is the compressor motor efficiency

$CompPower_{clg}$ is the compressor power (W)

$CompPower_{@PLR_{min}}$ is the compressor power at the minimum part-load ratio (W)

$C_{p,cw}$ is the chilled water specific heat (J/kg-K)

$CyclingRatio$ is the compressor cycling ratio which is equal to PLR_{actual} / PLR_{min}

$EvapCapAvail_{clg}$ is the available full-load cooling capacity at current conditions (W)

$EvapCapFT_{clg}$ is the cooling capacity function of temperature curve

$EIRFT_{clg}$ is the electric input to cooling output factor for temperature function curve

$EIRFPLR_{clg}$ is the electric input to cooling output factor for part-load function curve

\dot{m}_{cw} is the chilled water mass flow rate (kg/s)

$\dot{m}_{avail,cw}$ is the chilled water maximum available mass flow rate (kg/s)

PLR_{clg} is the cooling part-load ratio which is equal to $CoolingLoad / EvapCapAvail_{clg}$

PLR_{actual} is the actual part-load ratio at current conditions

PLR_{min} is the minimum part-load ratio

$QCond_{clg}$ is the total condenser heat transfer energy (J)

$\dot{Q}Cond_{clg}$ is the condenser heat transfer rate (W)

$QEvap_{clg}$ is the total evaporator heat transfer energy (J)

$\dot{Q}Evap_{clg}$ is the evaporator heat transfer rate (W)

$Q_{falseloading,clg}$ is the false loading rate (W)

$RefCOP_{clg}$ is the reference coefficient of performance (W/W)

$RefEvapCap_{clg}$ is the reference evaporator capacity (W)

$FullLoadPwr_{clg}$ is the reference full load power which is equal to $EvapCapAvail_{clg} / RefCOP_{clg}$ (W)

T_{cond} is either the entering or the leaving condenser water temperature depending on user input for the condenser water independent variable: $T_{cond,l}$ if “LeavingCondenser” is chosen or $T_{cond,e}$ if “EnteringCondenser” is chosen.

$T_{cond,e}$ is the entering condenser water temperature (°C)

$T_{cond,l}$ is the leaving condenser water temperature (°C)

$T_{cw,e}$ is the entering chilled water temperature (W)

$T_{cw,l}$ is the leaving chilled water temperature (W)

ΔT_{cw} is the chilled water inlet and outlet temperature difference (°C)

$\Delta T_{cw,max}$ is the maximum chilled water inlet and outlet temperature difference (°C).

The model sequentially calls each chiller-heater module in the order defined in the Central Heat Pump System object. It then determines cooling load that each chiller-heater needs to meet and water flow rates delivered to each chiller-heater. Once each chiller-heater is assumed to operate, it determines cooling capacity and efficiency using user-supplied performance information.

Three performance curves are used in the calculation of cooling capacity and efficiency as follows:

1. Cooling mode cooling capacity function of temperature curve ($EvapCapFT_{clg}$)
2. Cooling mode electric input to cooling output ratio function of temperature curve ($EIRFT_{clg}$)
3. Cooling mode electric input to cooling output ratio function of part load ratio curve ($EIRFPLR_{clg}$)

The Cooling Capacity Function of Temperature Curve ($EvapCapFT_{clg}$) represents the fraction of the cooling capacity of the chiller-heater as it varies by temperature. The curve should have a value of 1.0 at the reference conditions. The output of a bi-quadratic curve with the input variables being the leaving chilled water temperature and either the entering or leaving condenser water temperature is given by:

$$EvapCapFT_{clg} = a + bT_{cw,l} + cT_{cw,l}^2 + dT_{Cond} + eT_{Cond}^2 + fT_{cw,l}T_{Cond} \quad (17.83)$$

The Cooling Mode Electric Input to Cooling Output Ratio Function of Temperature ($EIRFT_{clg}$) curve represents the fraction of electricity to the chiller-heater at full load as it varies by temperature. The output of a bi-quadratic curve with the input variables being the leaving chilled water temperature and either the entering or leaving condenser water temperature is given by:

$$EIRFT_{clg} = a + bT_{cw,l} + cT_{cw,l}^2 + dT_{Cond} + eT_{Cond}^2 + fT_{cw,l}T_{Cond} \quad (17.84)$$

The Cooling Mode Electric Input to Cooling Output Ratio Function of Part Load Ratio ($EIRFPLR_{clg}$) curve represents the fraction of electricity to the chiller-heater as the load on the chiller varies at a given set of operating temperatures. The curve is normalized so that at full load the value of the curve should be 1.0. Note that the bi-cubic formulation below is generally only valid when LeavingCondenser variable is chosen for the field of Cooling Mode Condenser Water Temperature Curve Input Variable whereas the quadratic curve can be used for both choices, i.e., LeavingCondenser and EnteringCondenser. Bi-cubic may also be used when the chiller-heater uses a variable-speed compressor motor drive. The output of this curve can be determined by one of the following three performance curves:

$$EIRFPLR_{clg} = a + bT_{Cond,l} + cT_{Cond,l}^2 + dPLR + ePLR^2 + fT_{Cond,l}PLR + g \cdot 0 + hPLR^3 + i \cdot 0 + j \cdot 0 \quad (17.85)$$

$$EIRFPLR_{clg} = a + bPLR + cPLR^2 \quad (17.86)$$

$$EIRFPLR_{clg} = a + bPLR + cPLR^2 + dPLR^3 \quad (17.87)$$

The full-load cooling capacity at specific temperature operating conditions (i.e., at temperatures different from the design temperatures) is then computed as follows:

$$EvapCapAvail_{clg} = RefEvapCap_{clg} \cdot EvapCapFT_{clg} \quad (17.88)$$

The model then determines current chiller-heater's evaporator heat transfer rate based on the total cooling load required a central heat pump system to meet and the maximum available chiller-heater cooling capacity. The maximum evaporator temperature difference between the entering chilled water temperature ($T_{cw,e}$) and the leaving chilled water temperature ($T_{cw,l}$) obtained from the plant loop setpoint temperature can also be determined. It then calculates mass flow rate for variable flow control chiller-heaters and the temperature difference for constant flow control chiller-heaters, setting the cooling load each chiller-heater needs to meet equal to the evaporator heat transfer rate.

As for variable flow control chiller-heaters, the chilled water mass flow rate is computed as follows:

$$\dot{m}_{cw} = \frac{\dot{Q}Evap_{clg}}{C_{p,cw}\Delta T_{cw,max}} \quad (17.89)$$

The chilled water mass flow rate calculated is then compared to the maximum available mass flow rate for individual chiller-heaters. If the calculated one is bigger than the maximum, the model sets the chilled water mass flow rate equal to the maximum. It then adjusts the temperature difference based on the evaporator heat transfer rate and the maximum mass flow rate. If the adjusted temperature difference also exceeds the maximum, the model finally adjusts the evaporator heat transfer rate at the maximum temperature difference and mass flow rate as follows:

$$\dot{Q}Evap_{clg} = \dot{m}_{avail,cw}C_{p,cw}\Delta T_{cw,max} \quad (17.90)$$

As for constant flow control chiller-heaters, the model calculates chilled water temperature difference as follows:

$$\Delta T_{cw} = \frac{\dot{Q}Evap_{clg}}{\dot{m}_{avail,cw}C_{p,cw}} \quad (17.91)$$

The temperature difference calculated is then compared to the maximum temperature difference allowed. If the calculated one is bigger than the maximum, the model sets the chilled water temperature difference equal the maximum, and then adjusts the evaporator heat transfer rate at the given conditions as follows:

$$\dot{Q}Evap_{clg} = \dot{m}_{avail,cw}C_{p,cw}\Delta T_{cw,max} \quad (17.92)$$

The model then calculates the part-load ratio as the ratio of the evaporator heat transfer rate to the available chiller-heater capacity as follows:

$$PLR_{c\lg} = \frac{\dot{Q}Evap_{c\lg}}{\dot{Q}EvapAvail_{c\lg}} \quad (17.93)$$

The part-load ratio calculated is set to be between the maximum of 1.0 and the minimum of 0.0 when it is out of the range. Once the part-load ratio is calculated the cycling ratio and false loading rate can be obtained as follows:

$$CyclingRatio = \frac{PLR_{actual}}{PLR_{min}} \quad (17.94)$$

$$\dot{Q}_{falseloading,c\lg} = EvapCapAvail_{c\lg} \cdot PLR_{c\lg} \cdot CyclingRatio - \dot{Q}Evap_{c\lg} \quad (17.95)$$

The compressor power demand is then computed by:

$$CompPower_{c\lg} = RefFullLoadPower_{c\lg} \cdot EIRFT_{c\lg} \cdot EIRFPLR_{c\lg} \cdot CyclingRatio \quad (17.96)$$

The heat transfer rate for the chiller-heater condenser can then be computed as follows:

$$\dot{Q}Cond_{clg} = ComPower_{clg} \cdot CompMotorEffic + \dot{Q}Evap_{clg} + \dot{Q}_{falseloading,clg} \quad (17.97)$$

The total heat transfer energy by the evaporator and condenser can be calculated as follows:

$$QEvap_{clg} = \dot{Q}Evap_{clg} \cdot TimeStepSys \cdot 3600 \quad (17.98)$$

$$QCond_{c\lg} = \dot{Q}Cond_{c\lg} \cdot TimeStepSys \cdot 3600 \quad (17.99)$$

Water consumption for the evaporative-cooled condenser is calculated using the difference in air humidity level across the evaporative media and the condenser air mass flow rate:

$$V_{water} = \frac{\dot{m}_{air} (\omega_{evapcond,out} - \omega_{evapcond,in})}{\rho_{water}} (PLR) (TimeStepSys) (3600) \quad (17.100)$$

where:

V_{water} is the DX cooling coil evap condenser water consumption (m³)

\dot{m}_{air} is the evaporative condenser air mass flow rate (kg/s)

$\omega_{evapcond,in}$ is the humidity ratio of outdoor air entering the evap condenser (kg/kg)

$\omega_{evapcond,out}$ is the humidity ratio of air leaving the evap condenser (kg/kg)

ρ_{water} is the density of water at the outdoor dry-bulb temperature (kg/m³)

$TimeStepSys$ is the HVAC system simulation time step (hr).

17.9.2.2 Heating-only mode and Simultaneous cooling-heating mode

The following nomenclature is used in the heating equations:

$CompMotorEffic$ is the compressor motor efficiency

$CompPower_{htg}$ is the compressor power demand (W)

$CompPower@PLR_{min}$ is the compressor power at the minimum part-load ratio (W)

$C_{p,evap}$ is the evaporator water specific heat (J/kg-K)

$C_{p,hw}$ is the hot water specific heat (J/kg-K)

$CyclingRatio$ is the compressor cycling ratio which is equal to PLR_{actual} / PLR_{min}

$EvapCapAvail_{htg}$ is the available full-load cooling capacity at current conditions (W)

$EvapCapFT_{htg}$ is the heating mode cooling capacity function of temperature curve

$EIRFT_{htg}$ is the electric input to cooling output factor for temperature function curve

$EIRFPLR_{htg}$ is the electric input to cooling output factor for part-load function curve

$\dot{m}_{avail,evap}$ is the evaporator water maximum available mass flow rate (kg/s)

$\dot{m}_{avail,hw}$ is the condenser water maximum available mass flow rate (kg/s)

\dot{m}_{hw} is the hot water mass flow rate (kg/s)

PLR_{htg} is the cooling part-load ratio which is equal to $RefCap / EvapCapAvail_{htg}$

PLR_{max} is the maximum part-load ratio at current conditions

PLR_{min} is the minimum part-load ratio

$QCond_{htg}$ is the total condenser heat transfer energy (J)

$\dot{Q}CondAvail_{htg}$ is the available full-load heating capacity at current conditions (W)

$\dot{Q}Cond_{htg}$ is the condenser heat transfer rate (W)

$QEvap_{htg}$ is the total evaporator heat transfer energy (J)

$\dot{Q}Evap_{htg}$ is the evaporator heat transfer rate (W)

$\dot{Q}_{falseloading,htg}$ is the false loading rate (W)

$RefCOP_{htg}$ is the reference coefficient of performance (W/W)

$RefEvapCap_{htg}$ is the reference evaporator capacity (W)

$FullLoadPwr_{htg}$ is the reference full load power which is equal to $EvapCapAvail_{htg} / RefCOP_{htg}$ (W)

T_{cond} is either entering or leaving condenser water temperature depending on user input for condenser water independent variable. $T_{cond,l}$ if “LeavingCondenser” is chosen or $T_{cond,e}$ if “EnteringCondenser” is chosen.

$T_{cond,e}$ is the entering condenser water temperature (°C)

$T_{cond,l}$ is the leaving condenser water temperature (°C)

$T_{cw,l}$ is the leaving chilled water temperature (°C)

$T_{hw,e}$ is the entering hot water temperature (°C)

$T_{hw,l}$ is the leaving hot water temperature (°C)

ΔT_{evap} is the evaporator inlet and outlet water temperature difference (°C)

ΔT_{hw} is the hot water inlet and outlet temperature difference (°C)

$\Delta T_{hw,max}$ is the maximum hot water inlet and outlet temperature difference (°C).

The calculations for the evaporator side are similar to the cooling-only mode calculations. The evaporator capacity and efficiency is determined by a different set of three performance curves read in the cooling-only mode, and the performance curve set is used for both heating-only mode and simultaneous cooling-heating mode. During these modes, the evaporator side is not connected to the chilled water loop, but source water loop. The model thus assumes that each chiller-heater does

not meet the plant loop chilled water setpoint temperature while the evaporator operates at the full load capacity to produce heating at a constant water flow rate.

The model sequentially calls each chiller-heater module in the order of the definition in the central heat pump system. It then determines heating load that each chiller-heater needs to meet and water flow rates delivered to each chiller-heater. Once each chiller-heater is assumed to operate, it determines heating capacity and efficiency using the following performance curves:

1. Heating mode cooling capacity function of temperature curve ($EvapCapFT_{htg}$)
2. Heating mode electric input to cooling output ratio function of temperature curve ($EIRFT_{htg}$)
3. Heating mode electric input to cooling output ratio function of part load ratio curve ($EIRFPLR_{htg}$)

The output of a Heating Mode Cooling Capacity Function of Temperature curve with the input variables being the leaving chilled water temperature and either the entering or leaving condenser water temperature is given by:

$$EvapCapFT_{htg} = a + bT_{cw,l} + cT_{cw,l}^2 + dT_{Cond} + eT_{Cond}^2 + fT_{cw,l}T_{Cond} \quad (17.101)$$

The output of a Heating Mode Cooling Output Ratio Function of Temperature curve with the input variables being the leaving chilled water temperature and either the entering or leaving condenser water temperature is given by:

$$EIRFT_{htg} = a + bT_{cw,l} + cT_{cw,l}^2 + dT_{Cond} + eT_{Cond}^2 + fT_{cw,l}T_{Cond} \quad (17.102)$$

The output of Heating Mode Cooling Output Ratio Function of Part Load Ratio curve can be determined by one of the following three performance curves as follows:

$$EIRFPLR_{htg} = a + bT_{Cond,l} + cT_{Cond,l}^2 + dPLR + ePLR^2 + fT_{Cond,l}PLR + g \cdot 0 + hPLR^3 + i \cdot 0 + j \cdot 0 \quad (17.103)$$

$$EIRFPLR_{htg} = a + bPLR + cPLR^2 \quad (17.104)$$

$$EIRFPLR_{htg} = a + bPLR + cPLR^2 + dPLR^3 \quad (17.105)$$

The full-load evaporator capacity at specific temperature operating conditions is then given by:

$$EvapCapAvail_{htg} = RefEvapCap_{htg} \cdot EvapCapFT_{htg} \quad (17.106)$$

The part-load ratio is set to be between zero and the maximum, and the evaporator heat transfer rate is computed by:

$$\dot{Q}Evap_{htg} = EvapCapAvail_{htg}PLR_{htg} \quad (17.107)$$

The evaporator inlet and outlet temperature difference is then given by:

$$\Delta T_{evap} = \frac{\dot{Q}Evap_{htg}}{\dot{m}_{avail,evap}C_{p,evap}} \quad (17.108)$$

Once the part-load ratio is calculated the cycling ratio and false loading rate are computed by:

$$CyclingRatio = \frac{PLR_{actual}}{PLR_{min}} \quad (17.109)$$

$$\dot{Q}_{falseloading,htg} = EvapCapAvail_{htg} \cdot PLR_{htg} \cdot CyclingRatio - \dot{Q}Evap_{htg} \quad (17.110)$$

The compressor power demand is then computed by:

$$CompPower_{htg} = FullLoadPower_{htg} \cdot EIRFT_{htg} \cdot EIRFPLR_{htg} \cdot CyclingRatio \quad (17.111)$$

The heat transfer rate of the chiller-heater condenser is then computed as follows:

$$\dot{Q}CondAvail_{htg} = ComPower_{htg} \cdot CompMotorEffic + \dot{Q}Evap_{htg} + \dot{Q}_{falseloading,htg} \quad (17.112)$$

Once condenser available heating capacity is determined, the model calculates current chiller-heater's condenser heat transfer rate based on the total heating load required a central heat pump system to meet as well as available heating capacity of the chiller-heater. The maximum condenser temperature difference between the entering hot water temperature ($T_{hw,e}$) and the leaving hot water temperature ($T_{hw,l}$) obtained from the plant loop setpoint temperature can also be obtained. It then calculates condenser water mass flow rate for variable flow control chiller-heaters and the hot water temperature difference for constant flow control chiller-heaters, setting the cooling load that each chiller-heater needs to meet equal the evaporator heat transfer rate.

As for variable flow control chiller-heaters, the condenser water mass flow rate is computed as follows:

$$\dot{m}_{hw} = \frac{\dot{Q}Cond_{htg}}{C_{p,hw}\Delta T_{hw,max}} \quad (17.113)$$

The condenser water mass flow rate calculated is then compared to the maximum available mass flow rate for individual chiller-heaters. If the calculated one is bigger than the maximum, the model sets the condenser water mass flow rate equal the maximum. It then adjusts the hot water temperature difference at the maximum mass flow rate. If the adjusted temperature difference also exceeds the maximum, the model finally adjusts the condenser heat transfer rate at the maximum allowable conditions as follows:

$$\dot{Q}Cond_{htg} = \dot{m}_{avail,hw} C_{p,hw} \Delta T_{hw,max} \quad (17.114)$$

As for constant flow control chiller-heaters, the model calculates condenser temperature difference as follows:

$$\Delta T_{hw} = \frac{\dot{Q}Cond_{htg}}{\dot{m}_{avail,hw} C_{p,hw}} \quad (17.115)$$

The temperature difference calculated is then compared to maximum hot water temperature difference. If the calculated one is bigger than the maximum, the model sets the hot water temperature difference equal the maximum, and then adjusts the condenser heat transfer rate at the given conditions as follows:

$$\dot{Q}Cond_{htg} = \dot{m}_{avail,hw} C_{p,hw} \Delta T_{hw,max} \quad (17.116)$$

Finally, the total heat transfer energy by the evaporator and condenser can then be calculated as follows:

$$QEvap_{htg} = \dot{Q}Evap_{htg} \cdot TimeStepSys \cdot 3600 \quad (17.117)$$

$$QCond_{htg} = \dot{Q}Cond_{htg} \cdot TimeStepSys \cdot 3600 \quad (17.118)$$

17.10 Plant Temperature Source Component

This component (Object: PlantComponent:TemperatureSource) is a simple object used to simulate systems with a known supply temperature. This could include a river, well, or other configuration where a known temperature is pumped back into the plant system. This fluid could be isolated from chilled water and other loops by using a heat exchanger connection between the loops.

The temperature of the source of this object can be either constant or scheduled. If scheduled, it could also be actuated by EMS to allow a calculated temperature at run-time.

The logic of this component is quite simple: if there is flow through the component, the outlet temperature is always the source temperature. The component requests flow from the design flow rate, which can be autosized.

18.1 Radiant System Models

18.1.1 Low Temperature Radiant System Model

The input objects ZoneHVAC:LowTemperatureRadiant:ConstantFlow, ZoneHVAC:LowTemperatureRadiant:VariableFlow, and ZoneHVAC:LowTemperatureRadiant:Electric provide models for low temperature radiant heating and cooling systems that appear, on the surface, to be relatively simple systems. The system circulates hot or cold fluid through tubes embedded in a wall, ceiling, or floor or runs current through electric resistance wires embedded in a surface or a panel. Energy is thus either added to or removed from the space, and zone occupants are conditioned by both radiation exchange with the system and convection from the surrounding air that is also affected by the system. Unless specifically required for indoor air quality considerations, fans, ductwork, dampers, etc. are not needed.

Despite the relative simplicity of the low temperature radiant systems, the integration of such a system within an energy analysis program requires one to overcome several challenges. First, for systems with significant thermal mass, the conduction transfer function method for modeling transient conduction must be extended to include embedded heat sources or sinks. Second, one must integrate this formulation within an energy analysis program like EnergyPlus. Finally, one must

overcome the fact that the radiant system is both a zone heat balance element and a conditioning system. Each of these issues will be addressed in the next several subsections.

18.1.1.1 One Dimensional Heat Transfer Through Multilayered Slabs

One of the most important forms of heat transfer in energy analysis is heat conduction through building elements such as walls, floors, and roofs. While some thermally lightweight structures can be approximated by steady state heat conduction, a method that applies to all structures must account for the presence of thermal mass within the building elements. Transient one dimensional heat conduction through a homogeneous layer with constant thermal properties such as the one shown in Figure 18.1 is governed by the following equation:

$$\frac{\partial^2 T}{\partial x^2} = \frac{1}{\alpha} \frac{\partial T}{\partial t} \quad (18.1)$$

where:

T is the temperature as a function of position and time

x is the position

t is the time

α is the thermal diffusivity of the layer material which is equal to $\frac{k}{\rho c_p}$

k is the thermal conductivity

ρ is the density

c_p is the specific heat.

This equation is typically coupled with Fourier's law of conduction that relates the heat flux at any position and time to temperature as follows:

$$q''(x, t) = -k \frac{\partial T(x, t)}{\partial x} \quad (18.2)$$

While analytical solutions exist for the single homogeneous layer shown in Figure 18.1, the solution becomes extremely tedious for the multiple layered slab shown in Figure 18.2.

18.1.1.2 Time Series Solutions: Conduction Transfer Functions

Equations 18.1 and 18.2 can be solved numerically in a variety of ways. As mentioned in the previous section, other models have used control theory and numerical methods such as finite difference and finite element. However, each of these methods have drawbacks which render them inappropriate for use within an energy analysis program which requires both accuracy and efficiency from the simulation.

Another possible modeling method is a time series solution. Several of the detailed energy analysis programs such as EnergyPlus use a time series solution to transient heat conduction. The most basic time series solution is the response factor equation which relates the flux at one surface of an element to an infinite series of temperature histories at both sides as shown by:

$$q''_{i,t} = \sum_{m=1}^{\infty} X_m T_{i,t-m+1} - \sum_{m=1}^{\infty} Y_m T_{o,t-m+1} \quad (18.3)$$

where q'' is heat flux, T is temperature, i signifies the inside of the building element, o signifies the outside of the building element, and t represents the current time step.

Figure 18.1: Single Layered Building Element

Figure 18.2: Multilayered Building Element

While in most cases the terms in the series decay fairly rapidly, the infinite number of terms needed for an exact response factor solution makes it less than desirable. Fortunately, the similarity of higher order terms can be used to replace them with flux history terms. The new solution contains elements that are called conduction transfer functions (CTFs). The basic form of a conduction transfer function solution is shown by the following equation:

$$q''_{i,t} = \sum_{m=1}^M X_m T_{i,t-m+1} - \sum_{m=1}^M Y_m T_{o,t-m+1} + \sum_{m=1}^k F_m q''_{i,t-m} \quad (18.4)$$

where k is the order of the conduction transfer functions, M is a finite number defined by the order of the conduction transfer functions, and X , Y , and F are the conduction transfer functions. This equation states that the heat flux at the interior surface of any generic building element for which the assumption of one dimensional conduction heat transfer is valid is linearly related to the current and some of the previous temperatures at both the interior and exterior surface as well as some of the previous flux values at the interior surface. A similar equation holds for the heat flux at the exterior surface.

The final CTF solution form reveals why it is so elegant and powerful. With a single, relatively simple equation, the conduction heat transfer through an element can be calculated. The coefficients (CTFs) in the equation are constants that only need to be determined once. The only storage of data required is the CTFs themselves and a limited number of temperature and flux terms. The formulation is valid for any surface type and does not require the calculation or storage of element interior temperatures.

As the next several sections will detail, there are two main methods for calculating conduction transfer functions: the Laplace Transform method and the State Space method. Both methods are well suited for the main focus of this research, the extension of conduction transfer functions to

include heat sources or sinks.

18.1.1.3 Laplace Transform Formulation

The traditional method for calculating conduction transfer functions is described in detail by Hittle (1981). Beginning with the transient one dimensional heat conduction equation {Equation 18.1} and Fourier's law of conduction {Equation 18.2}, the Laplace transform method is used to convert the governing equations into the s-domain for a single layer such as the one shown in Figure 18.1.

$$\frac{d^2 T(x, s)}{dx^2} = \frac{s}{\alpha} T(x, s) \quad (18.5)$$

$$q''(x, s) = -k \frac{dT(x, s)}{dx} \quad (18.6)$$

The transformed equations are solved and then put in matrix form as shown below:

$$\begin{bmatrix} T_1(s) \\ q_1(s) \end{bmatrix} = \begin{bmatrix} A_1(s) & B_1(s) \\ C_1(s) & D_1(s) \end{bmatrix} \begin{bmatrix} T_2(s) \\ q_2(s) \end{bmatrix} \quad (18.7)$$

where:

$T_1(s)$, $T_2(s)$, $q_1(s)$, and $q_2(s)$ are the temperature and flux terms in the Laplace domain

$$A_1(s) = \cosh\left(\ell_1 \sqrt{s/\alpha_1}\right) \quad (18.8)$$

$$B_1(s) = \left(1/k_1 \sqrt{s/\alpha_1}\right) \sinh\left(\ell_1 \sqrt{s/\alpha_1}\right) \quad (18.9)$$

$$C_1(s) = k_1 \sqrt{s/\alpha_1} \sinh\left(\ell_1 \sqrt{s/\alpha_1}\right) \quad (18.10)$$

$$D_1(s) = \cosh\left(\ell_1 \sqrt{s/\alpha_1}\right) \quad (18.11)$$

k_1 is the thermal conductivity of the layer

α_1 is the thermal diffusivity of the layer

ℓ_1 is the thickness of the layer.

The 2 x 2 matrix consisting of $A_1(s)$, $B_1(s)$, $C_1(s)$, and $D_1(s)$ is called the transmission matrix and contains all of the thermophysical properties of the layer necessary to calculate transient conduction heat transfer through it. It can easily be shown that a second layer could be characterized in a similar way as:

$$\begin{bmatrix} T_2(s) \\ q_2(s) \end{bmatrix} = \begin{bmatrix} A_2(s) & B_2(s) \\ C_2(s) & D_2(s) \end{bmatrix} \begin{bmatrix} T_3(s) \\ q_3(s) \end{bmatrix} \quad (18.12)$$

where $A_2(s)$, $B_2(s)$, $C_2(s)$, and $D_2(s)$ are calculated using the properties of the second layer. This can be substituted into Equation to provide insight how the extension to multilayered slabs is achieved.

$$\begin{bmatrix} T_1(s) \\ q_1(s) \end{bmatrix} = \begin{bmatrix} A_1(s) & B_1(s) \\ C_1(s) & D_1(s) \end{bmatrix} \begin{bmatrix} A_2(s) & B_2(s) \\ C_2(s) & D_2(s) \end{bmatrix} \begin{bmatrix} T_3(s) \\ q_3(s) \end{bmatrix} \quad (18.13)$$

Thus, for a multilayered element as shown in Figure 18.2, each separate layer has a transmission matrix of $A_i(s)$, $B_i(s)$, $C_i(s)$, and $D_i(s)$ associated with it. The form of the matrix equation for the multilayered element is the same as the equation for a single layer:

$$\begin{bmatrix} T_1(s) \\ q_1(s) \end{bmatrix} = \begin{bmatrix} A(s) & B(s) \\ C(s) & D(s) \end{bmatrix} \begin{bmatrix} T_{n+1}(s) \\ q_{n+1}(s) \end{bmatrix} \quad (18.14)$$

but the transmission matrix is replaced by:

$$\begin{bmatrix} A(s) & B(s) \\ C(s) & D(s) \end{bmatrix} = \begin{bmatrix} A_1(s) & B_1(s) \\ C_1(s) & D_1(s) \end{bmatrix} \begin{bmatrix} A_2(s) & B_2(s) \\ C_2(s) & D_2(s) \end{bmatrix} \cdots \begin{bmatrix} A_n(s) & B_n(s) \\ C_n(s) & D_n(s) \end{bmatrix} \quad (18.15)$$

Equation 18.14 is typically rearranged as follows:

$$\begin{bmatrix} q_1(s) \\ q_{n+1}(s) \end{bmatrix} = \begin{bmatrix} \frac{D(s)}{B(s)} & \frac{-1}{B(s)} \\ \frac{1}{B(s)} & \frac{-A(s)}{B(s)} \end{bmatrix} \begin{bmatrix} T_1(s) \\ T_{n+1}(s) \end{bmatrix} \quad (18.16)$$

which relates the flux at either surface of the element to the temperature histories at both surfaces. When the temperature histories are formulated as triangular pulses made up of simple ramp functions, the roots of this equation can be found and result in response factors. The response factors can be simplified as described above through the introduction of flux history terms to form conduction transfer functions. A simplified method of finding the roots of the Laplace domain equations is described by Hittle and Bishop (1983) and is used by the current version of BLAST.

18.1.1.4 State Space Formulation

Recently, another method of finding conduction transfer functions starting from a state space representation has begun receiving increased attention (Ceylan and Myers 1980; Seem 1987; Ouyang and Haghighat 1991). The basic state space system is defined by the following linear matrix equations:

$$\frac{d[x]}{dt} = [A][x] + [B][u] \quad (18.17)$$

$$[y] = [C][x] + [D][u] \quad (18.18)$$

where x is a vector of state variables, u is a vector of inputs, y is the output vector, t is time, and A , B , C , and D are coefficient matrices. Through the use of matrix algebra, the vector of state variables (x) can be eliminated from the system of equations, and the output vector (y) can be related directly to the input vector (u) and time histories of the input and output vectors.

This formulation can be used to solve the transient heat conduction equation by enforcing a finite difference grid over the various layers in the building element being analyzed. In this case, the state variables are the nodal temperatures, the environmental temperatures (interior and exterior) are the inputs, and the resulting heat fluxes at both surfaces are the outputs. Thus, the state space representation with finite difference variables would take the following form:

$$\frac{d}{dt} \begin{bmatrix} T_1 \\ \vdots \\ T_n \end{bmatrix} = [A] \begin{bmatrix} T_1 \\ \vdots \\ T_n \end{bmatrix} + [B] \begin{bmatrix} T_i \\ T_o \end{bmatrix} \quad (18.19)$$

$$\begin{bmatrix} q''_i \\ q''_o \end{bmatrix} = [C] \begin{bmatrix} T_1 \\ \vdots \\ T_n \end{bmatrix} + [D] \begin{bmatrix} T_i \\ T_o \end{bmatrix} \quad (18.20)$$

where $T_1, T_2, \dots, T_{n-1}, T_n$ are the finite difference nodal temperatures, n is the number of nodes, T_i and T_o are the interior and exterior environmental temperatures, and q''_i and q''_o are the heat fluxes (desired output).

Seem (1987) shows that for a simple one layer slab with two interior nodes as in Figure 18.3 and convection at both sides the resulting finite difference equations are given by:

$$C \frac{dT_1}{dt} = hA(T_o - T_1) + \frac{T_2 - T_1}{R} \quad (18.21)$$

$$C \frac{dT_2}{dt} = hA(T_i - T_2) + \frac{T_1 - T_2}{R} \quad (18.22)$$

$$q''_i = h(T_i - T_2) \quad (18.23)$$

$$q''_o = h(T_1 - T_o) \quad (18.24)$$

where:

R is the thermal resistance which is equal to $\frac{\ell}{kA}$

C is the thermal capacitance which is equal to $\frac{\rho c_p \ell A}{2}$

T_o is the outside temperature

T_i is the inside temperature

T_1 is the temperature of node 1

T_2 is the temperature of node 2

A is the area of the surface exposed to the environmental temperatures.

In matrix format:

$$\begin{bmatrix} \frac{dT_1}{dt} \\ \frac{dT_2}{dt} \end{bmatrix} = \begin{bmatrix} \frac{-1}{RC} - \frac{hA}{C} & \frac{1}{RC} \\ \frac{1}{RC} & \frac{-1}{RC} - \frac{hA}{C} \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \end{bmatrix} + \begin{bmatrix} \frac{hA}{C} & 0 \\ 0 & \frac{hA}{C} \end{bmatrix} \begin{bmatrix} T_o \\ T_i \end{bmatrix} \quad (18.25)$$

$$\begin{bmatrix} q''_i \\ q''_o \end{bmatrix} = \begin{bmatrix} 0 & -h \\ h & 0 \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \end{bmatrix} + \begin{bmatrix} 0 & h \\ -h & 0 \end{bmatrix} \begin{bmatrix} T_o \\ T_i \end{bmatrix} \quad (18.26)$$

The important aspect of the state space technique is that through the use of relatively simple matrix algebra the state space variables (nodal temperatures) can be eliminated to arrive at a matrix equation that gives the outputs (heat fluxes) as a function of the inputs (environmental temperatures) only. This eliminates the need to solve for roots in the Laplace domain. In

Figure 18.3: Two Node State Space Example

addition, the resulting matrix form has more physical meaning than complex functions required by the Laplace transform method. The current version of EnergyPlus uses the state space method for computing CTFs.

The accuracy of the state space method of calculating CTFs has been addressed in the literature. Ceylan and Myers (1980) compared the response predicted by the state space method to various other solution techniques including an analytical solution. Their results showed that for an adequate number of nodes the state space method computed a heat flux at the surface of a simple one layer slab within 1% of the analytical solution. Ouyang and Haghghat (1991) made a direct comparison between the Laplace and state space methods. For a wall composed of insulation between two layers of concrete, they found almost no difference in the response factors calculated by each method.

18.1.1.5 Extension of Time Series Solutions to Include Heat Sources and Obtain Internal Temperatures

18.1.1.6 Laplace Transform Formulation

Degiovanni (1988) proposed two methodologies for including sources or sinks in the Laplace Transform Formulation. The first method shows how a source that varies as a function of time and location can be incorporated. The resulting equations involve some fairly complicated terms including spatial derivatives.

The second method that will be analyzed in more detail involves the addition of a source or sink at the interface between two layers. The derivation of the necessary equations is begun by analyzing the simple two layer element shown in Figure 18.4.

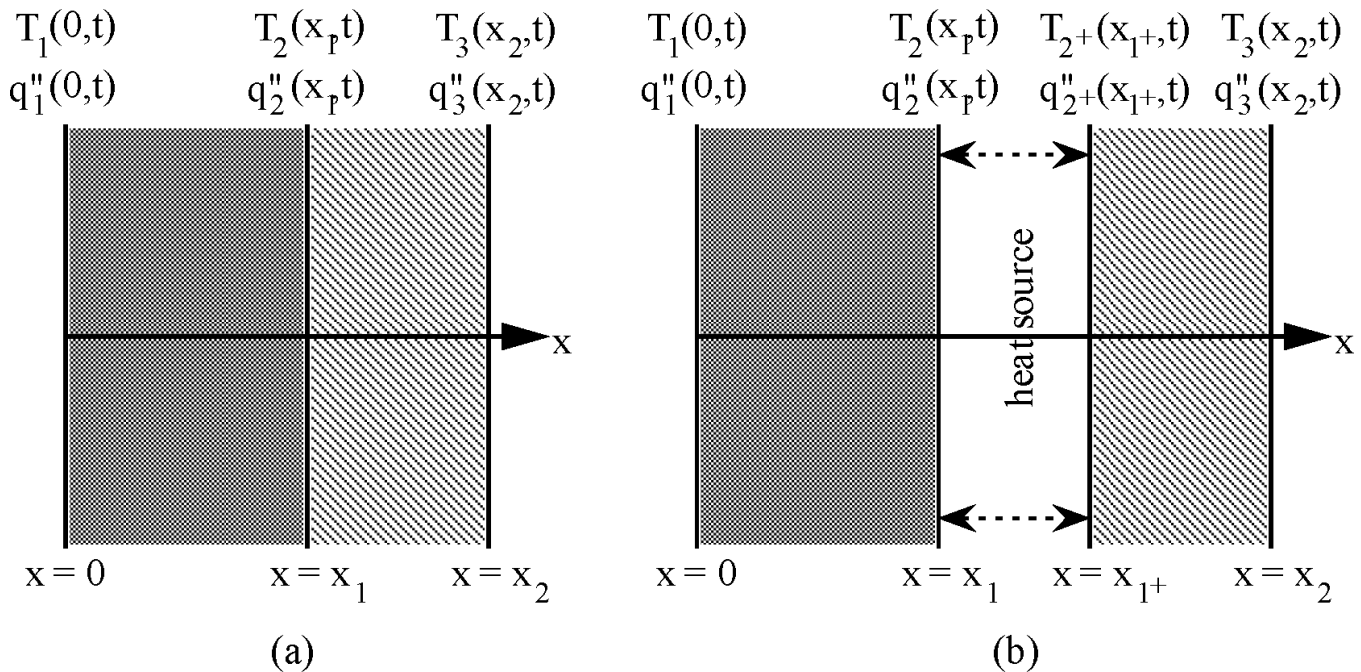

Figure 18.4: Two Layer Example for Deriving the Laplace Transform Extension to Include Sources and Sinks

For the first layer, it was determined that in the Laplace domain:

$$\begin{bmatrix} T_1(s) \\ q_1(s) \end{bmatrix} = \begin{bmatrix} A_1(s) & B_1(s) \\ C_1(s) & D_1(s) \end{bmatrix} \begin{bmatrix} T_2(s) \\ q_2(s) \end{bmatrix} \quad (18.27)$$

For the second layer:

$$\begin{bmatrix} T_2(s) \\ q_2(s) \end{bmatrix} = \begin{bmatrix} A_2(s) & B_2(s) \\ C_2(s) & D_2(s) \end{bmatrix} \begin{bmatrix} T_3(s) \\ q_3(s) \end{bmatrix} \quad (18.28)$$

To link the two layers and include the heat source between them, the following substitution is made:

$$\begin{bmatrix} T_2(s) \\ q_2(s) \end{bmatrix} = \begin{bmatrix} T_{2+}(s) \\ q_{2+}(s) \end{bmatrix} + \begin{bmatrix} 0 \\ q_{source}(s) \end{bmatrix} \quad (18.29)$$

which results in:

$$\begin{bmatrix} T_1(s) \\ q_1(s) \end{bmatrix} = \begin{bmatrix} A_1(s) & B_1(s) \\ C_1(s) & D_1(s) \end{bmatrix} \left\{ \begin{bmatrix} T_{2+}(s) \\ q_{2+}(s) \end{bmatrix} + \begin{bmatrix} 0 \\ q_{source}(s) \end{bmatrix} \right\} \quad (18.30)$$

$$\begin{bmatrix} T_1(s) \\ q_1(s) \end{bmatrix} = \begin{bmatrix} A_1(s) & B_1(s) \\ C_1(s) & D_1(s) \end{bmatrix} \left\{ \begin{bmatrix} A_2(s) & B_2(s) \\ C_2(s) & D_2(s) \end{bmatrix} \begin{bmatrix} T_3(s) \\ q_3(s) \end{bmatrix} + \begin{bmatrix} 0 \\ q_{source}(s) \end{bmatrix} \right\} \quad (18.31)$$

$$\begin{bmatrix} T_1(s) \\ q_1(s) \end{bmatrix} = \begin{bmatrix} A_1(s) & B_1(s) \\ C_1(s) & D_1(s) \end{bmatrix} \begin{bmatrix} A_2(s) & B_2(s) \\ C_2(s) & D_2(s) \end{bmatrix} \begin{bmatrix} T_3(s) \\ q_3(s) \end{bmatrix} + \begin{bmatrix} A_1(s) & B_1(s) \\ C_1(s) & D_1(s) \end{bmatrix} \begin{bmatrix} 0 \\ q_{source}(s) \end{bmatrix} \quad (18.32)$$

While Degiovanni concludes with this formula, some insight into what the generic equation for an element that has n layers might look like is gained by working with Equation 18.32. If a layer is added to the left of the first layer, the entire right hand side of Equation 18.32 is multiplied by the transmission matrix of the new layer. Conversely, if a layer is added to the right of the second layer in Figure 18.4, the vector containing the Laplace transform of the temperature and heat flux at interface 3 is replaced by the product of the transmission matrix of the new layer and the vector for temperature and heat flux at the next interface, and the term dealing with the heat source is not affected. The general equation for a building element with n layers and m layers between the left hand surface and the heat source can be derived as:

$$\begin{bmatrix} T_1(s) \\ q_1(s) \end{bmatrix} = \left(\prod_{i=1}^n \begin{bmatrix} A_i(s) & B_i(s) \\ C_i(s) & D_i(s) \end{bmatrix} \right) \begin{bmatrix} T_{n+1}(s) \\ q_{n+1}(s) \end{bmatrix} + \left(\prod_{i=1}^m \begin{bmatrix} A_i(s) & B_i(s) \\ C_i(s) & D_i(s) \end{bmatrix} \right) \begin{bmatrix} 0 \\ q_{source}(s) \end{bmatrix} \quad (18.33)$$

or in more compact form:

$$\begin{bmatrix} T_1(s) \\ q_1(s) \end{bmatrix} = \begin{bmatrix} A(s) & B(s) \\ C(s) & D(s) \end{bmatrix} \begin{bmatrix} T_{n+1}(s) \\ q_{n+1}(s) \end{bmatrix} + \begin{bmatrix} a(s) & b(s) \\ c(s) & d(s) \end{bmatrix} \begin{bmatrix} 0 \\ q_{source}(s) \end{bmatrix} \quad (18.34)$$

$$\text{where: } \begin{bmatrix} A(s) & B(s) \\ C(s) & D(s) \end{bmatrix} = \prod_{i=1}^n \begin{bmatrix} A_i(s) & B_i(s) \\ C_i(s) & D_i(s) \end{bmatrix} \quad \text{and} \quad \begin{bmatrix} a(s) & b(s) \\ c(s) & d(s) \end{bmatrix} = \prod_{i=1}^m \begin{bmatrix} A_i(s) & B_i(s) \\ C_i(s) & D_i(s) \end{bmatrix}$$

Next, Equation 18.34 must be rearranged to match the form of Equation 18.16, which relates the heat flux at both sides of the element to the temperature at each side. The matrix equation that is obtained shows that:

$$\begin{bmatrix} q_1(s) \\ q_{n+1}(s) \end{bmatrix} = \begin{bmatrix} \frac{D(s)}{B(s)} & \frac{-1}{B(s)} \\ \frac{1}{B(s)} & \frac{-A(s)}{B(s)} \end{bmatrix} \begin{bmatrix} T_1(s) \\ T_{n+1}(s) \end{bmatrix} + \begin{bmatrix} d(s) - \frac{D(s)b(s)}{B(s)} \\ \frac{b(s)}{B(s)} \end{bmatrix} [q_{source}(s)] \quad (18.35)$$

This equation bears a striking resemblance to Equation 18.16. If the source term in Equation 18.35 is dropped, then the equation is identical to Equation 18.16. This result conforms with the superposition principle which was used to develop the conduction transfer functions from the summation of a series of triangular pulses or ramp sets. Now, the effect of the heat source is simply added to the response to the temperature inputs.

While Equation 18.35 is correct for any single or multilayered element, the first term in the heat source transmission matrix does not appear to match the compactness of the other terms in the matrix equation. It can be shown (see Strand 1995: Equations 32 through 42 which detail this derivation) that the heat source transmission term for a two-layer problem reduces to:

$$\begin{bmatrix} q_1(s) \\ q_3(s) \end{bmatrix} = \begin{bmatrix} \frac{D(s)}{B(s)} & \frac{-1}{B(s)} \\ \frac{1}{B(s)} & \frac{-A(s)}{B(s)} \end{bmatrix} \begin{bmatrix} T_1(s) \\ T_3(s) \end{bmatrix} + \begin{bmatrix} \frac{B_2(s)}{B(s)} \\ \frac{B_1(s)}{B(s)} \end{bmatrix} [q_{source}(s)] \quad (18.36)$$

If this is extended to a slab with n layers and a source between the m and $m+1$ layers, the general matrix equation for obtaining heat source transfer functions using the Laplace transform method is:

$$\begin{bmatrix} q_1(s) \\ q_{n+1}(s) \end{bmatrix} = \begin{bmatrix} \frac{D(s)}{B(s)} & \frac{-1}{B(s)} \\ \frac{1}{B(s)} & \frac{-A(s)}{B(s)} \end{bmatrix} \begin{bmatrix} T_1(s) \\ T_{n+1}(s) \end{bmatrix} + \begin{bmatrix} \frac{\bar{b}(s)}{B(s)} \\ \frac{b(s)}{B(s)} \end{bmatrix} [q_{source}(s)] \quad (18.37)$$

where:

$$\begin{bmatrix} A(s) & B(s) \\ C(s) & D(s) \end{bmatrix} = \prod_{i=1}^n \begin{bmatrix} A_i(s) & B_i(s) \\ C_i(s) & D_i(s) \end{bmatrix} \quad (18.38)$$

$$\begin{bmatrix} a(s) & b(s) \\ c(s) & d(s) \end{bmatrix} = \prod_{i=1}^m \begin{bmatrix} A_i(s) & B_i(s) \\ C_i(s) & D_i(s) \end{bmatrix} \quad (18.39)$$

$$\begin{bmatrix} \bar{a}(s) & \bar{b}(s) \\ \bar{c}(s) & \bar{d}(s) \end{bmatrix} = \prod_{i=m+1}^n \begin{bmatrix} A_i(s) & B_i(s) \\ C_i(s) & D_i(s) \end{bmatrix} \quad (18.40)$$

At first glance, the terms in the heat source transmission matrix may appear to be reversed. It is expected that only the layers to the left of the source will affect $q_1(s)$, but the presence of $\bar{b}(s)$ in the element multiplied by $q_{source}(s)$ to obtain $q_1(s)$ seems to be contradictory. In fact, the entire term, $\bar{b}(s)/B(s)$, must be analyzed to determine the effect of $q_{source}(s)$ on $q_1(s)$. In essence, the appearance of $\bar{b}(s)$ removes the effects of the layers to the right of the source from $B(s)$ leaving

only the influence of the layers to the left of the source. The form displayed by Equation 18.37 is, however, extremely convenient because the terms in the heat source transmission matrix have the same denominators, and thus roots, as the terms in the temperature transmission matrix. Thus, the same roots that are calculated for the CTFs can be used for the QTFs, saving a considerable amount of computer time during the calculation of the transfer functions.

Once Equation 18.37 is inverted from the Laplace domain back into the time domain, the combined CTF-QTF solution takes the following form:

$$q''_{i,t} = \sum_{m=1}^M X_m T_{i,t-m+1} - \sum_{m=1}^M Y_m T_{o,t-m+1} + \sum_{m=1}^k F_m q''_{i,t-m} + \sum_{m=1}^M W_m q_{source,t-m+1} \quad (18.41)$$

This relation is identical to Equation 18.4 except for the presence of the QTF series that takes the heat source or sink into account.

18.1.1.7 State Space Formulation

The two-node example introduced by Seem (1987) can be utilized to examine the extension of the state space method to include heat sources or sinks. Figure 18.5 shows the simple two node network with a heat source added at node 1.

The nodal equations for the finite difference network shown in Figure 18.5 are:

$$C \frac{dT_1}{dt} = hA(T_o - T_1) + \frac{T_2 - T_1}{R} + q_{source}A \quad (18.42)$$

$$C \frac{dT_2}{dt} = hA(T_i - T_2) + \frac{T_1 - T_2}{R} \quad (18.43)$$

$$q''_i = h(T_i - T_2) \quad (18.44)$$

$$q''_o = h(T_1 - T_o) \quad (18.45)$$

In obtaining the matrix equivalent for this set of equations, it should be noted that the source term is not a constant but rather an input that varies with time. Thus, it must be grouped with the environmental temperatures as inputs. The resulting matrix equations take the following form:

$$\begin{bmatrix} \frac{dT_1}{dt} \\ \frac{dT_2}{dt} \end{bmatrix} = \begin{bmatrix} \frac{-1}{RC} - \frac{hA}{C} & \frac{1}{RC} \\ \frac{1}{RC} & \frac{-1}{RC} - \frac{hA}{C} \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \end{bmatrix} + \begin{bmatrix} \frac{hA}{C} & 0 & \frac{A}{C} \\ 0 & \frac{hA}{C} & 0 \end{bmatrix} \begin{bmatrix} T_o \\ T_i \\ q_{source} \end{bmatrix} \quad (18.46)$$

$$\begin{bmatrix} q''_1 \\ q''_2 \end{bmatrix} = \begin{bmatrix} 0 & -h \\ h & 0 \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \end{bmatrix} + \begin{bmatrix} 0 & h & 0 \\ -h & 0 & 0 \end{bmatrix} \begin{bmatrix} T_o \\ T_i \\ q_{source} \end{bmatrix} \quad (18.47)$$

Equation 18.47 appears to suggest that the source term has no direct effect on the heat flux at either side of the element because its coefficients are zero. This is not the case. Equation 18.47 only relates variables that have a direct influence on heat flux. So, while T_i has no direct influence

Figure 18.5: Two Node State Space Example with a Heat Source

on q''_o , it does have an indirect influence through the nodal network. The same would hold for the influence of q_{source} .

If this analysis is extended to a finite difference network with n nodes, the corresponding matrix equations can be shown to be:

$$\frac{d \begin{bmatrix} T_1 \\ \vdots \\ T_n \end{bmatrix}}{dt} = [A] \begin{bmatrix} T_1 \\ \vdots \\ T_n \end{bmatrix} + [B] \begin{bmatrix} T_o \\ T_i \\ q_{source} \end{bmatrix} \quad (18.48)$$

$$\begin{bmatrix} q''_i \\ q''_o \end{bmatrix} = [C] \begin{bmatrix} T_1 \\ \vdots \\ T_n \end{bmatrix} + [D] \begin{bmatrix} T_o \\ T_i \\ q_{source} \end{bmatrix} \quad (18.49)$$

The influence of the heat source is also confirmed by the final solution form, which is identical to the Laplace transform result shown in Equation 18.41. As with the Laplace solution method, the state space method results in a set of QTFs that relate the heat source at the current time step and several previous time steps to the current heat flux at the surface of the element.

Other similarities between the two solution methods are evident. It is interesting to note that as with the Laplace method there is no alteration of the CTFs calculated by the state space method. Thus, the principle of superposition is still valid. Furthermore, the introduction of the source term did not substantially increase the computing effort required to calculate the additional transfer functions. In the Laplace method, this was shown by the common roots, $B(s)$, shared by both the CTFs and the QTFs. In the state space method, it can be noted that the A matrices in Equations 18.25 and 18.46 are identical. Since the state space method requires the inversion and the exponentiation of the A matrix only, the additional QTF terms will not require a substantial amount of additional computing time for their calculation.

18.1.1.8 Two-Dimensional Solutions for Radiant Systems

One distinct advantage of the State Space method presented in the previous section over the Laplace Transform method is that it can be adapted to more than one dimension. In fact, as long as one can apply a network of nodes to a problem, the State Space method can be adapted to it. For EnergyPlus, the biggest implication is that conduction through a construction can be expanded from one-dimensional in nature to two-dimensional. This is particularly important in a hydronic radiant system where the presence of water tubes is clearly more than one-dimensional.

The modeling of two-dimensional conduction used when `ConstructionProperty:InternalHeatSource` objects are attached to surfaces is thus possible by expanding the network of nodes shown in the above examples in the direction perpendicular to the main direction of heat transfer. Essentially, when a user requests the two-dimensional solution for a `ConstructionProperty:InternalHeatSource` surface, the network of nodes is expanded perpendicular to the direction of heat transfer. While this is not an overly complex process, here are some rules and limitations to the application of two-dimensional solutions in EnergyPlus:

- Even though the solution internal to the surface is two-dimensional, in order to work within the confines of the standard EnergyPlus heat balance, the boundary condition at both the inside

and outside face of the surface is that the temperature across the surface is the same at all points or that the surfaces are still isothermal. The point of this is so that once the conduction transfer functions are calculated that the the surface heat balance formulations remain the same as any other surface that is using a one-dimensional assumption in EnergyPlus.

- The domain being modeled for a two-dimensional approach goes from one face of the surface to the other face as a one-dimensional model. In the second dimension, perpendicular to the main direction of heat transfer, the domain goes from the line that goes through the tubing to the line of symmetry at the mid-point between adjacent tubing. The perpendicular distance for this domain is given by the tubing spacing user input in the ConstructionProperty:InternalHeatSource object. This tubing spacing is halved to determine the perpendicular distance for the solution domain.
- While the number of nodes used for each layer of a construction is determined by the thermo-physical properties of the material for the layer to maintain solution stability, the number of nodes in the perpendicular direction is fixed for all layers of the construction. Currently in EnergyPlus, the number of nodes in the perpendicular direction is fixed at 7. This number was chosen as a result of testing with an evaluation version of one of the predecessor programs of EnergyPlus. This number of nodes was a balance between accuracy requirements and solution speed. Because the speed of the process required to calculate conduction transfer functions increases greatly as the number of nodes used in the model increases, increasing the number of nodes in the perpendicular direction too much will result in an unacceptable increase in the time required to calculate the conduction transfer functions.
- The heat source or sink is applied evenly over the entire node where the user defines the location of the source through the ConstructionProperty:InternalHeatSource input. For calculating the conduction transfer functions, the model ignores the presence of the tubing and fluid and simply assumes that the entire layer consists of the appropriate material as defined by the Construction:InternalSource input. The radiant model does take into account heat transfer between the material and the fluid being circulated through the system.
- The location of the heat source and the calculation of an additional point that can be used for controlling the slab (see next section) are defined by input provided in the ConstructionProperty:InternalHeatSource input. The location of the tubing where heat is added or subtracted from the slab is always defined at one side of the solution domain. The location of the additional user temperature request is controlled by both the fields for the location of the user temperature request (between two layers) and the perpendicular direction for this temperature. This temperature can then be used for controlling a radiant system. (See section on **Low Temperature Radiant System Controls** for more information about controlling a radiant system.

These assumptions are applied to a low temperature radiant system within EnergyPlus and their impact can be seen in the next three diagrams. First, one can see the symmetry inherent in a low temperature radiant system in Figure 18.6 below.

Given the lines of symmetry in Figure 18.6, the solution domain can be narrowed down to what is shown in Figure 18.7 below.

Once the solution domain has been set, a network of nodes can be applied to this solution domain for the State Space method using the assumptions given above. An example of this is shown in

Figure 18.6: Cross Section of a Low Temperature Radiant System with Planes of Symmetry

Figure 18.8 below. Note that in EnergyPlus there are actually 7 nodes in perpendicular direction, not 5 as shown in this figure.

As mentioned in the figure above, the source or sink is applied at a node along the left side of this solution domain and the depth established by user input. The number of nodes in the main direction of heat transfer for each layer of the construction is calculated in the same manner as for a standard layer with 1-D heat conduction. The number of nodes chosen for the perpendicular direction is set to 7 in EnergyPlus as a balance between calculation accuracy and solution speed.

18.1.1.9 Determination of Internal Temperatures

One aspect of low temperature radiant systems that has not been addressed to this point is the appropriateness of specifying the effect of the system on slab response via a heat source term. For a heating system that employs electrical resistance heating, the use of a heat source as the input variable is logical. The heat produced by such a system can easily be related to the current passing through the heating wire. However, for a hydronic heating or cooling system, the known quantity is not heat but rather the temperature of the water being sent to the building element.

The use of a temperature to simulate the presence of a heating or cooling system presents one major obstacle. When fluid is not being circulated, there is no readily available temperature value available for use as an input variable.

In a hydronic system, a link between the fluid temperature being sent to the slab and the heat delivered to the slab exist. The most effective way of relating these two variables is to consider the slab to be a heat exchanger. Using heat exchanger relationships, an equation could then be formulated to obtain the heat delivered to the slab based on the inlet fluid temperature.

Most heat exchangers are used to thermally link two fluids. In the case of a hydronic radiant system, there is only one fluid and a stationary solid. Presumably, if the inlet fluid temperature, the system geometry, and the solid temperature are known, then the outlet temperature and thus the heat transfer to the building element can be computed. This leads to an interesting question: what

Figure 18.7: Two-Dimensional Solution Domain for a Low Temperature Radiant System

Figure 18.8: Two-Dimensional Node Example for a Low Temperature Radiant System

is the solid temperature?

By definition, for one dimensional conduction heat transfer, the solid temperature is the temperature of the building element at the depth where the hydronic loop is located. Typically, this temperature is not known because it is not needed. The goal of both methods of calculating CTFs was the elimination of internal temperatures that were not needed for the simulation. For a hydronic system, it is necessary to extract this information to solve for the heat source term. Two methods of accomplishing this are described below.

Returning to the two layer example shown in Figure 18.4, it can be shown that the final solution form in the time domain for the slab with a source at the interface between the two layers is:

$$q''_{1,t} = \sum_{m=1}^M X_{k,m} T_{1,t-m+1} - \sum_{m=1}^M Y_{k,m} T_{3,t-m+1} + \sum_{m=1}^k F_m q''_{1,t-m} + \sum_{m=1}^M W_m q_{source,t-m+1} \quad (18.50)$$

A similar equation could be written for the response of the first layer in absence of any source term and is given by:

$$q''_{1,t} = \sum_{m=1}^M x_{k,m} T_{1,t-m+1} - \sum_{m=1}^M y_{k,m} T_{2,t-m+1} + \sum_{m=1}^k f_m q''_{1,t-m} \quad (18.51)$$

While the current temperature at the interface is not known, presumably the previous values of this parameter will be known. In addition, the temperatures and the flux histories at surface 1 are also known. The unknowns in Equation 18.51 are the current heat flux at surface 1 and the temperature at surface 2. However, Equation 18.50 does define the current value of the heat flux at surface 1 based on temperature, heat flux, and heat source histories. Thus, if this value is used in Equation 18.51, the only remaining unknown in this equation is the current temperature at surface 2, the surface where the heat source or sink is present. Rearranging Equation 18.51 provides an equation from which the temperature at the source location may be calculated:

$$T_{2,t} = \sum_{m=1}^M \bar{X}_{k,m} T_{1,t-m+1} - \sum_{m=1}^{M-1} \bar{Y}_{k,m} T_{2,t-m} + \sum_{m=1}^{k+1} \bar{F}_m q''_{1,t-m+1} \quad (18.52)$$

where the new coefficients are obtained from the standard conduction transfer functions for the first layer via the following equations:

$$\bar{X}_{k,m} = \frac{x_{k,m}}{y_1} \quad (m = 1, \dots, M) \quad (18.53)$$

$$\bar{Y}_{k,m} = \frac{y_{k,m+1}}{y_1} \quad (m = 1, \dots, M-1) \quad (18.54)$$

$$\bar{F}_1 = \frac{1}{y_1} \quad (18.55)$$

$$\bar{F}_m = \frac{f_{m-1}}{y_1} \quad (m = 2, \dots, k+1) \quad (18.56)$$

This system for backing out an internal temperature through the use of a second, rearranged CTF equation is valid regardless of whether the Laplace transform or state space method is utilized

to calculate the CTFs and QTFs. The state space method, however, offers a more direct method of obtaining an internal temperature through its definition as an additional output variable.

Consider again the state space example shown in Figure 18.5. Two output variables were defined for this example: q''_i and q''_o . The temperature of the node where the source is present can also be defined as an output variable through the identity equation:

$$T_1 = T_1 \quad (18.57)$$

When this equation for T_1 is added to Equation 18.47, the resulting output matrix equation for the heat flux at both surfaces and the internal temperature is:

$$\begin{bmatrix} q''_i \\ q''_o \\ T_1 \end{bmatrix} = \begin{bmatrix} 0 & -h \\ h & 0 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \end{bmatrix} + \begin{bmatrix} 0 & h & 0 \\ -h & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} T_i \\ T_o \\ q_{source} \end{bmatrix} \quad (18.58)$$

The only difference between this relation and Equation 18.47 is the presence of T_1 on both the right and left hand side of the equation. The dual role of T_1 as a state variable and an output parameter may seem to contradict the goal of the state space method of eliminating the state variables. However, due to the flexibility of the formulation, nodal temperatures can be extracted in the same manner that any other output quantity would be obtained. For an element with n layers, Equation 18.58 becomes:

$$\begin{bmatrix} q''_i \\ q''_o \\ T_s \end{bmatrix} = [C] \begin{bmatrix} T_1 \\ \vdots \\ T_n \end{bmatrix} + [D] \begin{bmatrix} T_i \\ T_o \\ q_{source} \end{bmatrix} \quad (18.59)$$

where T_s is the temperature of the node where the heat source or sink is present. The transfer function equation for the calculation of T_s that results from Equation 18.59 is identical in form to Equation 18.41:

$$T_{s,t} = \sum_{m=1}^M x_{k,m} T_{i,t-m+1} - \sum_{m=1}^M y_{k,m} T_{o,t-m+1} + \sum_{m=1}^k f_m T_{s,t-m} + \sum_{m=1}^M w_m q_{source,t-m+1} \quad (18.60)$$

Instead of the flux at either side of the element characterized as a function of temperature, flux, and source history terms, the temperature at the source location is related to source and temperature histories including histories of T_s . The validity of these internal temperature calculation methods as well as heat source transfer functions in general will be discussed in the next chapter.

18.1.1.10 Low Temperature Radiant System Controls

The use of this equation allows the low temperature radiant system to be handled like any other surface within the heat balance framework. Heat balances at the inside and outside surfaces take on the same form as other surfaces, and the participation of the radiant system in the radiation balance within the space and thermal comfort models is automatically included. Thus, the radiant system model is fully integrated into the heat balance, and any improvements that are made in areas such as convection coefficients, shading models, etc. are immediately available to the radiant system as part of the overall heat balance solution.

Once the transient nature of the system is accounted for, one must then turn to the next difficult issue: controls. Controls are problematic for almost any simulation program. The problem is not whether something can be simulated because typically a simulation program offers the ability to experiment with many different control strategies. Rather, the problem is typically the diversity of controls that are implemented and keeping the controls that can be simulated up to date. EnergyPlus offers two different flow control schemes: variable flow (ZoneHVAC:LowTemperatureRadiant:VariableFlow) and constant flow/variable temperature (ZoneHVAC:LowTemperatureRadiant:ConstantFlow). The control strategies are different enough that they were developed as separate system types. More details of the controls are described below.

The controls for variable flow low temperature radiant systems within EnergyPlus are fairly simple though there is some flexibility through the use of schedules. The program user is allowed to define a setpoint temperature as well as a throttling range through which the system varies the flow rate of water (or current) to the system from zero to the user defined maximum flow rate. The flow rate is varied linearly with the flow reaching 50% of the maximum when the controlling temperature reaches the setpoint temperature. Setpoint temperatures can be varied on an hourly basis throughout the year if desired.

The controlling temperature can be the mean air temperature, the mean radiant temperature, the operative temperature of the zone, the outdoor dry-bulb temperature, the outdoor wet-bulb temperature, the surface inside face temperature, or the surface interior temperature. The choice of controlling temperature is left to the user's discretion and set by input as described in the Input Output Reference. For radiant system controls, the operative temperature is calculated as the average of MAT and MRT. The surface inside face temperature is the temperature of the surface in which the radiant system is embedded at the inside face (the side facing the zone being conditioned).

When the user opts to control the radiant system on the surface interior temperature, this temperature is inside the slab itself, and its location is defined using input that describes the construction of the slab (ConstructionProperty:InternalHeatSource—see the Input Output Reference for more details). Note that this user defined temperature still must be at the interface between two layers, but this is easy to overcome by splitting any material into two separate layers. When the user elects to perform a two-dimensional solution, an additional input parameter in the ConstructionProperty:InternalHeatSource object allows the user to choose the location of the user requested temperature in the direction perpendicular to the main direction of heat transfer. This location can be in-line with the hydronic tubing, at the mid-point between two adjacent pipes, or at any node/point in between. Due to the State Space method and a fixed number of nodes in the direction (currently seven), the user's decimal input for location between one side of the solution domain and the other is converted to a specific node. However, this does allow the user quite a bit of flexibility in the solution and also defining a point on the interior of a radiant system that can be used for controlling a radiant system.

Since flow rate is varied in a variable flow radiant system, there is no explicit control on the inlet water temperature or mixing to achieve some inlet water temperature in a hydronic system. However, the user does have the ability to specify on an hourly basis through a schedule the temperature of the water that would be supplied to the radiant system. Graphical descriptions of the controls for the low temperature radiant system model in EnergyPlus are shown in Figure 18.9 for a hydronic system. In a system that uses electric resistance heating, the power or heat addition to the system varies in a manner similar to mass flow rate variation shown in Figure 18.9.

In the constant flow/variable temperature systems, the controls are also considered piecewise

linear functions, but in this case the user selects both the control temperatures and the water temperatures via schedules. This offers greater flexibility for defining how the radiant system operates though it may not model every situation. Figure 18.10 shows how the “desired” inlet water temperature is controlled based on user schedules. The user has the ability to specify the high and low water and control temperature schedules for heating and cooling (separately; a total of eight temperature schedules). Note that this inlet temperature is a “desired” inlet temperature in that there is no guarantee that the system will provide water to the system at that temperature. The model includes a local loop that attempts to meet this demand temperature through mixing and recirculation. Finally, the control temperature options are the same for a constant flow/variable temperature system as they are for the variable flow and electric radiant systems: mean air temperature, mean radiant temperature, operative temperature, outdoor dry-bulb temperature, outdoor wet-bulb temperature, surface inside face temperature, and surface interior temperature.

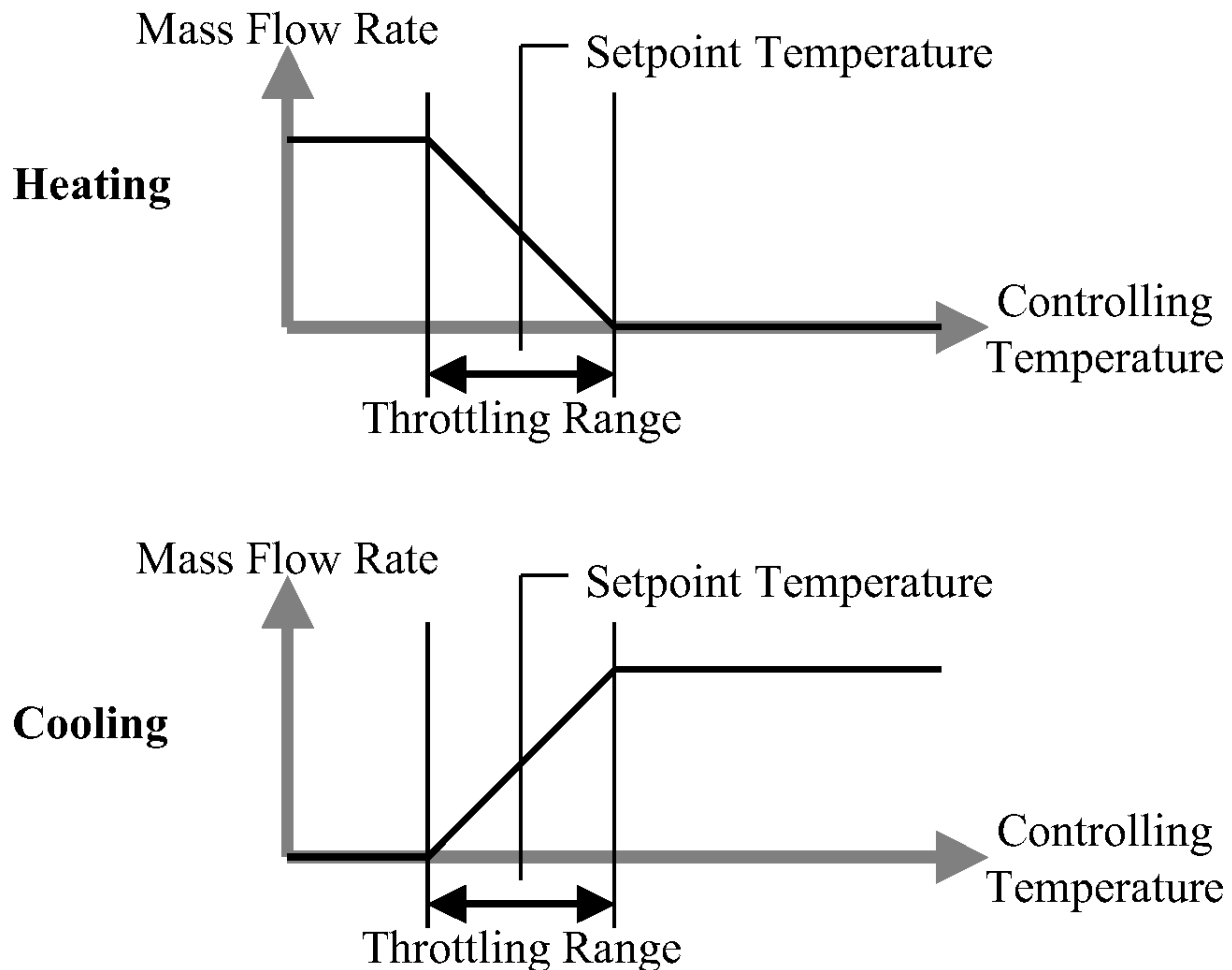

Figure 18.9: Variable Flow Low Temperature Radiant System Controls

The constant flow (variable temperature) low temperature radiant system model is actually a combination of mixing valves, a pump (constant speed, but the maximum flow can be modified by a schedule), and the radiant system (surface, panel, or group of surfaces/panels). This is connected to the main loop through the standard inlet connections as shown in Figure 18.11. The system controls determine the desired inlet temperature and system flow rate while loop controls determine

Figure 18.10: Variable Temperature Low Temperature Radiant System Controls

the flow rate and temperature of the loop. Note that pump heat also factors into the model through a simple constant speed pump model and user input.

There are four possible conditions (separate for heating and cooling). First, if the loop has adequate temperature and flow to meet system requests, then the model sets the radiant system inlet temperature and controls to the desired values based on the controls and simulates. This is the best condition and recirculation and bypass amounts are adjusted accordingly based on radiant system outlet temperatures. Second, if the loop temperature is adequate but the loop flow rate is less than the radiant system flow rate, we may or may not be able to meet the desired inlet temperature since recirculation might lower the temperature below the desired temperature. In this second case, the model first simulates the radiant system with the desired conditions and then resimulates it to solve for the actual inlet temperature (see later in this section) if it cannot achieve the desired inlet temperature. Third, if the loop flow is greater than the radiant flow but the temperature of the loop is not adequate, then there is no amount of mixing that will solve this problem. All of the radiant flow comes from the loop and the loop temperature (after pump heat addition) becomes the radiant system inlet regardless of the temperature controls. Finally, if both the temperature and the flow of the loop are inadequate, then the model simply solves for the actual radiant system inlet temperature and does not try to meet the controls (merely tries to get as close as physically possible given the loop conditions).

Figure 18.11: Variable Temperature Low Temperature Radiant System Component Details

One remaining challenge is the merging of the low temperature radiant system model with an integrated building simulation program. In the past, most simulation programs have simulated the building envelope, the space conditioning systems, and the central plant equipment in three separate steps. While this had some advantages and was partly due to a lack of computing capacity, the large drawback for this arrangement is that there is no feedback from the space conditioning system or central plant response to the building conditions. Thus, if the system or plant was undersized, it was reported as an “unmet load” and does not affect the temperatures experienced within the

building. IBLAST, a predecessor (Taylor 1991) to EnergyPlus, resolved this issue by integrating all three major components of a building simulation and thus allowing feedback between the equipment and the building envelope.

This integration was not a trivial task and required that the systems be simulated at shorter time steps in some cases to maintain solution stability. In essence, the system simulation will shorten its time step whenever it senses that conditions are changing too rapidly. While this is effective in maintaining solution stability, it can present problems for a radiant system. The radiant system has either a direct or an indirect impact on the surfaces within a building. So, it must be simulated with the building envelope. Yet, it is also a space conditioning system that must act on the space like any other system and thus must also be simulated at the system time step, which can be less than the building time step and can also vary within EnergyPlus.

This issue was handled using a multi-step approach. In EnergyPlus, the heat balance is always simulated first. When this happens, the radiant system is temporarily shut-off to find how the building would respond if there was no heat source/sink. Then, as the system and plant are simulated at multiple shorter time steps, the radiant system is allowed to operate per the controls specified by the user. Flow rate is allowed to vary at each system time step, and the radiant system model is simulated at each time step as if the current flow rate was being used throughout the entire zone time step. This means that each time the heat source/sink in the radiant system is varied during the system simulation the zone heat balance must be recomputed to see what the reaction of the rest of the zone is to this change in the conditions of one (or more) of the surfaces.

In reality, this is not physically correct because each change in the flow rate throughout the system simulation will have an impact on the system time steps remaining before the heat balance is simulated during the next zone time step. Yet, other approaches to solving the mismatch between the system and the zone response of radiant systems are not feasible. One could force the system to run at the same time step as the zone, but this could result in instabilities in other types of systems that might be present in the simulation. On the other hand, one could try to force the zone to run at the shorter time steps of the system, but this could lead to instability within the heat balance due to limits on the precision of the conduction transfer function coefficients.

Despite the fact that the simulation algorithm described above may either over- or under-predict system response dependent on how the system has been controlled in previous system time steps, it is reasonable to expect that the effect of these variations will balance out over time even though it might lead to slightly inaccurate results at any particular system time step. The long-term approach is also in view in the final simulation step at each zone time step. After the system has simulated through enough system time steps to equal a zone time step, the radiant system will rerun the heat balance using the average heat source/sink over all of the system time steps during the past zone time step. This maintains the conservation of energy within the heat balance simulation over the zone time steps and defines more appropriate temperature and flux histories at each surface that are critical to the success of a conduction transfer function based solution. A graphical picture of this somewhat complex multiple step simulation is shown in Figure 18.12.

18.1.1.11 Heat Exchanger Formulation for Hydronic Systems

As has been mentioned previously, the actual heat transferred between the building element and the hydronic loop is related to the temperature of the building element at the source location as well as the water system inlet and outlet temperatures. In EnergyPlus, it is assumed that the inlet temperature to the slab (defined by a user schedule and the plant simulation) and the mass

Figure 18.12: Resolution of Radiant System Response at Varying Time Steps

flow rate (determined by the control algorithm) are known and that the remaining parameters must be calculated. However, the heat balance equations require the heat transferred to the building element from the water loop in order to calculate the heat transferred from the element to the building environment.

Even though systems defined by this model can vary somewhat, the same characteristic link between the system variables exist. For modeling purposes, the overall water/slab system can be thought of as a heat exchanger. While in principle there are two alternative heat exchanger methodologies, it is more convenient to use the effectiveness-NTU method in this case.

Several assumptions will be incorporated into the heat exchanger analysis. It is assumed that the building element that contains the hydronic loop is stationary and that its temperature along the length of the tubing is constant. The latter part of this assumption stems from assumptions made in both the one and two dimensional heat source transfer function derivations. In either case, the source was added at a single node that was characterized by a single temperature. For consistency, this assumption must be made again in the heat exchanger analysis. Another assumption for the current EnergyPlus model is that the fluid in the tubing is water. Additionally, it is assumed that the thermal properties of the water do not vary significantly over the length of the tubing and that the water flows at a constant flow rate. Finally, the temperature at the inside surface of the water tubing is assumed to be equal to the temperature at the source location. In other words, it is assumed that the water tubing itself has no appreciable effect on the heat transfer process being modeled.

Using these assumptions and the effectiveness-NTU heat exchanger algorithm, several equations can be defined which establish the relationship between the heat source and the water temperatures. First, a heat balance on the water loop results in:

$$q = (\dot{m}c_p)_{water} (T_{wi} - T_{wo}) \quad (18.61)$$

where q is the energy transferred between the water loop and the building element, \dot{m} is the mass flow rate of the water, c_p is the specific heat of the water, T_{wi} is the inlet water temperature, and T_{wo} is the outlet water temperature.

The maximum amount of heat transfer that is possible according to the Second Law of Thermodynamics is:

$$q_{max} = (\dot{m}c_p)_{water} (T_{wi} - T_s) \quad (18.62)$$

where q_{max} is the maximum amount of energy transfer that is possible and T_s is the temperature at the source location.

The effectiveness of the heat exchanger, ε , is defined as the ratio of the actual energy transfer to the maximum possible, or:

$$\varepsilon \equiv \frac{q}{q_{max}} \quad (18.63)$$

For a heat exchanger where one fluid is stationary, the effectiveness can be related to NTU, the number of transfer units, by the following equation (Incropera and DeWitt 1985):

$$\varepsilon = 1 - e^{-NTU} \quad (18.64)$$

where NTU is defined by:

$$NTU \equiv \frac{UA}{(\dot{m}c_p)_{water}} \quad (18.65)$$

EnergyPlus includes two possible methods for calculating the heat exchange between the circulating fluid and the rest of the system and these are controlled by user input: *ConvectionOnly* and *ISOStandard*. Both are described in more detail below.

ConvectionOnly Heat Transfer Model. In this model, the water tubes were assumed to have no effect on the heat transfer process. So, the only term present in the overall heat transfer coefficient, UA, is a convection term. Thus, the equation for UA is:

$$UA = h(\pi DL) \quad (18.66)$$

where h is the convection coefficient, D is the interior tube diameter, and L is the total length of the tube.

The convection coefficient can be obtained from internal flow correlations that relate the Nusselt dimensionless number to other flow properties. For laminar flow in a tube of constant surface temperature, the Nusselt number is defined by:

$$Nu_D = \frac{hD}{k} = 3.66 \quad (18.67)$$

where k is the thermal conductivity of the water.

For turbulent internal flow, the Colburn equation can be used to define the Nusselt number:

$$Nu_D = \frac{hD}{k} = 0.023 Re_D^{4/5} Pr^{1/3} \quad (18.68)$$

where Pr is the Prandtl number of water and Re_D is the Reynolds number which is defined by:

$$Re_D = \frac{4\dot{m}}{\pi\mu D} \quad (18.69)$$

The parameter μ is the absolute viscosity of water. For internal pipe flow, the flow is assumed to be turbulent for $Re_D \geq 2300$.

ISOStandard Heat Transfer Model. In this model, the convection between the fluid and the tubes and the conduction resistance of the tubes themselves are assumed to have an impact on the overall heat transfer. The method used in EnergyPlus for this model is based on ISO Standard 11855-2(2012) which is entitled “Building environment design — Design, dimensioning, installation and control of embedded radiant heating and cooling systems — Part 2: Determination of the design heating and cooling capacity”. The key equations from the ISO Standard are summarized in Appendix B of Standard 11855-2 and are outlined below.

In ISO Standard 11855-2, the heat convection for turbulent flow between the circulating fluid and the inside wall of the tube is characterized by the following equation:

$$R_{conv} = \frac{W^{0.13}}{8\pi} \left(\frac{D_{out} - D_{in}}{\dot{m}L} \right)^{0.87} \quad (18.70)$$

where W is the tube separation in the direction perpendicular to the main heat transfer direction, D_{out} is the outside tube diameter, D_{in} is the inside tube diameter, \dot{m} is the fluid mass flow rate in the tube, and L is the tube length.

The resistance of the pipe wall is characterized by this equation:

$$R_{tube} = \frac{W \ln \frac{D_{out}}{D_{in}}}{2\pi k_{tube}} \quad (18.71)$$

where k_{tube} is the thermal conductivity of the tube material.

Finally, the U-value for this model is calculated using:

$$U = \frac{1}{R_{conv} + R_{tube}} \quad (18.72)$$

This U-value is then used in Equation 18.65 to calculate NTU in the heat exchanger formulation shown above.

Knowledge of the flow conditions allows Equations 18.63 through 18.69 to be calculated. This essentially eliminates ε as an unknown. The controls and the plant define the water mass flow rate and the inlet water temperature, leaving two equations (Equations 18.61 and 18.62) and three unknowns. The third equation that can be used in conjunction with Equations 18.61 and 18.62 is Equation 18.60, which is the CTF/QTF equation for the temperature at the source location.

Knowing the inlet water temperature and water mass flow rate, the calculation procedure is somewhat involved and requires, in addition to Equations 18.60, 18.61, and 18.62, the use of a modified form of Equation 18.41. Equation 18.41 is the standard conduction transfer function formula for a building element with an embedded source/sink of heat. In EnergyPlus, the surface flux on the left hand side of the equation is replaced with a surface heat balance:

$$\begin{bmatrix} \text{Surface} \\ \text{Heat} \\ \text{Balance} \end{bmatrix} = \sum_{m=1}^M X_{k,m} T_{1,t-m+1} - \sum_{m=1}^M Y_{k,m} T_{3,t-m+1} + \sum_{m=1}^k F_m q''_{1,t-m} + \sum_{m=1}^M W_m q_{source,t-m+1} \quad (18.73)$$

The surface heat balance includes terms for incident solar energy, radiation heat transfer from internal heat sources such as lights and electrical equipment, radiation between surfaces using Hottel's Gray Interchange concept, and convection to the surrounding air. The presence of the surface temperature in the heat balance does not pose any problems since Equation 18.73 will be rearranged to solve for this temperature. Since the radiation heat balance is dependent on conditions at the other surfaces, an iteration loop is required to provide a more accurate estimate of the radiative exchange within the building. This is not the case with the mean air temperature. An assumption of the heat balance is that the mean temperature of the surrounding air is equal to the final air temperature of the previous time step. Using this estimate in the heat balance avoids a second iterative loop around the radiative iteration loop.

Thus, the terms of the heat balance on the left hand side of the equation have been set with the only unknown quantity being T_i , the inside surface temperature at the current time step. On the right hand side of Equation 18.73, most of the terms are already defined since they depend on known values from previous time steps (temperature, flux, and source histories). The only terms which are not defined are the inside surface temperature (T_i), outside surface temperature (T_o), and internal heat source/sink (q_{source}) of the current time step.

The outside surface temperature will depend on the type of environment to which it is exposed. For example, if the surface is a slab on grade floor, the outside surface temperature is

defined as ground temperature and does not require an outside surface heat balance. If the element is an interior surface which has both surfaces exposed to the same air space, the outside surface temperature is redefined to be equal to the inside surface temperature. In cases where the outside surface temperature is not simply defined such as a surface exposed to the exterior environment, a heat balance similar to Equation 18.73 is required to define the outside surface temperature. However, to again avoid iteration, the heat balance equation for the outside surface assumes that conditions at the inside surface were the same as the previous time step. In most cases, since the influence of the current inside surface temperature on the outside surface temperature is very small, this is a valid assumption. In cases where the inside surface temperature has a significant effect, an approximate inside surface heat balance which defines the inside surface temperature is used. This approximate inside balance uses mean air and radiant temperatures from the previous time step.

At this point in the simulation algorithm then, all of the terms in Equation 18.73 have been defined except the value at the current time step of the inside surface temperature and the heat source/sink. Thus, Equation 18.73 can be rewritten in a simpler form:

$$T_{i,t} = C_1 + C_2 q_{source,t} \quad (18.74)$$

where the variable C_1 includes surface heat balance and past history terms as well as the influence of the current outside temperature. The term C_2 will depend on the heat source transfer function term and the coefficients of terms linked directly to $T_{i,t}$.

Equation 18.60, which was the CTF/QTF equation for the temperature at the source location, can be simplified in a similar manner. Grouping the temperature and source history terms which are known quantities together with the effect of the outside surface temperature which is defined as described above, the original equation (Equation 18.60 repeated here):

$$T_{s,t} = \sum_{m=1}^M x_{k,m} T_{i,t-m+1} - \sum_{m=1}^M y_{k,m} T_{o,t-m+1} + \sum_{m=1}^k f_m T_{s,t-m} + \sum_{m=1}^M w_m q_{source,t-m+1} \quad (18.75)$$

can be reduced to:

$$T_s = C_3 + C_4 q_{source,t} + C_5 T_{i,t} \quad (18.76)$$

where C_3 includes all of the history terms and the effect of the current outside temperature, C_4 is the heat source transfer function for the current time step, and C_5 is the conduction transfer function for the inside surface temperature at the current time step.

Substituting Equation 18.74 into Equation 18.76 and noting that $q_{source,t}$ is the same quantity as q in Equations 18.61 and 18.62 results in:

$$T_s = C_3 + C_4 q + C_5 (C_1 + C_2 q) \quad (18.77)$$

When this equation is combined with Equation 18.62, the heat source, which results from a known water inlet temperature, can be shown to be:

$$q = \frac{T_{wi} - C_3 - C_1 C_5}{\frac{1}{\varepsilon(\dot{m}c_p)_{water}} + C_4 + C_2 C_5} \quad (18.78)$$

With both q and T_{wi} known, it is a trivial matter to calculate T_{wo} and T_s from Equations 18.74 and 18.76, respectively. Even though the coefficients in Equation 18.78 are fairly complex, the final equation relating the heat source directly to inlet water temperature is compact and does not require any iteration. As with flux control, once the heat source/sink is defined, the inside surface heat balance can be performed to determine the surface temperatures.

It should be noted that Equations 18.74 through 18.78 are a slight simplification of the actual implementation in EnergyPlus. The development shown above follows the heat balance conventions that assume previous values of the inside temperature to calculate the outside temperature. This, in reality, is not necessary and since the radiant system can be significantly influenced by the delay that such an assumption might cause, the initial implementation of radiant systems in EnergyPlus used a development (shown below) that does not lag either the inside or the outside surface temperature. In effect, we can establish three basic equations for the temperature at the inside and outside surface as well as at the location of the heat source/sink:

$$T_{inside} = C_a + C_b T_{outside} + C_c q'' \quad (18.79)$$

$$T_{outside} = C_d + C_e T_{inside} + C_f q'' \quad (18.80)$$

$$T_{source} = C_g + C_h q'' + C_i T_{inside} + C_j T_{outside} \quad (18.81)$$

where:

T_{inside} is the temperature at the inside surface

$T_{outside}$ is the temperature at the outside surface

T_{source} is the temperature within the radiant system at the location of the source/sink

C_a is all of the other terms in the inside heat balance (solar, LW exchange, conduction history terms, etc.)

C_b is the current cross CTF term

C_c is the QTF inside term for the current heat source/sink

C_d is all of the other terms in the outside heat balance (solar, LW exchange, conduction history terms, etc.)

C_e is the current cross CTF term (should be equal to C_b)

C_f is the QTF outside term for the current heat source/sink

C_g is the summation of all temperature and source history terms at the source/sink location

C_h is the QTF term at the source/sink location for the current heat source/sink

C_i is the CTF inside term for the current inside surface temperature

C_j is the CTF outside term for the current outside surface temperature.

Equations 18.79 and 18.80 above can be solved to remove the other surface temperature. Substituting the new equations for T_{inside} and $T_{outside}$ as a function of C and q'' into the equation for T_{source} and simplifying results in the following equation:

$$T_{source} = C_k + C_l q'' \quad (18.82)$$

where:

$$C_k = C_g + \frac{C_i (C_a + C_b C_d) + C_j (C_d + C_e C_a)}{1 - C_e C_b} \quad (18.83)$$

$$C_l = C_h + \frac{C_i (C_c + C_b C_f) + C_j (C_f + C_e C_c)}{1 - C_e C_b} \quad (18.84)$$

Combining this with heat exchanger analysis as shown above, we eventually arrive at the following equation to relate the flux to the slab to the water inlet temperature and mass flow rate:

$$q'' = \frac{T_{water,in} - C_k}{\frac{C_l}{A} + \frac{1}{\varepsilon(\dot{m}c_p)_{water}}} \quad (18.85)$$

which includes all of the inside and outside heat balance terms (“hidden” in the C_k and C_l coefficients). Once the flux to the slab is known, the remaining terms of interest (outlet water temperature, inside and outside surface temperatures, etc.) can be calculated using the relatively simpler equations shown above.

Note that the above development is valid for both the hydronic (variable flow) low temperature radiant system and for constant flow (variable temperature) low temperature radiant systems where the inlet temperature is known (based on controls). However, when due to loop conditions and the presence of recirculation, it is not possible to know the inlet temperature to the radiant system without simulating it, we must either iterate or perform more mathematics to arrive at the inlet temperature. The implementation in EnergyPlus chose to avoid iteration and solved for the inlet temperature as shown in the next paragraphs.

The previous equation combines with the following equation which is valid for an surface in the current radiant system:

$$q_j = \dot{m}_j c_p (T_{water,in} - T_{water,out,j}) \quad (18.86)$$

where q_j is the heat transfer to the j th surface in the radiant system, \dot{m}_j is the mass flow rate only to this surface, and $T_{water,out,j}$ is the outlet temperature for the j th surface. Combining the previous two equations results in:

$$(T_{water,in} - T_{water,out,j}) = \frac{\varepsilon_j (T_{water,in} - C_{k,j})}{1 + \frac{\varepsilon_j \dot{m}_j c_p C_{l,j}}{A}} \quad (18.87)$$

If for each surface in the radiant system, we let:

$$C_{m,j} = \frac{\varepsilon_j}{1 + \frac{\varepsilon_j \dot{m}_j c_p C_{l,j}}{A}} \quad (18.88)$$

then the previous equations become the slightly less complex:

$$(T_{water,in} - T_{water,out,j}) = C_{m,j} (T_{water,in} - C_{k,j}) \quad (18.89)$$

Rearranging to obtain the outlet temperature for the j th surface:

$$T_{water,out,j} = (1 - C_{m,j}) T_{water,in} + C_{m,j} C_{k,j} \quad (18.90)$$

The overall outlet temperature from the radiant system is just a simple mixing of all of the surface outlet temperatures based on flow fraction and results in $T_{water,out}$.

An energy balance on the mixing valve-pump group results in the following equation that relates the radiant system inlet temperature ($T_{water,in}$) to the loop inlet water temperature ($T_{loop,in}$), the radiant system outlet temperature ($T_{water,out}$), and the pump heat addition:

$$T_{\text{water,in}} = \frac{\dot{m}_{\text{loop}}}{\dot{m}_{\text{system}}} T_{\text{loop,in}} + \frac{\dot{m}_{\text{recirc}}}{\dot{m}_{\text{system}}} T_{\text{water,out}} + \frac{PumpHeat}{\dot{m}_{\text{system}} c_p} \quad (18.91)$$

Plugging in the definition of $T_{\text{water,out}}$ based on the summation of $T_{\text{water,out},j}$ equations results in:

$$T_{\text{water,in}} = \frac{LoopTerm + RecircTerm}{Twicoeff} \quad (18.92)$$

where:

$$LoopTerm = \frac{\dot{m}_{\text{loop}}}{\dot{m}_{\text{system}}} T_{\text{loop,in}} + \frac{PumpHeat}{\dot{m}_{\text{system}} c_p} \quad (18.93)$$

$$RecircTerm = \frac{\dot{m}_{\text{recirc}}}{\dot{m}_{\text{system}}} \sum_j \text{FlowFraction}_j T_{\text{water,out},j} \quad (18.94)$$

$$Twicoeff = \left(1 - \frac{\dot{m}_{\text{recirc}}}{\dot{m}_{\text{system}}} \right) \sum_j [\text{FlowFraction}_j (1 - C_{m,j})] \quad (18.95)$$

Once the actual water inlet temperature is calculated with this equation, it is then possible to calculate individual outlet temperatures for each surface, the overall outlet temperature, and finally all of the necessary flow and loop quantities. This procedure avoids iteration but is somewhat complex to follow. However, this second mathematical process is only needed for select cases of the constant flow radiant system when the inlet temperature is not known explicitly. With the proper establishment of input data, it can be avoided.

NOTE: In some “low-energy” applications, it is possible that during cooling mode the elevated water temperatures may result in a heat source (or net heating) to the radiant system. To avoid heating the slab when cooling is desired, EnergyPlus performs a temperature limit check. If heating would result during cooling mode or cooling during heating mode, the model will cut-off the flow rate until the inlet water temperature will produce the proper effect.

18.1.2 High Temperature Radiant Heater Model

The input object ZoneHVAC:HighTemperatureRadiant provides a model for a high temperature radiant heater that is intended to encapsulate an entire class of heating devices that seek to heat the occupants within a zone by direct radiation. This encompasses a wide variety of heaters including both gas-fired and electric. In most cases, the heater appears much like a lamp or a tube that is suspended from the ceiling of a space, and the surface temperatures are high enough that the heaters must be a safe distance away from the occupied portion of the space for safety concerns.

In EnergyPlus, the high temperature radiant heater model allows the user a reasonable amount of flexibility. Rather than specifying an exact location for the radiant heater(s), the user is allowed to specify the percentage of heat leaving the heater as radiation and then on which surfaces this radiation is incident. In addition, the user is also allowed the ability to define what fraction of radiation leaving the heater is incident directly on a person within the zone for thermal comfort purposes. This amount of heat is then used in the thermal comfort models as shown in Equations 19.7 for Fanger, 19.26 for Pierce Two-Node and 19.50 for KSU Two-node. These equations

are similar in form to the equation promoted by Fanger (1970). The input parameters for the high temperature radiant heater model are shown below.

$$T_{\text{radiant}} = \left[(T_{\text{MRT}}^4) + \left(\frac{Q_{\text{heater} \rightarrow \text{person}}}{\sigma A_{\text{person}}} \right) \right]^{0.25} \quad (18.96)$$

The input for the high temperature radiant heater has two additive relationships that are assumed. First, the fractions of radiant, convective, latent, and lost heat must sum to unity. The user is required to enter the fractions radiant, latent, and lost with the remainder assumed to be convective energy. The fraction latent is added to the latent energy balance and will affect moisture levels within the zone. The fraction lost is assumed to have no impact on the energy balance of the zone and is assumed to be lost or vented to the exterior environment.

The second additive relationship is within the distribution of the radiant fraction. This energy is distributed to people and to the surfaces within the zone. The sum of all of these distribution fractions (the last six lines of input shown above) must sum to unity. Note that each high temperature radiant heater is allowed to distribute energy to up to 20 surfaces and that radiant energy placed on a surface using these distribution fractions is assumed to be completely absorbed. Thus, the distribution fractions should also take into account any differences in long wavelength absorptivity among the surfaces.

Several things should be noted about the fraction of heat that is radiated directly to people. This parameter is somewhat sensitive and will have a direct impact on the thermal comfort models. This is exactly the intent of the high temperature radiant heaters; however, one must use caution when determining this fraction since overestimation of this number might lead to predictions of thermal comfort where in fact it does not exist. In addition, this fraction of radiant energy to people does not have a direct impact on any of the surface heat balances. The thermal comfort energy balance is completely separate from and has no bearing on the zone air or the surface heat balances. Thus, in order to not “lose” this amount of energy from the perspective of the zone air or the surface heat balances, the model assumes that any radiation from the high temperature radiant heater that

is incident directly on people is accounted for in the thermal comfort model using Equation 18.96 but is also assumed to be added to the zone air heat balance via convection from people to the surrounding air. This guarantees that the people within the space feel the direct radiative effect of the heaters and that this quantity of energy is not “lost” within the heat balance routines.

Many of the control and integration aspects of the high temperature radiant system model in EnergyPlus are very similar to the low temperature radiant system model. The controls are the same as shown in “Figure 18.9. Variable Flow Low Temperature Radiant System Controls” where the amount of heat generated by the radiant heater varies as a function of the difference between the controlling and the setpoint temperatures. As with the low temperature radiant system, the controlling temperature is allowed to be the mean air, the mean radiant, or the operative temperature, and the setpoint temperature is allowed to vary hourly based on a user defined schedule. (Operative temperature for radiant system controls is the average of MAT and MRT.) Also, since the high temperature radiant heater has a direct impact on the surfaces within a zone, the surface heat balances are recalculated to determine an approximate response to the radiation from the heater. A final “average” heat balance calculation is done after all of the system time steps have been simulated to maintain continuity within the surface heat balances. The algorithm shown in “Figure 18.12. Resolution of Radiant System Response at Varying Time Steps is also used for high temperature radiant heaters.

18.1.3 Simple Cooling Panel

18.1.3.1 Overview

The simple chilled ceiling model (ZoneHVAC:CoolingPanel:RadiantConvective:Water) is similar to the high temperature radiant system and the hot water radiant/convective baseboard models and was developed to make the modeling of certain radiant systems easier. The existing chilled beam model in EnergyPlus, while useful for modeling active chilled beam systems, is a convective heat transfer only model that is not suitable for all radiant panels or passive chilled beam systems.

18.1.3.2 Modeling Considerations/Assumptions

The model is intended to be simple so several assumptions have been made regarding the performance of this system type:

- Water is flowing through a pipe and that the water has a known inlet temperature defined by the plant loop. The outlet water temperature is unknown and must be calculated as part of the simulation process.
- No information regarding the shape or material of the chilled ceiling panel is required as this is intended to be a simple model only.
- The air conditions of the space are known quantities and though the presence of this system will potentially impact this temperature, it will be assumed that the air temperature is “constant” for the time step in question.
- The entity being modeled is essentially a heat exchanger with flowing water on one side and air on the other.
- Since the water is changing temperature but the air is “not”, we effectively have a similar sort of heat exchanger formulation as the low temperature radiant heating system, but here the water temperature varies while the air temperature is “constant”. Thus, an effectiveness-NTU

heat exchanger formulation is best and allows the calculation of total heat gain to the panel and outlet water temperature.

- The total net heat loss to the zone is determined using a user defined coefficient to calculate a zone temperature. This “fraction” radiant parameter defines what portion of the zone temperature is based on the zone MRT with the remainder determined by the zone MAT. While this user defined coefficient remains constant throughout the simulation in keeping with the simple nature of this model, it is not the same as defining a fixed radiant/convective split since this will vary with changing MRT and MAT. More information on this is given below.
- The load met by the system is included in the zone air heat balance just as with any other system. The impact of the system includes the convective load, the radiant gain that is distributed to people (assumed that it is converted into a convective loss), and the increased convection loss from the zone surfaces.
- The radiant loss/gain is distributed to the surfaces as per the radiant surface list that lists which surfaces the radiant cooling panel will interact with and what fraction of radiation each surface will “see”. This is similar to the existing radiant-convective baseboard model and these fractions are user inputs.
- The model is an HVAC level model but interacts with the zone heat balances much like the radiant system and radiant/convective baseboard models.
- Controls are based on controlling water flow rate (like the hydronic radiant system) to meet the thermostatic setpoint temperature of the unit with control types options including MAT, MRT, OpTemp, ODB, or OWB much like the low temperature radiant systems. Controls based on standard air system thermostatic controls are also possible.
- In the event that condensation is predicted on the surface of a panel, the model uses the same condensation control options as the low temperature radiant system. These include: ignoring the problem and allowing the simulation to continue, shutting the system down when condensation is predicted, and a variable response that tries to keep the system running at a lower output while avoiding condensation conditions.
- In order to avoid any violations of the Second Law of Thermodynamics or heating by the system, the cooling panel will be shut off if the inlet water temperature is above the zone temperature.

18.1.3.3 Algorithm Details: Unit Performance and Calculation of the UA Value

As stated above in the assumptions, the most prudent simple method for calculating the performance of a radiant cooling panel is to use a heat exchanger style formulation. Since the air within the space (and the other surfaces of the space) will presumably be at a “constant” temperature while the water flowing through the panel will change temperature, we have a situation where one fluid is changing temperature and one remains at the same temperature. This is very similar to the low temperature radiant system models which use the effectiveness-NTU method for calculating heat exchange between the water in the loop and the slab in which the pipes are embedded. A summary of how this is modeled for the radiant cooling panel follows in the next paragraphs.

Several heat balances can be constructed that relate to the situation at hand. First, a heat balance on the water loop results in:

$$q = (\dot{m}c_p)_{water} (T_{wi} - T_{wo}) \quad (18.97)$$

where q is the energy transferred between the water loop and the surrounding space to which

the cooling panel is exposed, \dot{m} is the mass flow rate of the water, c_p is the specific heat of the water, T_{wi} is the inlet water temperature and T_{wo} is the outlet water temperature.

The maximum amount of heat transfer that is possible according to the Second Law of Thermodynamics is:

$$q_{max} = (\dot{m}c_p)_{water} (T_{wi} - T_z) \quad (18.98)$$

where q_{max} is the maximum possible energy transfer and T_z is the temperature of the surroundings (assumes that the air and the unconditioned surfaces in the space are at the same temperature for the sake of this development and the calculation of a UA; more explanation of T_z is given in the next section).

The ratio of the actual energy exchange to the maximum possible is known as the effectiveness of the heat exchanger, ε :

$$\varepsilon = \frac{q}{q_{max}} \quad (18.99)$$

For the case when one fluid is stationary in a heat exchanger, Incropera and DeWitt (1985) state that the effectiveness of a heat exchanger can be related to the number of transfer units (NTU) through the following relation:

$$\varepsilon = 1 - e^{-NTU} \quad (18.100)$$

and NTU is defined by:

$$NTU = \frac{UA}{(\dot{m}c_p)_{water}} \quad (18.101)$$

The above equations will be used to model the performance of the panel within EnergyPlus and also to obtain a “design” UA value for the panel.

Calculating the UA value of a cooling panel or coming up with a relationship for such a term is not a simple matter. However, most devices are either rated or tested by the manufacturer under certain conditions. From this rating information, a UA value can be calculated. The EnergyPlus model requests rating information (inlet water temperature, mass flow rate, “air” temperature, and panel output under rating conditions) and then uses it to calculate a UA value that is used to model the performance of the panel.

The development of the method for estimating the panel UA value uses the same equations shown above but simply with the purpose of calculating UA rather than the performance of the device, i.e. determining the output of the panel. The method for estimating the UA value of the panel begins with the panel rating data that includes the following values:

- Rating Inlet Water Temperature (T_{rwi})
- Rating Air/Surroundings Temperature (T_{rz})
- Rating Water Mass Flow Rate (\dot{m}_r)
- Rated Output Capacity (Q_r)

To find UA, first rearrange the equations above to make NTU a function of effectiveness as follows:

$$\varepsilon = 1 - e^{-NTU} \quad (18.102)$$

$$NTU = -\ln(1 - \varepsilon) \quad (18.103)$$

where $\varepsilon = Q_r/q_{max}$ and q_{max} is calculated using design conditions. This leads to:

$$NTU = -\ln\left(1 - \frac{Q_r}{(\dot{m}_r c_p)_{water}(T_{rwi} - T_{rz})}\right) \quad (18.104)$$

Finally, substituting the definition of NTU as shown above, one can obtain an equation for UA that is calculated directly from the rated values that the user supplies:

$$UA = -(\dot{m}_r c_p)_{water} \ln\left(1 - \frac{Q_r}{(\dot{m}_r c_p)_{water}(T_{rwi} - T_{rz})}\right) \quad (18.105)$$

This UA value is used by the simple model to calculate the output of the radiant cooling panel based on the current water inlet temperature and mass flow rate as well as the space temperature (combination of air and radiant temperature) as described below.

18.1.3.4 Algorithm Details: Zone Temperature for Radiant Panel Output and “Fraction Radiant” Input

The output from the panel will be based on the mean air temperature (MAT) and the mean radiant temperature (MRT) from the space. These two temperatures are combined to create a “zone” temperature that is used in the model to calculate the radiant cooling panel output. As shown in the previous section, a UA value is calculated using rated conditions. This UA value is assumed to be constant and used in conjunction with the effectiveness-NTU method described in the previous section to determine the output of the panel based on water inlet temperature, water mass flow rate, and space conditions. The space conditions take into account both the mean air temperature and the mean radiant temperature via the following equation:

$$T_z = x_r MRT + (1 - x_r) MAT \quad (18.106)$$

where x_r is the “Fraction Radiant” for the radiant cooling panel that the user provides.

This is then used in the equation for q_{max} above to calculate the maximum possible panel output. Knowing UA and knowing what the water mass flow rate for the system is based on controls, the NTU parameter can be calculated. Once NTU is calculated, the effectiveness can be computed and used with the maximum possible panel output to calculate the actual panel output (q) from:

$$q = \varepsilon q_{max} \quad (18.107)$$

Thus, the modeling equation to find the panel output is:

$$q = \left(1 - e^{\frac{-UA}{(\dot{m}c_p)_{water}}}\right) (\dot{m}c_p)_{water} (T_{wi} - T_z) \quad (18.108)$$

Using the results of the above equation, the outlet water temperature can also be calculated using a rearranged form of the water loop heat balance equation given at the beginning of this section.

There has been some concern expressed that the “Fraction Radiant” value (x_r) used to calculate the zone temperature (T_z) is difficult to estimate and that the correct modeling of the performance

of certain models, particularly the high temperature radiant heater, are highly dependent on having a good estimate for this value. The high temperature radiant heater is a high output device that is highly radiant and the control of these high output devices can be difficult to simulate. The radiant cooling panels discussed here are generally not high output devices. A reasonable estimate for x_r , generally falls within a range of 0.6-0.7 when calculating T_z above. While this value could vary for different scenarios, choosing a value within this range should be a reasonable approximation of the performance of a radiant cooling panel and should not result in significant inaccuracies in the model.

18.2 Refrigeration Equipment

18.2.1 Overview

EnergyPlus can model refrigerated case equipment consisting of a compressor rack, multiple refrigerated cases and walk-in coolers, secondary loop equipment, and optional heat reclaim air and water heating coils. The refrigerated case equipment models perform four major functions:

- calculate the electric consumption of refrigerated cases and walk-in coolers connected to a compressor rack
- determine the impact of refrigerated cases and walk-in coolers on zone cooling and dehumidification loads (i.e., case credits), including the effects of HVAC duct configuration
- calculate the electric consumption and COP of the compressor rack, and the electric and water (if applicable) consumption related to cooling the compressor rack’s condenser.
- determine the total amount of heat rejected by the compressor rack’s condenser and store this information for use by waste heat recovery models (e.g., using Desuperheater heating coil (object: Coil:Heating:Desuperheater) as an air reheat coil for high humidity control in a supermarket)

The case and walk-in models account for nearly all performance aspects of typical supermarket refrigeration equipment. Refrigerated case and walk-in performance are based on the combined effects of evaporator load, fan operation, lighting, defrost type, and anti-sweat heater operation. Optional air and water heating coils can be modeled to reclaim available waste heat (superheat) from the compressor rack.

The user has two options when describing the balance of the system. Energy used to cool the condenser is simulated in both approaches. The simplest option is to use a compressor rack object, combining the compressors and condenser into a single unit with the performance determined by

the heat rejection environment and the total case load. An example schematic of a compressor rack system is shown in Figure 18.13 below.

A detailed refrigeration system object models compressor and condenser performance separately. The detailed refrigeration system also includes the ability to transfer refrigeration load from one system to another using subcoolers, cascade condensers, and secondary loops. An example schematic of the detailed refrigeration system is shown in Figure 18.14 below. Subcooler #2 is shown twice on Figure 18.14 because it represents a liquid suction heat exchanger. This type of subcooler uses the cool suction gas to subcool the warmer condensed liquid. Subcoolers #1 and #3 on Figure 18.14 represent mechanical subcoolers. These subcoolers are used to subcool the condensate on a lower-temperature system using the cold liquid refrigerant from a higher temperature system. On this example, only subcoolers #1 and #2 would be defined as a part of the refrigeration system. However, subcooler #3 would place a refrigerating load, similar to the load of a refrigerated case, on the system.

Figure 18.13: Typical Compressor Rack Equipment Schematic

Four classes of secondary refrigeration loops can be modeled:

- a separate water loop is used to remove heat rejected by the condenser,
- a lower-temperature refrigeration system rejects heat to a higher-temperature refrigeration system via a cascade condenser,
- a fluid, such as a brine or glycol solution, is cooled in a secondary evaporator and is then circulated to chill the refrigerated cases and walk-ins, and
- a refrigerant, such as CO_2 , is partially evaporated in the refrigerated cases and walk-ins in a liquid-overfeed circuit, and then condensed in a secondary evaporator.

The first two classes of secondary loops are modeled using Refrigeration:System objects with Refrigeration:Condenser:WaterCooled and Refrigeration:Condenser:Cascade objects, respectively. Figure 18.14 shows how cascade condensers and secondary evaporators are treated as

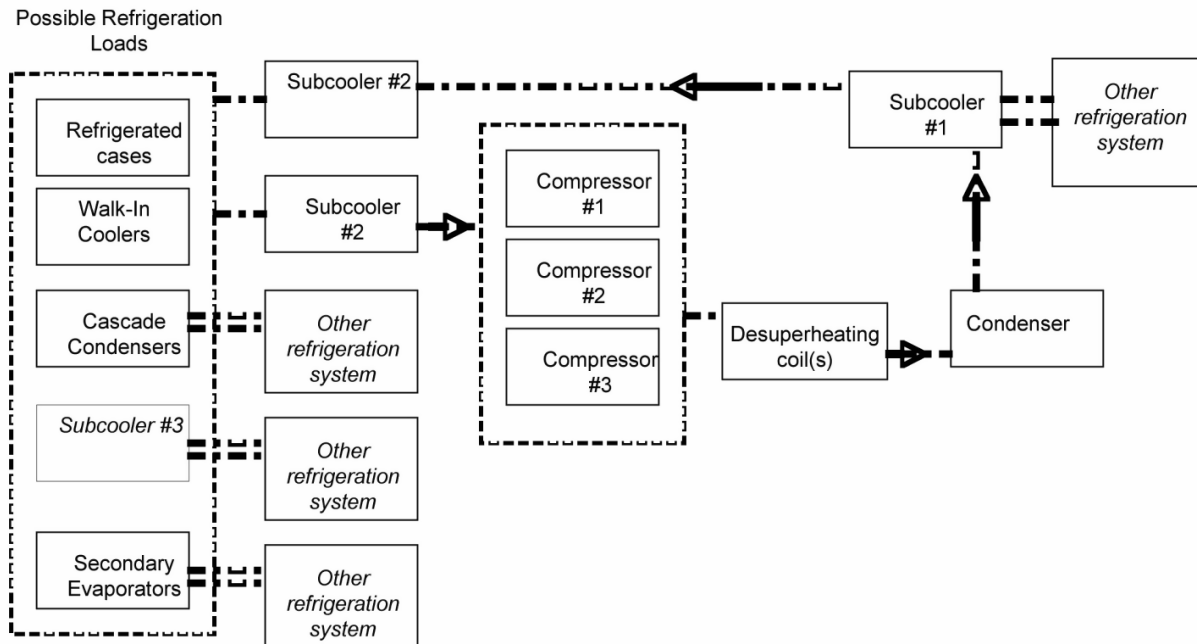

Figure 18.14: Typical Detailed Refrigeration System Equipment Schematic

a refrigeration load on a primary detailed system. The second two classes are modeled with a `Refrigeration:SecondarySystem` object described later in this section.

The compressor rack, detailed and secondary refrigeration systems, refrigerated case, and other component models are described below. The optional air and water heating coils are described elsewhere in this document (Ref. objects `Coil:Heating:Desuperheater` and `Coil:WaterHeating:Desuperheater`).

18.2.2 Refrigeration Compressor Racks

The refrigerated case compressor rack object works in conjunction with the refrigerated case and walk-in cooler objects (`Refrigeration:Case` and `Refrigeration:WalkIn`) to simulate the performance of a simple supermarket-type refrigeration system. This object (`Refrigeration:CompressorRack`) models the electric consumption of the rack compressors and the cooling of the compressor rack's condenser. Heat removed from the refrigerated cases and walk-ins and compressor/condenser fan heat can be rejected either outdoors or to a zone. Compressor rack condenser waste heat can also be reclaimed for use by an optional air heating coil (Ref. object `Coil:Heating:Desuperheater`) or by a user-defined plant water loop (Ref. object `Coil:WaterHeating:Desuperheater`).

The performance of the compressor rack is simulated using the sum of the evaporator loads for all refrigerated cases and walk-ins connected to the rack. Whether a single refrigerated case is connected to a rack (e.g., stand-alone refrigerated case, meat cooler, or produce cooler) or several cases are connected to a rack, the rack electric consumption is calculated based on the total evaporator load for the connected cases and walk-ins and the coefficient of performance (COP) for the compressor rack. At least one refrigerated case or walk-in must be connected to the compressor rack. The model assumes the compressor rack has sufficient capacity to meet the connected refrigeration load for any simulation time step. Additionally, the model neglects compressor cycling losses at part-load conditions.

For condenser heat rejection to the outdoors, condenser cooling can be modeled as dry air cooling, wet evaporative cooling, or water loop cooling. Using evaporative cooling rather than dry air cooling will allow for more efficient condenser heat rejection based on the entering air approaching the wet-bulb temperature rather than the dry-bulb temperature. Analyses under the International Energy Agency’s (IEA) Heat Pumping Programme Annex 26 indicates that this measure can improve refrigeration system efficiency by up to 10% (IEA 2003). The use of an evaporative-cooled condenser requires a water pump and, optionally, a basin sump water heater (to protect against freezing). Makeup water will also be required to replace that lost by evaporation. In colder climates, some evaporative-cooled condensers are drained for the winter months and run as dry air units. This scenario can be modeled by using an optional evaporative condenser availability schedule.

The simulation of the evaporative cooled condenser utilizes an effective air dry-bulb temperature that is assumed to be the result of evaporation of water in the air stream (similar to object `EvaporativeCooler:Direct:CelDekPad`). As discussed below, this effective temperature is used by performance curves that are a function of temperature. While some designs of evaporative coolers use water film cascading across the condenser coil for evaporative cooling, the current model uses the effective temperature method as a surrogate for the more complex water film on coil calculations.

If the condenser heat rejection is specified as water cooled, an appropriate plant water loop must be defined by the user (see documentation on *Plant/Condenser Loops* for additional details about plant loops). This will include defining cooling supply components, such as pumps, water storage tanks, and cooling towers, as well as related branches, nodes, and connectors. The heat rejection from the refrigeration condenser is modeled as a cooling demand, which is satisfied by heat extraction devices (e.g., water tank and cooling tower) on the cooling supply side of a water loop. An example of such an arrangement is shown in Figure 18.15.

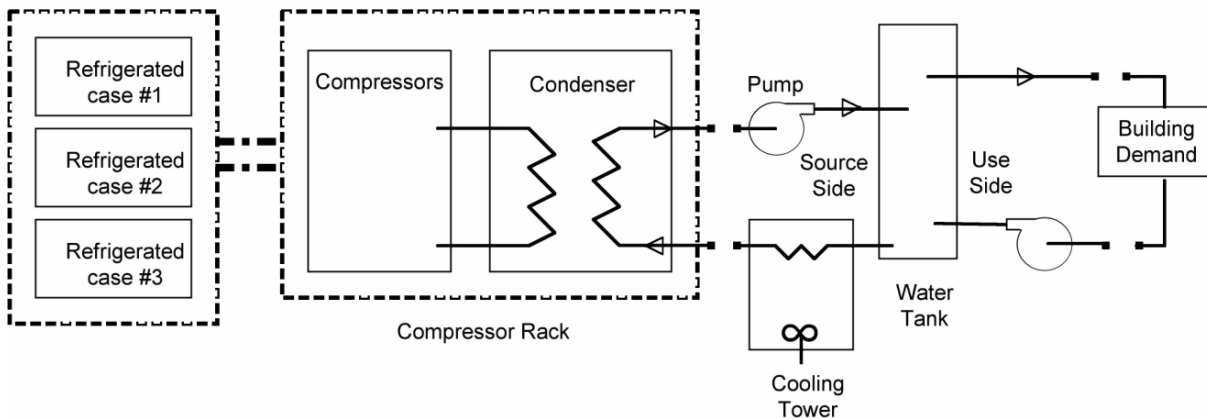

Figure 18.15: Example Of Condenser Heat Recovery To Water Storage Tank

18.2.2.1 Compressor Energy Use

Calculation of compressor rack electric power uses a simple model based on the total evaporator load (sum of the evaporator loads for all refrigerated cases and walk-ins connected to a rack) and the compressor rack operating COP which accounts for the air temperature entering the condenser:

$$COP_{operating} = COP_{design}(COPfTemp) \quad (18.109)$$

where:

$COP_{operating}$ is the compressor coefficient of performance at actual operating conditions (W/W)

COP_{design} is the compressor coefficient of performance at design conditions (W/W)

$COPfTemp$ is the output of the normalized “Compressor Rack COP as a Function of Temperature Curve” (dimensionless).

Because the COP curve is defined only as a function of the condensing temperature, it is important that this curve definition corresponds to the lowest evaporating temperature served by the compressor rack. The air temperature used to evaluate the “Compressor Rack COP as a Function of Temperature Curve” depends on where the compressor rack’s condenser is located (Heat Rejection Location). When modeling condenser heat rejected directly to a zone (typical of a stand-alone packaged refrigerated case with integral condenser located in a building zone), the zone air dry-bulb temperature is used to calculate the change in compressor COP from the design value. If more than one refrigerated case and no walk-ins are attached to a compressor rack that rejects its condenser heat to a zone, then all cases served by this rack must reside in the same zone. When modeling a compressor rack serving at least one walk-in, OR with condenser heat rejected to outdoors, the refrigerated cases and walk-ins connected to this rack may be located in different zones. If the condenser type is specified as “Air Cooled”, the outdoor air dry-bulb temperature is used to evaluate the “Compressor Rack COP as a Function of Temperature Curve.” If the condenser type is specified as “Evap Cooled”, the air temperature leaving the condenser is related to the effectiveness of the evaporative cooling system. If the evaporative process were 100% effective, the effective temperature of air leaving the evaporative media would equal the air wet-bulb temperature. However, the efficiency of the direct evaporative process is typically less than 100%, and the effective temperature leaving the condenser is determined by:

$$T_{effective} = T_{owb} + (1 - \varepsilon) * [T_{odb} - T_{owb}] \quad (18.110)$$

where:

$T_{effective}$ is the effective dry-bulb temperature of air leaving the condenser cooling coil (°C)

T_{owb} is the outdoor air wet-bulb temperature (°C)

T_{odb} is the outdoor air dry-bulb temperature (°C)

ε is the evaporative condenser effectiveness.

If the user is modeling an evaporative cooled condenser and is using COPfTemp curve data (e.g., manufacturer’s data) based on wet-bulb temperature rather than dry-bulb temperature, the evaporative condenser effectiveness should be set to 1.0 for consistency.

If the condenser is water cooled, the effective temperature experienced by the condenser is based on the return water temperature from the plant loop heat rejection system (e.g., cooling tower) that is defined by the user. This return water temperature is typically related to the outdoor ambient conditions at each time step.

The electric power input to the rack compressor(s) is calculated for each simulation time step as the sum of the connected refrigerated case evaporator loads divided by the operating COP:

$$P_{rack} = \frac{\sum \dot{Q}_{case} + \sum \dot{Q}_{walkin}}{COP_{operating}} \quad (18.111)$$

where:

P_{rack} is the output variable “Refrigeration Compressor Rack Electric Power [W]”, electric power input to the rack compressor(s)

\dot{Q}_{case} is the evaporator load for each refrigerated case connected to the rack (W)

\dot{Q}_{walkin} is the refrigeration load for each walk-in connected to the rack (W).

18.2.2.2 Condenser Heat Rejection, Energy Use, and Water Use

The compressor rack can reject heat to an air-, water-, or evaporative-cooled condenser. The condenser type determines the heat rejection temperature used for the compressor rack COP calculation. The compressor rack also allows superheat heat reclaim and heat rejection to a conditioned zone.

18.2.2.2.1 Condenser Fan Energy Use

Condenser fan power for any simulation time step is calculated by multiplying the design fan power by the condenser fan power as a function of temperature curve.

$$P_{CondFan} = P_{CondFan,design} (CondFanfTemp) \quad (18.112)$$

where:

$P_{CondFan}$ is the output variable “Refrigeration Compressor Rack Condenser Fan Electric Energy [W]”

$P_{CondFan,design}$ is the design condenser fan power (W)

$CondFanfTemp$ is the output of the optional “Condenser Fan Power as a Function of Temperature Curve”.

Similar to the compressor rack energy use described above, the air temperature used to evaluate the “Condenser Fan Power as a Function of Temperature Curve” depends on where the condenser rack’s condenser is located (i.e., zone air dry-bulb temperature if the condenser is located in a zone, outdoor air dry-bulb temperature if the condenser is located outdoors and is specified as air cooled, or effective temperature if the condenser is outdoors and is specified as evaporative cooled). If the sum of the evaporator loads for the refrigerated cases connected to the rack is equal to zero, the condenser fan power is set equal to zero. If the user does not provide a “Condenser Fan Power as a Function of Temperature Curve”, then the model assumes the condenser fan power is at the design power level when any of the refrigerated cases connected to this rack are operating.

If the user is modeling an evaporative cooled condenser and is using CondFanfTemp curve data based on wet-bulb temperature rather than dry-bulb temperature, the evaporative condenser effectiveness should be set to 1.0 for consistency.

For a water cooled condenser, there is no fan load at the condenser (i.e., the water/refrigerant heat exchanger). Any fan load would be related to and accounted for at the heat rejection object (e.g., cooling tower).

18.2.2.2.2 Superheat Reclaim Heating Coil

EnergyPlus can simulate waste heat being reclaimed from a compressor rack for use by a refrigerant-to-air or refrigerant to water heating coil. Heat reclaimed from the compressor rack is assumed to be recovered from the superheated refrigerant gas leaving the compressor(s) and does not directly impact the performance of the compressor rack or refrigerated cases connected to the rack. The total heat rejected by the condenser (in Watts) is calculated each time step as follows:

$$\dot{Q}_{condenser} = \left(\sum \dot{Q}_{case} + \sum \dot{Q}_{walkin} \right) \left(1 + \frac{1}{COP_{operating}} \right) \quad (18.113)$$

The heat reclaim heating coil is able to transfer a fixed percentage of this total amount of rejected energy (not to exceed 30%) and use it to heat air and water. Refer to objects Coil:Heating:Desuperheater and Coil:WaterHeating:Desuperheater for a complete description of how these coils are modeled.

NOTE: When modeling a heat reclaim coil, the heat rejection location in the Refrigeration:CompressorRack object must be “Outdoors”. If the compressor rack heat rejection location is “Zone”, the total amount of waste heat available for reclaim (e.g., by a desuperheater heating coil) is set to zero by the compressor rack object and the simulation proceeds.

18.2.2.2.3 Heat Rejection to Zone

The compressor rack model can simulate condenser heat being rejected to a zone. As explained previously, if this heat rejection option is selected then all refrigerated cases connected to the rack must be located in the same zone and a superheat heat reclaim heating coil can not be modeled (Ref. Superheat Reclaim Heating Coil).

The refrigerated case and walk-in objects (Refrigeration:Case and Refrigeration:WalkIn) already calculate and report the sensible case credits which impact the zone air heat balance (Ref. Sensible Case Credits). When refrigerated cases and/or walk-ins are served by a compressor rack that rejects condenser waste heat directly to the zone (e.g., a stand-alone refrigerated case with integral compressor and condenser), this condenser waste heat also impacts the zone air heat balance and offsets some or all of the sensible case credits.

If only cases are served, the amount of condenser waste heat rejected to the zone and/or the HVAC return air (zone return air path outlet node) is calculated and reported by the refrigerated case compressor rack object as follows:

$$\dot{Q}_{Zone,heating} = \frac{\sum (\dot{Q}_{case}[1 - RAF])}{\sum (\dot{Q}_{case})} (\dot{Q}_{condenser} + P_{CondFan}) \quad (18.114)$$

$$\dot{Q}_{HVAC,heating} = (\dot{Q}_{condenser} + P_{CondFan}) - \dot{Q}_{zone,heating} \quad (18.115)$$

where:

$\dot{Q}_{Zone,heating}$ is the output variable “Refrigeration Compressor Rack Zone Sensible Heating Rate” (W)

RAF is the return air factor for each case connected to the rack (Ref. Figure 18.16)

$\dot{Q}_{HVAC,heating}$ is the output variable “Refrigeration Compressor Rack Return Air Sensible Heating Rate” (W).

If the HVAC system is off for a simulation time step (no return air mass flow), the rack condenser heat normally attributed to the HVAC return is set equal to zero and all condenser heat energy is applied to the zone air heat balance.

If, however, walk-in cooler(s) are also served by this compressor rack, no condenser heat is rejected to the HVAC return air. For walk-in cooler(s), the user must specify the zone that accepts the condenser heat rejection (because walk-ins can exchange heat with multiple zones). In that case:

$$\dot{Q}_{Zone,heating} = \dot{Q}_{condenser} + P_{CondFan} \quad (18.116)$$

18.2.2.2.4 Water Cooled Condenser

If the refrigeration condenser is water cooled, a water plant loop must be defined in the input file. At a minimum, the loop must contain a pump and one or more heat sinks of sufficient capacity to remove the condenser heat load. In the system shown in Figure 18.15, the heat sinks are the water heater tank and the cooling tower. The water pump in the loop can be either constant (Ref. Pump:ConstantSpeed) or variable speed (Ref. Pump:VariableSpeed). A variable speed pump permits the loop flow to vary and allows for a setpoint to be established on the condenser outlet water temperature. As the refrigeration condenser heat load varies through time, the speed of the pump can be adjusted to achieve a mass flow consistent with a desired outlet water temperature according to

$$\dot{m} = \frac{Q_{condenser}}{c_p \cdot (T_{out} - T_{in})} \quad (18.117)$$

where:

\dot{m} is the mass flow in the water loop

$Q_{condenser}$ is the heat rejected by the condenser

c_p is the specific heat of water

T_{out} is the desired water outlet temperature

T_{in} is the return water inlet temperature.

The desired water outlet temperature is specified using a schedule, subject to a maximum water outlet temperature (input specified). The maximum temperature is typically defined by constraints on the refrigerant loop pressures and temperatures. The desired mass flow in the water loop to meet the temperature schedule is also compared to the user-supplied maximum flow rate. If the desired mass flow is greater than the maximum allowed flow, the flow rate is set to the maximum value and the resulting water outlet temperature is determined.

The return water inlet temperature is a function of the cooling system defined by the user. A minimum return water temperature may need to be taken into consideration to prevent lowering the resulting refrigerant condensing pressure to the point that refrigerant expansion valve operation becomes impaired. When ambient conditions produce low temperature warnings based on the minimum return water temperature, an outlet temperature setpoint control may need to be placed on the water heat sink object (e.g., cooling tower) to keep the return water temperature above the minimum.

If the water loop flow is constant (i.e., driven by a constant speed pump), then the outlet water temperature will vary with the amount of heat rejected by the condenser. Using the equation above, the resulting water outlet temperature is calculated as

$$T_{out} = \frac{Q_{condenser}}{c_p \cdot \dot{m}} + T_{in} \quad (18.118)$$

18.2.2.2.5 Evaporative Condenser Water Pump

If the condenser type is specified as “Evap Cooled”, a water pump is required to circulate water in the evaporative condenser. The pump power can be input directly or be autocalculated using a relationship of 0.004266 W per watt [15 W/ton] of rated total cooling capacity where the total cooling capacity is the sum of the rated total cooling capacities for the refrigeration load connected to this compressor rack. Following manufacturer’s recommendations regarding the avoidance of scaling, the water pump does not cycle when there is no cooling demand (i.e., when the compressors

are not running), but rather runs continuously. However, if the evaporative condenser availability schedule is set such that evaporative cooling is not available (e.g., during very cold months to avoid freezing), then the pump power consumption will be zero during that period.

18.2.2.2.6 Evaporative Condenser Water Consumption

With evaporative cooling of the condenser's entering air, makeup water is needed to replenish the water lost due to evaporation. The quantity required is calculated as the product of the air mass flow rate and the difference between the entering and leaving air humidity ratio, divided by the density of water. The air mass flow rate is determined by multiplying the evaporative condenser air volume flow rate times the density of the entering air (i.e., at the condenser air inlet node if provided, or outdoor air conditions [e.g., no adjustment for height above ground] if the condenser air inlet node field is left blank). The volumetric air flow rate is either specified directly in the user input or is autocalculated using the relationship 0.000144 m³/s per watt of rated total cooling capacity [850 cfm/ton] where the total cooling capacity is the sum of the rated total cooling capacities for the refrigerated cases and walk-ins connected to this compressor rack (Ref. Refrigeration:Case and Refrigeration:WalkIn). The air mass flow rate is multiplied by the variable *CondFanfTemp*, described above, to simulate the modulation of air flow by the condenser fans (e.g., staging, multi-speed, or variable speed) as a function of temperature. Mathematically,

$$\dot{V}_{evaporation,makeup} = \frac{\dot{m}_{air} (CondFanfTemp) (\omega_{air,outlet} - \omega_{air,inlet})}{\rho_{water}} \quad (18.119)$$

where:

$\dot{V}_{evaporation,makeup}$ is the Refrigeration Compressor Rack Evaporative Condenser Water Volume Flow Rate (m³/s)

\dot{m}_{air} is the mass flow rate of air through the evaporative condenser (kg/s)

$\omega_{air,outlet}$ is the humidity ratio of air leaving the evaporative media (kg_{water}/kg_{dryair}) based on the effective dry-bulb temperature $T_{effective}$, as described above, outdoor air wet-bulb temperature, and outdoor barometric pressure

$\omega_{air,inlet}$ is the humidity ratio of inlet air (kg_{water}/kg_{dryair}) based on conditions at the condenser air inlet node if provided, or outdoor air conditions (e.g., no adjustment for height above ground) if the condenser air inlet node field is left blank

ρ_{water} is the density of water evaluated at the effective air temperature (kg/m³).

The source of the makeup water may be specified as a water storage tank. If not specified, the makeup water is assumed to come from the building mains (Ref. Water Mains Temperatures).

18.2.2.2.7 Evaporative Condenser Basin Heater

In cold climates, a basin heater may be needed to prevent freezing of the evaporative cooling water. This feature is included in the model whereby an electric basin heater provides heat to the sump water only when the condenser cooling system is idle (i.e., no refrigeration load) and when the outdoor air dry-bulb temperature is below a user-specified setpoint. Since heat balances and basin water temperatures are not explicitly determined, a linear loading relationship, as a function of the difference in outdoor air dry-bulb temperature and the setpoint temperature, is used calculate the power demand at a given time step by the basin heater.

$$P_{basinheater} = P_{heatercapacity} * (T_{setpoint} - T_{OutDb}) \quad (18.120)$$

where:

$P_{basinheater}$ is the electric power demand for basin heater in current time step (W)

$P_{heatercapacity}$ is the electric heater capacity as a function of differential temperature (W/K)

$T_{setpoint}$ is the setpoint temperature below which the heater turns on ($^{\circ}\text{C}$)

T_{OutDb} is the outdoor air dry-bulb temperature ($^{\circ}\text{C}$).

A default value for the basin heater capacity of 200 W/K has been established based on manufacturer data.

18.2.2.2.8 Evaporative Condenser Availability Schedule

Some manufacturer's evaporative cooling systems for refrigeration condensers permit seasonal draining in the colder months and operation as an air-cooled system during that time. This optional feature is available through an availability schedule. This is important in climates subject to freezing weather in order to avoid excessive ice formation on the condenser surfaces and surroundings. (The Availability Schedule is the correct way to model the use of evaporative condensers in cold climates. However, some users may take a single input description and use it to model a building with a refrigeration system in a variety of climates. To avoid modeling the use of evaporative coolers in freezing weather, the code includes a cutout to switch to dry operation whenever the outdoor drybulb temperature drops below 4°C .) During periods when evaporative cooling is not available, the outdoor condenser behaves as an air-cooled system with no water consumption or pump and basin heater loads. The effective temperature of air entering the condenser coil during this period (used to evaluate COPfTemp and CondFanfTemp) is equal to the outdoor air dry-bulb temperature at the condenser air inlet node if provided, or outdoor air conditions (e.g., no adjustment for height above ground) if the condenser air inlet node field is left blank.

18.2.3 Refrigerated Cases

The refrigerated case object (Refrigeration:Case) works in conjunction with the compressor rack, detailed refrigeration system, or secondary refrigeration system object (Refrigeration:CompressorRack, Refrigeration:System, or Refrigeration:SecondarySystem) to simulate the performance of a refrigerated case system. The refrigerated case model uses performance information at rated conditions along with performance curves for latent case credits and defrost heat load to determine performance at off-rated conditions. Energy use for lights, fans and anti-sweat heaters is modeled based on inputs for nominal power, schedules, and control type. The refrigerated case model accounts for the sensible and latent heat exchange with the surrounding environment (termed “case credits”) which impacts the temperature and humidity in the zone where the case is located. The simplified model described here provides the flexibility to simulate a broad range of refrigerated case types.

The total load on the refrigerated case evaporator is made up of various components:

$$\dot{Q}_{case} = \dot{Q}_{walls} + \dot{Q}_{rad} + \dot{Q}_{inf,sens} + \dot{Q}_{inf,lat} + \dot{Q}_{lights} + \dot{Q}_{as} + \dot{Q}_{def} + \dot{Q}_{fan} + \dot{Q}_{restock} \quad (18.121)$$

where:

\dot{Q}_{case} is the total load on the refrigerated case evaporator (W)

\dot{Q}_{walls} is the heat transfer through case walls due to the difference between the refrigerated case operating dry-bulb temperature and the zone air dry-bulb temperature (W)

\dot{Q}_{rad} is the radiant heat transfer to the refrigerated case (W)

$\dot{Q}_{inf,sens}$ is the sensible heat transfer by air infiltration to the refrigerated case through the air curtain or via door openings (W)

$\dot{Q}_{inf,lat}$ is the latent heat transfer by air infiltration to the refrigerated case through the air curtain or via door openings (W)

\dot{Q}_{lights} is the lighting heat load (W)

\dot{Q}_{as} is the anti-sweat heater load (W)

\dot{Q}_{def} is the defrost heat load (W)

\dot{Q}_{fan} is the fan heat load (W)

$\dot{Q}_{restock}$ is the sensible load on the refrigerated case due to restocking of products that are at a higher temperature than the case (W).

The model assumes that these load components are known for a refrigerated case at rated ambient air conditions (typically 23.9°C [75°F] and 55% relative humidity) and the specified case operating temperature. A combination of user input curves and fixed correlations (defined within EnergyPlus) adjust for case performance at off-rated conditions. Several of the load components are typically provided by the case manufacturer (e.g., total rated load, fan, lighting, anti-sweat heater, and defrost loads). The remaining load components are not usually provided by the manufacturer and must be estimated (heat conduction through case walls, radiation heat transfer, sensible/latent air infiltration, and restocking).

For estimating the latent air infiltration load, the model requires that the user provide the latent heat ratio (LHR) for the refrigerated case at rated conditions. Research results are available to provide guidance in selecting this value (ASHRAE 2002, Howell 1993a, Howell 1993b). The rated LHR for refrigerated cases typically ranges from 0.1 to 0.3 depending on case configuration (e.g., glass door reach-in versus multi-deck open case) and case operating temperature.

The case loads due to wall heat conduction, radiation, and sensible air infiltration are estimated by the model as a single lumped value (sensible case credits). The sensible case credits are calculated by subtracting the known loads at rated conditions (fan, lighting, anti-sweat heater, defrost and latent case credits) from the rated total cooling capacity of the case which is provided by the case manufacturer ($\dot{Q}_{case,rated}$).

Using these assumptions and the schedule inputs provided by the user, the refrigerated case evaporator load components in Equation 18.121 are determined for each simulation time step. The variation in certain loads with respect to changes in ambient air temperature and/or humidity (e.g., latent and sensible case credits, defrost load, and anti-sweat heater load) are factored into the calculation based on user-provided inputs or by the model itself.

Whenever the total heat load on the case is greater than the available evaporator capacity, such as during defrost (when the evaporator capacity is set to zero) or restocking, the load is accumulated to be met during subsequent time steps. This accounts for the energy required to bring the case back down to the rated operating temperature even though the rise in case temperature during defrost or restocking is not explicitly modeled. Following defrost, it may take multiple time steps to meet this accumulated load.

The specific calculations for case evaporator load components and electric power for these loads (as applicable) are provided below.

18.2.3.1 Case Evaporator Fan

The refrigerated case evaporator fan electric power is calculated for each simulation time step as the product of the operating case fan power per unit length of case, the length of the refrigerated

case, and the fraction of time that the case is not being defrosted. For cases with hot-gas or electric defrost (with or without temperature termination), the fan is disabled during the entire scheduled defrost drip-down time period. The evaporator fan operates continuously for off-cycle defrost or no defrost.

$$P_{fan} = P'_{fan,oper}(L_{case})(1 - SCH_{defrost,dripdown}) \quad (18.122)$$

where:

P_{fan} is the output variable “Refrigerated Case Evaporator Fan Electric Power [W]”

$P'_{fan,oper}$ is the operating case fan power per unit length (W/m)

L_{case} is the case length (m)

$SCH_{defrost,dripdown}$ is the fraction of time case is being defrosted (0 to 1), including drip-down period (based on the defrost drip-down schedule) for hot-gas or electric defrost. For off-cycle defrost or no defrost, this value is set to zero for this calculation.

The model assumes that the evaporator fan is entirely contained within the thermal envelope of the case, and that all fan power results in a direct heat load on the case evaporator:

$$\dot{Q}_{fan} = P_{fan} \quad (18.123)$$

18.2.3.2 Case Lighting

The refrigerated case lighting electric power is calculated for each simulation time step as the product of the installed case lighting power per unit length of case, the lighting schedule value, and the length of the refrigerated case:

$$P_{lights} = P'_{lights,installed}(L_{case})(SCH_{lights}) \quad (18.124)$$

where:

P_{lights} is the output variable “Refrigerated Case Lighting Electric Power [W]”

$P'_{lights,installed}$ is the installed case lighting power per unit length (W/m)

SCH_{lights} is the case lighting schedule value (0 to 1).

A maximum schedule value of 1.0 means the lights are fully on at the installed case lighting power level. Schedule values of 0.0 indicate the lights are off and 0.5 at half-power.

The user can specify the fraction of lighting energy that directly contributes to the case evaporator heat load:

$$\dot{Q}_{lights} = P_{lights}(F_l) \quad (18.125)$$

where F_l is the fraction of lighting energy to case.

The remainder of the lighting energy ($1 - F_l$) is a heating load to the zone where the case is located, which is discussed further in section Sensible Case Credits below. This fraction ($1 - F_l$) can be used to represent lighting ballasts and/or bulbs located outside the air curtain of the refrigerated case.

18.2.3.3 Anti-Sweat Heater Performance

Anti-sweat heaters warm the refrigerated case rails or doors to provide protection from moisture condensation. Different anti-sweat heater control strategies are used depending on the case temperature and the type of anti-sweat heater installed. Several types of anti-sweat heater control

strategies can be simulated with this model: constant, linear variation with ambient relative humidity or dewpoint temperature, and a theoretical model that determines the minimum anti-sweat heater power required to maintain the case surface just above the temperature where condensation would occur. Additionally, anti-sweat heater performance can be disregarded if the type of refrigerated case does not warrant its use. For the control strategies described below (except “None” and “Constant Method”), the model does not allow the anti-sweat heater power to be less than the minimum power nor greater than the case anti-sweat heater power specified by the user. Each anti-sweat heater control type is described in detail below.

18.2.3.3.1 None

Used for refrigerated cases that do not require an anti-sweat heater.

$$\dot{Q}_{as} = 0 \quad (18.126)$$

where \dot{Q}_{as} is the anti-sweat heater load on the case evaporator (W).

18.2.3.3.2 Constant Method

For refrigerated cases requiring constant anti-sweat heater output, the power use is simply calculated as the case anti-sweat heater power per unit length multiplied by the length of the case. This method is used when the manufacturer recommends that cycling of the heaters not occur.

$$P_{as} = P'_{as} (L_{case}) \quad (18.127)$$

where:

P_{as} is the output variable “Refrigerated Case Anti-Sweat Heater Electric Power” (W)

P'_{as} is the case anti-sweat heater power per unit length (W).

18.2.3.3.3 Relative Humidity Method

Anti-sweat heater power can be reduced at lower ambient relative humidity levels to save energy while still protecting from moisture condensation on cold surfaces. For this control type, anti-sweat heater power use is reduced linearly based on case anti-sweat heater power at the rated ambient relative humidity (typically 55% RH), the relative humidity specified by the user where no anti-sweat heater power is required, and the relative humidity of the ambient (zone) air surrounding the case.

$$P_{as} = P'_{as} (L_{case}) \left(1 - \left[\frac{RH_{rated} - RH_{air}}{RH_{rated} - RH_{min}} \right] \right) \quad (18.128)$$

where:

RH_{air} is the relative humidity of the ambient (zone) air (%)

RH_{rated} is the rated ambient relative humidity (%)

RH_{min} is the relative humidity at zero anti-sweat heater energy (%).

18.2.3.3.4 Dewpoint Method

Anti-sweat heater power can also be reduced as a function of ambient air dewpoint temperature based on a similar correlation to that used by the relative humidity method. This control method varies the anti-sweat heater power linearly based on the ambient air dewpoint temperature, the

case operating temperature, and the rated ambient dewpoint temperature (calculated by the model using the rated ambient temperature and rated ambient relative humidity entered by the user).

$$P_{as} = P'_{as}(L_{case}) \left(\frac{T_{dp,air} - T_{case}}{T_{dp,rated} - T_{case}} \right) \quad (18.129)$$

where:

$T_{dp,air}$ is the dewpoint temperature of the ambient (zone) air (°C)

$T_{dp,rated}$ is the rated ambient dewpoint temperature (°C)

T_{case} is the case operating temperature (°C).

18.2.3.3.5 Heat Balance Method

A theoretical model may also be used to simulate the performance of anti-sweat heater operation at various indoor dewpoint temperatures (Henderson and Khattar 1999). The model calculates that amount of heat required to hold the case or door surface at (or slightly above) the dewpoint temperature of the ambient air using the following simple heat balance equation:

$$P_{as} = \left(\frac{(T_{dp,air} - T_{db,air}) H_{case}}{R_{air}} + \frac{(T_{dp,air} - T_{case}) H_{case}}{R_{case}} \right) L_{case} \quad (18.130)$$

where:

$T_{dp,air}$ is the dewpoint temperature of the ambient (zone) air (°C)

$T_{db,air}$ is the dry-bulb temperature of the ambient (zone) air (°C)

H_{case} is the height of the case (m)

R_{air} is the air film resistance (assumed constant at 0.3169 m²-°C/W)

R_{case} is the heat transfer resistance of case (m²-°C/W)

T_{case} is the case operating temperature (°C)

L_{case} is the case length (m).

The model above provides a linear relationship of anti-sweat heater power with varying ambient air dewpoint temperature at constant ambient air dry-bulb and case temperatures. By assuming that the ‘nominal’ anti-sweat heater power entered by the user is required to avoid moisture condensation at rated ambient air conditions, the value of R_{case} can be determined by rearranging the equation and solving as follows:

$$R_{case} = \frac{(T_{dp,rated} - T_{case})}{\left(\frac{P'_{as}}{H_{case}} \right) - \left(\frac{T_{dp,rated} - T_{db,rated}}{R_{air}} \right)} \quad (18.131)$$

where $T_{db,rated}$ is the rated ambient temperature (°C)

With R_{case} known, P_{as} can be calculated for each simulation time step using the actual ambient (zone) air dry-bulb and dewpoint temperatures.

18.2.3.3.6 All Anti-Sweat Heater Control Methods

For all control methods, the user can specify the fraction of anti-sweat heater energy that directly contributes to the case evaporator heat load:

$$\dot{Q}_{as} = P_{as}(F_{as}) \quad (18.132)$$

where F_{as} is the fraction of anti-sweat heater energy to case.

The remainder of the anti-sweat heater energy ($1 - F_{as}$) is a heating load to the zone where the case is located, which is discussed further in section Sensible Case Credits below.

18.2.3.4 Case Restocking

The impact of restocking the refrigerated case with product that is not at the case operating temperature is modeled with the case restocking schedule. The schedule is entered as a heat gain rate per unit length of the refrigerated case (W/m). The heat load due to restocking is calculated as the scheduled load multiplied by the length of the refrigerated case. The load due to product restocking is assumed to be only sensible (temperature) heat; a latent (moisture) component is not modeled.

$$\dot{Q}_{restock} = SCH_{restock} (L_{case}) \quad (18.133)$$

where $SCH_{restock}$ is the refrigerated case restocking schedule value (W/m).

The restocking heat load is removed by the refrigerated case evaporator any time the case is not being defrosted and excess sensible cooling capacity is available. If the evaporator cooling capacity is insufficient to remove the entire restocking load, the unmet portion is carried over to the next simulation time step.

18.2.3.5 Case Defrost

Eight refrigerated case defrost strategies can be simulated: none, off-cycle, electric, electric with temperature termination, hot-gas, hot-gas with temperature termination, hot-brine, and hot-brine with temperature termination. Some research has shown that the defrost times for cases defrosted using hot brine can be significantly shorter than defrost times for electric or hot gas. (Terrell, W. J. Jr., 1999) For each of these strategies, the refrigerated case evaporator is turned off for the required time period to allow accumulated frost to melt. Additional time can be scheduled (drip-down) to allow the water to drip from the evaporator and drain from the case.

Refrigerated cases typically require a specific number of defrost cycles per day for a pre-determined length of time. Refer to manufacturer's recommendations for proper defrost frequency and duration. For example, a refrigerated case may have a single defrost period each day with defrost scheduled from 7:00 – 7:40 am and defrost drip-down scheduled from 7:00 – 7:55 am. Notice the drip-down schedule and the defrost schedule start at the same time, and the drip-down schedule is longer than the defrost schedule. These schedules should normally repeat for each day of the year.

For electric, hot gas, and hot brine defrost types, energy use by the defrost heater occurs during the scheduled defrost period. For defrost with temperature termination, the energy is also multiplied by the defrost ratio simulating a defrost duration shorter than the defined (maximum) period. For all non-electric defrost types, defrost electric power is set equal to zero (and is not available as an output variable). For hot gas and hot brine defrost types in cases served by a detailed system, the condenser heat rejection load is reduced by the amount of heat recovered for use in the defrost system. This condenser credit is not applied for the simple compressor rack system.

If DefrostType is electric, then:

$$P_{def} = P'_{def} L_{case} SCH_{defrost} \quad (18.134)$$

Else if DefrostType is ElectricWithTempTermination, then:

$$P_{def} = P'_{def} L_{case} SCH_{defrost} (DefrostRatio) \quad (18.135)$$

Otherwise:

$$P_{def} = 0.0 \quad (18.136)$$

where:

P_{def} is the output variable “Refrigerated Case Defrost Electric Power” (W)

P'_{def} is the case defrost power per unit length (W)

L_{case} is the case length (m)

$SCH_{defrost}$ is the case defrost schedule value (0 to 1)

$DefrostRatio$ is the fraction of maximum defrost time, used with temperature termination.

Frost accumulation on the case evaporator will vary with the humidity level in the ambient air surrounding the case. Therefore, defrost heater operation can be reduced when ambient air humidity levels are low. Several methods are used to reduce unnecessary defrost heater operation, including terminating heater operation when the measured evaporator temperature indicates that the accumulated frost has been completely melted. For modeling refrigerated cases with temperature-terminated defrost, EnergyPlus allows the user to specify a defrost energy correction curve to account for variations in defrost energy as ambient air humidity levels change. The user can select from four correction curve types: None, Case Temperature Method, Relative Humidity Method, or Dewpoint Method.

For type None (default):

$$DefrostRatio = 1 \quad (18.137)$$

For type Case Temperature Method:

$$DefrostRatio = 1 - (RH_{rated} - RH_{air}) (a + bT_{case} + cT_{case}^2 + dT_{case}^3) \quad (18.138)$$

For type RH Method:

$$DefrostRatio = e + f (RH_{air}) + g (RH_{air}^2) + h (RH_{air}^3) \quad (18.139)$$

For type Dewpoint Method:

$$DefrostRatio = i + jT_{dp,air} + kT_{dp,air}^2 + lT_{dp,air}^3 \quad (18.140)$$

where:

RH_{rated} is the rated ambient relative humidity (%)

RH_{air} is the relative humidity of the ambient (zone) air (%)

T_{case} is the case operating temperature (°C)

$T_{dp,air}$ is the dewpoint temperature of the ambient (zone) air (°C)

a, \dots, l is the user-defined coefficients using a cubic curve object (Curve:Cubic).

The user specifies the defrost energy correction curve type and the name of the cubic curve object (Curve:Cubic) that defines the curve coefficients. Representative curve coefficients for curve type “Case Temperature Method” are provided in Table 18.1.

Table 18.1: Representative Defrost Energy Correction Curve Coefficients for Case Temperature Method

Coefficient	Single-shelf horizontal display case	Multi-shelf vertical display case
a	2.3632E-2	2.4598E-2
b	6.2320E-4	7.6439E-4
c	2.8320E-5	-3.8637E-5
d	4.4035E-7	7.45686E-7

Note: Coefficients derived for $RH_{rated} = 55\%$ and a rated ambient temperature of 23.9°C (75°F). Source: Howell 1993b.

As mentioned above, the refrigerated case evaporator is turned off while it is being defrosted. Heat gains during defrost must be removed once the defrost period (drip-down schedule) has ended. The model assumes that heat gains due to defrost heater operation are at least partially offset by converting accumulated frost to liquid water (condensate) which drains from the case. Frost accumulation during each simulation time step is estimated by the model using the actual latent heat transfer to the refrigerated case and the heat of vaporization plus the heat of fusion for water. The model assumes that frost is not accumulated on the evaporator during the defrost drip-down time period.

$$Frost = Frost + \left(\frac{\dot{Q}_{case,rated} (L_{case}) (RTF_{rated}) (LHR_{rated}) (LatentRatio) (t_{zn})}{(h_f + h_{fg})} \right) (1 - SCH_{defrost,dripdown}) \quad (18.141)$$

where:

$Frost$ is the amount of accumulated frost on the case evaporator (kg)

$\dot{Q}_{case,rated}$ is the case rated total cooling capacity per unit length (W/m)

L_{case} is the case length (m)

RTF_{rated} is the runtime fraction of the refrigerated case at rated conditions

LHR_{rated} is the latent heat ratio of the refrigerated case at rated conditions

$LatentRatio$ is the ratio of actual latent load to rated latent load on the case, based on latent case credit curve (see section Latent Case Credits below)

t_{zn} is the duration of zone simulation time step (s)

h_{fg} is the heat of vaporization of water (assumed constant at 2,498,000 J/kg)

h_f is the heat of fusion of water (335,000 J/kg)

$SCH_{defrost,dripdown}$ is the defrost drip-down schedule value (0 to 1).

During defrost ($SCH_{defrost}$), the model assumes that the hot gas, hot brine, or electric heater energy directly contributes to melting the frost (heat of fusion of water). Defrost energy not attributed to melting frost from the evaporator coil results in a heat load on the refrigerated case evaporator (\dot{Q}_{def}). When the defrost drip-down time period ends, this defrost energy heat load is added to the actual case load (up to the maximum evaporator capacity) until the total defrost energy heat load is removed (which may take several simulation time steps).

If DefrostType is Electric, HotGas, or HotBrine, then:

$$\dot{Q}_{def} = \max \left[0.0, \left(P'_{def} L_{case} SCH_{def} - \frac{Frost(h_f)}{t_{zn}} \right) \right] \quad (18.142)$$

Otherwise:

$$\dot{Q}_{def} = 0.0 \quad (18.143)$$

where \dot{Q}_{def} is the defrost heat load (W).

18.2.3.6 Sensible Case Credits

Refrigerated cases remove sensible energy from the surrounding environment (termed “sensible case credits”). In this model, the sensible case credits are composed of wall heat conduction, radiation heat transfer, and sensible heat transfer by air infiltration ($\dot{Q}_{walls} + \dot{Q}_{rad} + \dot{Q}_{inf,sens}$ in Equation 18.121). To quantify this energy transfer, the model first calculates the rated sensible case credits by subtracting the known loads at rated conditions (fan, lighting, and anti-sweat heater) from the rated sensible cooling capacity of the case. It should be noted that the lighting and fan heat discussed here are for standard-efficiency equipment. Manufacturers typically provide ratings for both standard and high-efficiency fan and lighting equipment; however, the standard equipment is used to determine rated sensible case credits. (Some manufacturers no longer include any lighting in their rated capacity values. For these cases, $P'_{lights,std}$ will equal zero.)

$$\dot{Q}_{CC_{sens,rated}} = \left[\dot{Q}_{case,rated} (RTF_{rated}) (1 - LHR_{rated}) - P'_{lights,std} (F_l) - P'_{as} (F_{as}) - P'_{fan,std} \right] L_{case} \quad (18.144)$$

where:

$\dot{Q}_{CC_{sens,rated}}$ is the sensible case credits at rated conditions (W)

$\dot{Q}_{case,rated}$ is the case rated total cooling capacity per unit length (W/m)

RTF_{rated} is the runtime fraction of the refrigerated case at rated conditions

LHR_{rated} is the latent heat ratio of the refrigerated case at rated conditions

$P'_{lights,std}$ is the standard case lighting power per unit length (W/m)

F_l is the fraction of lighting energy to case

P'_{as} is the case anti-sweat heater power per unit length (W)

F_{as} is the fraction of anti-sweat heater energy to case

$P'_{fan,std}$ is the standard case fan power per unit length (W/m)

L_{case} is the case length (m).

For every simulation time step, the rated sensible case credits are then adjusted to account for variations at off-rated ambient air temperatures. The model also allows the user to define a case credit fraction using a schedule object. This case credit fraction can be useful for modeling cases that operate differently during specific time periods. For example, metal or plastic coverings may be installed on refrigerated display cases during unoccupied hours which would significantly reduce case credits (e.g., air infiltration) compared to occupied hours when the coverings are removed. If the user does not define a case credit fraction schedule, then the fraction is assumed to be 1 for the entire simulation.

$$\dot{Q}_{cc_{sens}} = \dot{Q}_{cc_{sens},rated} \left(\frac{T_{db,air} - T_{case}}{T_{db,rated} - T_{case}} \right) (SCH_{cc}) \quad (18.145)$$

where:

$\dot{Q}_{cc_{sens}}$ is the sensible case credits adjusted for ambient temperature and case credit fraction (W)

$T_{db,air}$ is the dry-bulb temperature of the ambient (zone) air (°C)

T_{case} is the case operating temperature (°C)

$T_{db,rated}$ is the rated ambient (zone) dry-bulb temperature (°C)

SCH_{cc} is the case credit fraction (schedule value, 0 to 1).

The sensible case credits calculated above are considered heat loads on the refrigerated case evaporator. The **net** impact of the case credits on the surrounding zone includes adjustment for the portion of the lighting and anti-sweat heater power that does *not* directly contribute to the case evaporator load. Sensible case credits are negative values when heat is removed from the zone load.

$$\dot{Q}_{cc_{sens},NET} = P_{lights}(1 - F_l) + P_{as}(1 - F_{as}) - \dot{Q}_{cc_{sens}} \quad (18.146)$$

where:

$\dot{Q}_{cc_{sens},NET}$ is the net impact of the sensible case credits on the surrounding zone, negative for cooling (W)

P_{lights} is the case lighting electric power (W)

F_l is the fraction of lighting energy to case

P_{as} is the anti-sweat heater electric power (W)

F_{as} is the fraction of anti-sweat heater energy to case.

When refrigerated cases are served by a compressor rack that rejects condenser waste heat directly to the zone (e.g., a stand-alone refrigerated case with integral compressor and condenser), this condenser waste heat offsets some or all of the sensible case credits. The amount of condenser waste heat rejected to the zone is calculated and reported by the refrigerated case compressor rack object (Ref. Heat Rejection to Zone).

18.2.3.7 Latent Case Credits

Refrigerated cases also remove latent energy (moisture) from the surrounding environment (termed “latent case credits”). In this model, the latent case credit is composed solely of the latent heat transfer by air infiltration $\dot{Q}_{inf,lat}$ in Equation 18.121. The latent case credits are calculated as the product of the case length and the total cooling capacity per unit length, latent heat ratio, and runtime fraction at rated conditions. As described previously (Ref. Sensible Case Credits), a case credit fraction schedule is used to model cases that operate differently during specific time periods. The same case credit fraction is used to modify both the sensible and latent case credits. If the user does not define a case credit fraction schedule, then the fraction is assumed to be 1 for the entire simulation. The calculation of latent case credits also includes a factor (*LatentRatio*) that accounts for lower ambient humidity levels. Latent case credits are set to zero during the defrost-dripdown periods.

$$\dot{Q}_{inf,lat} = -\dot{Q}_{cc_{lat}} = \dot{Q}_{case,rated} (LHR_{rated}) (RTF_{rated}) (SCH_{cc}) (LatentRatio) L_{case} \quad (18.147)$$

where:

$\dot{Q}_{inf,lat}$ is the latent load on the refrigerated case evaporator at current ambient conditions (W)

$\dot{Q}_{cc,lat}$ is the latent case credit impact on zone load, negative for dehumidification (W)

$Q_{case,rated}$ is the case rated total cooling capacity per unit length (W/m)

LHR_{rated} is the latent heat ratio of the refrigerated case at rated conditions

RTF_{rated} is the runtime fraction of the refrigerated case at rated conditions

SCH_{CC} is the case credit fraction (schedule value, 0 to 1)

$LatentRatio$ is the ratio of actual latent load to rated latent load on the case, based on latent case credit curve

L_{case} is the case length (m).

Latent load on the refrigerated case evaporator will vary with ambient humidity levels. Therefore, the refrigerated case model allows the user to specify a latent case credit curve to adjust case credits based on ambient humidity, and the user can select from three curve types: Case Temperature Method, Relative Humidity Method, or Dewpoint Method.

If CurveType is Case Temperature Method:

$$LatentRatio = 1 - (RH_{rated} - RH_{air}) (m + nT_{case} + oT_{case}^2 + pT_{case}^3) \quad (18.148)$$

Else if CurveType is RH Method:

$$LatentRatio = q + r(RH_{air}) + s(RH_{air}^2) + t(RH_{air}^3) \quad (18.149)$$

Else if CurveType is Dewpoint Method:

$$LatentRatio = u + vT_{dp,air} + wT_{dp,air}^2 + xT_{dp,air}^3 \quad (18.150)$$

where:

RH_{rated} is the rated ambient relative humidity (%)

RH_{air} is the relative humidity of the ambient (zone) air (%)

T_{case} is the case operating temperature (°C)

$T_{dp,air}$ is the dewpoint temperature of the ambient (zone) air (°C)

m, \dots, x is the user-defined coefficients using a cubic curve object (Curve:Cubic).

The user specifies the latent case credit curve type and the name of the cubic curve object (Curve:Cubic) that defines the curve coefficients. Representative curve coefficients for curve type “Case Temperature Method” are provided in Table 18.2.

Table 18.2: Representative Latent Case Credit Curve Coefficients for Case Temperature Method

Coefficient	Single-shelf horizontal	Multi-shelf vertical
m	2.0376E-2	2.6520E-2
n	2.4378E-4	1.0780E-3
o	1.1400E-5	-6.0256E-5
p	1.8110E-7	1.2373E-6

Note: Coefficients derived for $RH_{rated} = 55\%$ and a rated ambient temperature of 23.9°C (75°F). Source: Howell 1993b.

18.2.3.8 Refrigerated Case Credits With Under Case Return Air

For certain refrigerated case types, the sensible case credits provided to the zone can create an uncomfortably cold environment in the surrounding area. For this reason, return air ducts are frequently placed behind these cases to draw this cold air under the case and direct it back to the HVAC system. This reduces localized over-cooling and improves occupant comfort.

Figure 18.16: Return Air Factor Versus Under Case HVAC Return Air Fraction

Since under case return ducts reduce the temperature and humidity of the air being recirculated to the HVAC system, this can impact HVAC system performance. Figure 18.16 shows the relationship that is used by the refrigerated case model to determine the fraction of case credits that directly cool and dehumidify the HVAC system return air. This fraction, referred to as the Return Air Factor (RAF), is a function of the fraction of the HVAC system return air that comes from under the cases. The remaining fraction of the case credits (1-RAF) becomes part of the overall zone air energy balance. If the HVAC system is off for a simulation time step (no return air mass flow), the sensible and latent case credits normally attributed to the HVAC return are set equal to zero (even though they get calculated and reported here as non-zero values) and all case credit energy is applied to the zone air heat balance.

$$\dot{Q}_{CC_{sens},zone} = \dot{Q}_{CC_{sens},NET} (1 - RAF) \quad (18.151)$$

$$\dot{Q}_{CC_{lat},zone} = \dot{Q}_{CC_{lat}} (1 - RAF) \quad (18.152)$$

$$\dot{Q}_{CC_{sens},HVAC} = \dot{Q}_{CC_{sens},NET} (RAF) \quad (18.153)$$

$$\dot{Q}_{cc_{lat},HVAC} = \dot{Q}_{cc_{lat}}(RAF) \quad (18.154)$$

where:

$\dot{Q}_{cc_{sens},zone}$ is the sensible case credit applied to the zone air heat balance (W)

$\dot{Q}_{cc_{lat},zone}$ is the latent case credit applied to the zone air heat balance (W)

$\dot{Q}_{cc_{sens},HVAC}$ is the sensible case credit applied to the HVAC return air (zone return air path outlet node) (W)

$\dot{Q}_{cc_{lat},HVAC}$ is the latent case credit applied to the HVAC return air (zone return air path outlet node) (W)

RAF is the return air factor (see Figure 18.16 above).

18.2.3.9 Variable Evaporator Temperature

Control systems are now available that increase the evaporator temperature to improve compressor efficiency whenever the total loads on a system are less than the system capacity. To model these systems, a variable evaporator temperature is an option available with the detailed refrigeration system object (Refrigeration:System). If this option is selected, the model will compare the refrigeration load on each case to the load at rated conditions. If the case load in a particular time step is less than the rated load, an acceptable elevated evaporator temperature is determined for that case. The evaporator temperature for the whole refrigeration system is then set by the minimum evaporator temperature needed for any particular case.

$$LF_{case} = \frac{\dot{Q}_{case,actual}}{\dot{Q}_{case,rated}} \quad (18.155)$$

$$T_{Evap,Allowed} = T_{case} - LF_{case}(T_{case} - T_{Evap,Design}) \quad (18.156)$$

where:

LF_{case} is the load factor for a particular case

T_{Evap} is the evaporator temperature (°C).

18.2.4 Walk-In Coolers and Freezers

The walk-in object (Refrigeration:WalkIn) is another type of refrigeration load that can be placed on either a refrigeration compressor rack, detailed refrigeration system, or secondary refrigeration system object (Refrigeration:CompressorRack, Refrigeration:System, or Refrigeration:SecondarySystem). Walk-in coolers and freezers differ from refrigerated cases in that they may have surfaces facing more than one zone and in that they are always equipped with doors, that is, they do not have open shelves. Their sensible and latent exchange with zones is therefore calculated in a different manner than for refrigerated cases. Also, the walk-in model does not interact directly with the HVAC system, that is, the return air fraction option available in the refrigerated case model is not included.

The walk-in cooler performance is based on the ASHRAE load model, which includes infiltration through door openings and sensible loss through walls/ceilings described by the user for each zone. (ASHRAE 2006d, ASHRAE 2006e, Gosney, W.B., Olama, G.A.-L. 1975) All equipment loads (fan, light, heaters) are modeled as well. Sensible and latent exchange with multiple adjoining zones is included. A master schedule is used for the Walk In operation and additional schedules

control the lights, defrost, and heater operation. Just as for cases, unmet refrigeration loads are accumulated to be met the following time step. This usually occurs during defrost and restocking.

18.2.4.1 Walk-In Sensible and Latent Heat Exchange

A walk-in can exchange both sensible and latent energy with multiple zones. The heat transfer calculations are performed separately for each zone so that the heat transfer impact, or zone credits, can be determined. The area of all walls and ceilings facing each zone are described by the user by their thermal conductance and area. Sensible energy exchange takes place between these surfaces and the surrounding zones. Because these walls interface with conditioned zones at relatively constant temperatures, this heat exchange is modeled very simply:

$$Q_{SurfacesZn} = U_{SurfacesZn} \cdot A_{SurfacesZn} \cdot \Delta T_{Zn} \quad (18.157)$$

$$Q_{DoorSensZn} = U_{DoorZn} \cdot Area_{DoorZn} \cdot \Delta T_{Zn} \quad (18.158)$$

The heat transfer through the floor is similarly modeled.

$$Q_{Floor} = A_{Floor} \cdot U_{Floor} \cdot (T_{Ground} - T_{WalkIn}) \quad (18.159)$$

Where:

A_{Floor} is the area of the walkin floor (m²)

$A_{SurfacesZn}$ is the area of surfaces facing Zone n (m²)

$Q_{DoorSensZn}$ is the sensible heat transfer through the closed door(s) facing Zone n (W)

$Q_{surfacesZn}$ is the sensible heat transfer through walls and ceilings facing Zone n (W)

T_{Ground} is the ground temperature (°C)

T_{WalkIn} is the walk-in operating temperature (°C)

U_{Floor} is the thermal conductance of floor (W/m²-K)

U_{DoorZn} is the thermal conductance of doors facing Zone n (W/m²-K)

$U_{SurfacesZn}$ is the thermal conductance of surfaces facing Zone n (W/m²-K)

ΔT_{Zn} is the difference between walk-in operating temperature and Zone n drybulb temperature (°C).

Infiltration through doorways places both a sensible and a latent load upon the walk-in, and corresponding credits upon the adjacent zone. Two types of doors are available, nominally called 'stock' and 'glass' doors, to enable the user to model doors that differ in thermal conductance, door protection type, and frequency of opening. The sensible and latent infiltration loads are modeled according to the guidance specified in (ASHRAE 2006d, ASHRAE 2009, and Gosney and Olama, 1975). The air within the cooler is assumed to be at 90% relative humidity. Equal air exchange is assumed, that is, the mass of dry air infiltrating into the walkin is assumed to equal the mass of dry air infiltrating out of the walkin.

$$Q_{Infiltration} = Q_{FullFlow} \cdot Factor_{DoorOpen} \cdot Factor_{Flow} \cdot (1 - Factor_{Protection}) \quad (18.160)$$

$$Q_{FullFlow} = 0.221 \cdot A_{Door} \cdot (h_{ZoneAir} - h_{AirWalkIn}) \cdot \rho_{AirWalkIn} \cdot (1 - \rho_{ZoneAir} / \rho_{AirWalkIn})^{0.5} \cdot (g \cdot H_{Door})^{0.5} \cdot Factor_{Density} \quad (18.161)$$

$$Factor_{Density} = (2/(1 + (\rho_{AirWalkIn}/\rho_{ZoneAir})^{0.333}))^{1.5} \quad (18.162)$$

$$m_{DryAir} = Q_{Infiltration}/(h_{ZoneAir} - h_{AirWalkIn}) \quad (18.163)$$

$$m_{Water} = m_{DryAir} \cdot (W_{ZoneAir} - W_{AirWalkIn}) \quad (18.164)$$

$$Q_{WalkInLatentZn} = m_{Water} \cdot \Delta h_{IcetoVapor} \cdot (1 - SCH_{Defrost,DripDown}) \quad (18.165)$$

$$Q_{WalkInSensInfZn} = Q_{Infiltration} - (m_{Water} \cdot \Delta h_{IcetoVapor}) \quad (18.166)$$

where:

A_{door} is the area of door facing Zone n (m^2)

$Factor_{DoorOpen}$ is the value scheduled by user, fraction of time door open during time step

$Factor_{Flow}$ is the doorway flow factor, = 0.8 if $\Delta T_{Zn} \geq 11^\circ C$; = 1.1 if $\Delta T_{Zn} < 11^\circ C$

$Factor_{Protection}$ is the doorway protection factor, = 0 for no protection; = 0.5 for an air curtain; and 0.9 for a strip curtain

g is the gravitational constant

$h_{AirWalkIn}$ is the enthalpy of the air within the walk in, = $f(T_{WalkIn}, P_{Outdoor}, 90\%RH)$ (J/kg)

$h_{ZoneAir}$ is the enthalpy of the air in Zone n (J/kg)

H_{door} is the height of door facing Zone n (m)

$Q_{FullFlow}$ is the sensible and latent refrigeration load for fully established flow (W)

$Q_{Infiltration}$ is the average infiltration (sensible and latent) refrigeration load for the time step (W)

$Q_{WalkInLatentZn}$ is the latent load upon the walk in facing Zone n (W)

$Q_{WalkInSensInfZn}$ is the sensible load due to infiltration upon the walkin facing Zone n (W)

m_{DryAir} is the mass of dry air infiltrating into the walk-in (kg/s)

m_{Water} is the mass of water removed from the infiltrating air (kg/s)

$P_{Outdoor}$ is the outdoor air pressure (Pa)

$SCH_{Defrost,DripDown}$ is the value from 0 to 1 indicating whether the system is in the dripdown period

$W_{AirWalkIn}$ is the humidity ratio of the air within the walk in, = $f(T_{WalkIn}, P_{Outdoor}, 90\%RH)$ (kg/kg)

$W_{ZoneAir}$ is the humidity ratio of Zone n air, kg/kg

$\Delta h_{IcetoVapor}$ is the latent heat absorbed to change ice to vapor (J/kg)

$\rho_{AirWalkIn}$ is the density of the air within the walk in = $f(T_{WalkIn}, P_{Outdoor}, 90\%RH)$ (kg/m³)

$\rho_{ZoneAir}$ is the density of air in Zone n (kg/m³).

The sensible load on the case and the sensible credit to the zone continue throughout the defrost and dripdown periods. However, to be consistent with the treatment of refrigerated cases, there is no latent credit to the zone or latent load upon the cooler during the dripdown period. Latent load and latent credit are both based on reducing the infiltrating vapor to ice. The sensible heat exchange between the walk in and the zone is then the total of the heat transfer through the doors and surfaces and the infiltration sensible load. The latent load upon the walkin is converted to the amount of frost added to the coils during each time step. This accumulating value is used later to determine the load placed upon the walkin during the defrost cycle.

$$Q_{WalkInSensZn} = Q_{WalkInSensInfZn} + Q_{DoorZn} + Q_{surfacesZn} \quad (18.167)$$

$$Q_{ZoneLatent} = -Q_{WalkInLatentZn} \quad (18.168)$$

$$Q_{ZoneSens} = -Q_{WalkInSensZn} \quad (18.169)$$

$$\Delta Frost_{Zn} = (m_{Water} \Delta time) \cdot (1 - SCH_{Defrost,DripDown}) \quad (18.170)$$

where:

$Q_{WalkInSensZn}$ is the total sensible heat exchange between the walkin and Zone n (W)

$Q_{ZoneLatent}$ is the latent load upon the Zone n (W)

$Q_{ZoneSens}$ is the sensible load upon Zone n (W)

$\Delta Frost_{Zn}$ is the change in frost inventory (kg)

$\Delta time$ is the length of time step (s).

After the heat exchange with each zone is calculated, the total load on the walkin is calculated:

$$Q_{WalkInLatentTot} = \sum Q_{WalkInLatentZn} \quad (18.171)$$

$$Q_{WalkInSensTot} = \sum Q_{WalkInSensZn} + Q_{Light} + Q_{Fan} + Q_{Heater} + Q_{Defrost} + Q_{Stocking} + Q_{Floor} \quad (18.172)$$

$$Q_{WalkInTotal} = Q_{WalkInLatentTot} + Q_{WalkInSensTot} \quad (18.173)$$

$$\Delta Frost_{Tot} = \sum \Delta Frost_{Zn} \quad (18.174)$$

where Q_{Light} , Q_{Fan} , Q_{Heater} , $Q_{Stocking}$, and $Q_{Defrost}$ are described below.

18.2.4.2 Walk-In Fans, Heaters, Lighting, and Restocking

Sensible heat loads are placed on a walk-in by fans, heaters, and lighting. Unlike refrigerated cases, there is no option to allocate any portion of these heat loads to the surrounding zone(s). Larger walk-ins will have separate fans at the cooling coil and for general circulation. The general circulation fan is assumed to run at all times. The cooling coil fan is assumed to be off for Hot-Fluid and Electric defrost. Lighting, heating, and restocking are modeled according to the schedule values entered by the user. For lighting and heating, the maximum power is entered along with a scheduled ratio (between 0 and 1) to be applied for any point in time. The heating power includes all heaters except those used for defrost purposes. The heater power should include anti-sweat, door, floor, and drain-pan heaters. For restocking, the total sensible load in Watts is scheduled for each point in time (the restocking latent load is assumed to be zero).

$$Q_{Light} = RatedQ_{Lighting} * SCH_{Lighting} \quad (18.175)$$

$$Q_{Fan} = Power_{CircFan} + Power_{CoilFan} * (1 - SCH_{DripDown}) \quad (18.176)$$

$$Q_{Heater} = Power_{Heater} * SCH_{Heater} \quad (18.177)$$

$$Q_{Stocking} = SCH_{Stocking} \quad (18.178)$$

where:

Q_{Light} is the refrigeration load due to lighting during current time step (W)

$RatedQ_{Lighting}$ is the maximum lighting load specified for the walk-in (W)

$SCH_{Lighting}$ is the scheduled value between 0 and 1 for the current time step

Q_{Fan} is the refrigeration load due to fan power during the current time step (W)

$Power_{CircFan}$ is the rated circulating fan power (W)

$Power_{CoilFan}$ is the rated coil fan power (W)

$SCH_{DripDown}$ is the scheduled value between 0 and 1 for the current time step

Q_{Heater} is the refrigeration load due to heaters during current time step (W)

$Power_{Heater}$ is the rated total heater(s) power (including anti-sweat, floor, door, etc.) (W)

SCH_{Heater} is the scheduled value between 0 and 1 for the current time step

$Q_{Stocking}$ is the refrigeration load due to stocking during the time step (W)

$SCH_{Stocking}$ is the scheduled value of load due to stocking (W).

18.2.4.3 Defrost

The defrost types available for the walk-in model include none, off-cycle, electric, and hot-fluid. Defrosts are started according to scheduled times and can be ended either by schedule or by temperature termination. Dripdown schedules are used to keep the cooling coil off long enough to drain any condensate from the system.

For defrost types none and off-cycle, the refrigeration load on the walk-in due to defrost is zero. For off-cycle, the walk-in refrigeration capacity is set to zero during the drip-down scheduled time.

The energy required for hot-fluid defrost is assumed to be reclaimed from the compressor exhaust (for detailed systems, this energy appears as a credit against the heat rejection needed at the condenser). The energy used by electric defrost is available as an output variable.

If the defrost cycle is controlled by the schedule, the refrigeration load placed upon the walk-in is calculated as the product of the defrost capacity and the defrost schedule. The load is then reduced according to the amount of accumulated ice melted during that time step.

$$Q_{Defrost} = Capacity_{Defrost} \cdot SCH_{Defrost} - \Delta frost \cdot \Delta h_{IceMelt} / \Delta time \quad (18.179)$$

where:

$Q_{Defrost}$ is the refrigeration load imposed by defrost heat (W)

$Capacity_{Defrost}$ is the rated defrost power (W)

$SCH_{Defrost}$ is the scheduled value between 0 and 1 for the current time step

$\Delta frost$ is the amount of frost melted during time step (kg)

$\Delta h_{IceMelt}$ is the heat of fusion for ice (J/kg)

$\Delta time$ is the time step (s)

If the defrost is controlled by temperature termination, the defrost cycle is assumed to end when all the ice is melted. However, we need to recognize not all defrost heat goes to melt ice. Some of the defrost heat goes to raising the temperature of the coil mass to greater than 0C, and some

is transferred to the walk-in environment as some of the coils are defrosted before others. The user enters a ‘defrost energy fraction’ to specify the portion of the defrost energy that goes directly to melting ice. The default for defrost energy fraction is 0.7 for electric defrost and 0.3 for warm fluid defrost. (Baxter, V. D., Mei, V.C., 2002) For this type of defrost control, the model calculates the amount of energy available to melt the ice in each time step. The accumulated amount of ice is then reduced accordingly. When all the ice is melted, the defrost schedule value is set to zero and no further defrost load is placed upon the walk-in cooler. If the defrost schedule ends before the ice is melted, the schedule is used and the ice continues to accumulate until the next defrost cycle. The refrigeration capacity is kept at zero until the end of the drip-down schedule. Until the accumulated ice is melted, the defrost heat load upon the walk-in is:

$$Q_{Defrost} = Capacity_{Defrost} \cdot SCH_{Defrost} \cdot (1 - Fraction_{DefrostEnergy}) \quad (18.180)$$

18.2.5 Air Chillers and Air Chiller Sets

The Air Chiller object (Refrigeration:AirChiller) is another type of refrigeration load that can be placed on either a refrigeration compressor rack, detailed refrigeration system, or secondary refrigeration system object (Refrigeration:CompressorRack, Refrigeration:System, or Refrigeration:SecondarySystem). Air chillers are used to model the type of equipment typically used in refrigerated warehouses. For that reason, there is a major difference between the air chiller model and those for refrigerated cases or walk-ins. For cases and walk-ins, a portion of the model is directed toward calculating the amount of refrigeration needed to maintain the refrigerated volume at the desired temperature due to heat exchange with the surrounding zone, and that zone is conditioned to a nearly constant temperature. In a refrigerated warehouse, the refrigeration load is caused by heat exchange with a variable external environment. For that reason, the loads for these zones are calculated by the usual EnergyPlus zone heat balance. The amount of refrigeration needed to maintain the specified temperature set points is then passed to the air chiller model, in a similar fashion to the load passed to a window air conditioner model. The air chillers are therefore solved using the system time step, not the zone time step used for cases and walk-ins.

The air chiller performance is based on three types of manufacturers ratings, Unit Load Factor, Total Capacity Map, or a set of European standards. Correction factors for material and refrigerant are applied to all of these ratings.

18.2.5.1 Unit Load Factor Capacity

Bruce Nelson has provided a useful description of the Unit Load Factor approach. (Nelson, B.I., 2010)

“One well-known method used to calculate the sensible cooling capacity of evaporators is the effectiveness method. (Kays, W.M., A.L. London, 1964) *Heat exchanger effectiveness is defined as the ratio of the actual amount of heat transferred to the maximum possible amount of heat that could be transferred with an infinite area. This method is extremely useful because cooling capacity can be calculated directly knowing only the dimensional characteristics of the coil and the initial temperature difference (entering air temperature minus the evaporating temperature). This initial temperature difference is referred to as “DT1” ... in the refrigeration industry. Sensible cooling capacity is calculated as follows:*

$$q_{sens} = \dot{m} \times c_p \times \varepsilon \times (T_{coil,inlet} - T_{evap}) = \dot{m} \times c_p \times \varepsilon \times DT1 \quad (18.181)$$

For a given size of coil operating with constant airflow rate, the effectiveness can be considered constant over the small operating temperature ranges typical of refrigeration applications, and therefore, capacity can be considered to be proportional to the ratio of DT1. Hence, if evaporator coil sensible capacity is known for a given DT1, then capacity at a new initial temperature difference, DT1*, can be found by multiplying the original capacity by the ratio DT1*/DT1.”

where:

q_{sens} is the cooling capacity (sensible only) (W)

\dot{m} is the mass flow rate of air (kg/s)

c_p is the specific heat capacity of moist air (J/kg-°C)

ε is the effectiveness ($= (T_{coil,inlet} - T_{coil,exit}) / (T_{coil,inlet} - T_{evap})$)

$T_{coil,inlet}$ is the dry-bulb air temperature entering the coil (°C)

T_{evap} is the average refrigerant evaporating temperature (°C)

$T_{coil,exit}$ is the dry-bulb air temperature leaving the coil (°C)

DT1 is the initial temperature difference (°C).

Using this approach, the manufacturer specifies the Unit Load Factor in terms of sensible capacity per degree of temperature difference.

$$ULF = Capacity_{Rated,Sensible} / DT1_{Rated} \quad (18.182)$$

The total capacity is the sum of the sensible and latent capacity. The sensible heat ratio (SHR) is the sensible heat transfer divided by the total (sensible plus latent) heat transfer. Again, from Nelson, (Nelson, B.I., 2010)

The mass transfer process is much more “thermally effective” than the sensible heat transfer process, that is, the heat flux through the evaporator surfaces during the mass transfer process is extremely high. (AHRI, 2001) Consequently, if the surface effectiveness of the coil were to remain constant, the increase in the evaporator cooling capacity during combined sensible and latent cooling would be equal to the sensible cooling capacity divided by the SHR... However, the increase in heat flux through the fin surfaces has the effect of decreasing fin efficiency and overall surface effectiveness due to an increase in the fin surface temperature gradient. The result is a slightly lower total cooling capacity.

$$Q_{ideal} = \frac{q_{sens}}{SHR} \quad (18.183)$$

$$SHR = \frac{q_{sens}}{Q_{total}} \quad (18.184)$$

where:

Q_{ideal} is the cooling capacity (total) if fin efficiency and total effectiveness were constant (W)

Q_{Total} is the cooling capacity (total), actual.

The total capacity is therefore a function of the sensible heat ratio, which is a function of the total capacity, and they are both, of course a function of the psychometrics of the air flowing through the chiller. This is handled with a two step estimation process.

$$\begin{aligned}
\Delta T &= \min \Delta T_{max}, (T_{coil,inlet} - T_{evap}) \\
q_{sens,max} &= ULF \cdot \Delta T \cdot (1 - SCH_{Defrost,DripDown}) \cdot SCH_{Coil} \\
T_{Coil,exit,estimate} &= T_{Coil,inlet} - \frac{q_{sens,max}}{\dot{m}_{DryAir} C_{p,CoilInletDryAir}} \\
h_{Coil,exit,estimate} &= f(T_{Coil,exit,estimate}, P_{Barometric}) \quad \text{at a Relative Humidity of 1} \\
Q_{Total,estimate} &= \dot{m}_{max} (h_{Coil,Inlet} - h_{Coil,exit,estimate}) \\
SHR &= \frac{q_{sens,max}}{Q_{Total,estimate}} \\
\text{Correction} &= f(SHR); \text{Function input by user, linear or quadratic curve} \\
Q_{Total} &= \text{Correction} \times q_{sens,max}
\end{aligned} \tag{18.185}$$

where:

ΔT is the temperature difference between the inlet air and the average evaporating temperature (°C)

ΔT_{Max} is the maximum temperature difference specified by the user (°C)

SCH_{Coil} is the coil availability schedule

$h_{Coil,exit}$ is the enthalpy of air at the coil exit

$h_{Coil,inlet}$ is the enthalpy of air at the coil inlet

$P_{Barometric}$ is the barometric air pressure (Pa).

The “Correction” function must be obtained from the chiller manufacturer. Some curves typical of ammonia chillers have been published (see, for example, Fig. 2 in (Nelson, B.I., 2010)). A default linear approximation of this curve is provided as an input option.

18.2.5.2 European Standard Ratings

Five standard rating conditions have been defined in a European rating system. The capacity is reported at the rating condition as either the “Nominal” or “Standard” capacity. The “Nominal” capacity includes both latent and sensible loads and the “Standard” capacity includes sensible loads only. “Wet Coil Factors” are provided with the ratings to translate between the two, along with a chart giving the impact of Air Inlet Temperature on the Wet Coil Factor. The user identifies the rating condition used and whether the capacity input is “Nominal” or “Standard”. These rating factors, along with the air inlet temperature and evaporating temperature are used to calculate the actual cooling capacity.

$$Q_{Total} = Q_{Nominal} \times \frac{WetCoilFactor(T_{Coil,inlet})}{WetCoilFactor(StandardCondition)} \times \frac{\Delta T}{\Delta T_{Rated}} \tag{18.186}$$

18.2.5.3 Total Capacity Map

Some manufacturers are beginning to provide more comprehensive performance information. For these air chillers, the manufacturers specify a Rated Total Capacity at a given inlet air relative humidity. A table or set of curves is then provided to calculate the total capacity Q_{Total} , as a function of the inlet air temperature and relative humidity, and the average evaporating temperature.

18.2.5.4 Sensible and Latent Capacity

The sensible and latent loads served are then calculated as:

$$\begin{aligned}
 h_{Coil,exit} &= h_{Coil,Inlet} - \frac{Q_{Total}}{\dot{V}_{Air,Max} \rho_{Coil,Inlet}} \\
 T_{Coil,exit} &= f(h_{Coil,exit}) \quad \text{at a Relative Humidity of 1} \\
 HR_{Coil,exit} &= f(T_{Coil,exit}, h_{Coil,exit}) \\
 \dot{m}_{Water} &= \dot{m}_{dryair,max} (HR_{Coil,exit} - HR_{Coil,inlet}) \\
 q_{latent} &= \dot{m}_{water} h_{icetovapor} \\
 q_{sens} &= Q_{Total} - q_{latent}
 \end{aligned} \tag{18.187}$$

where:

$\dot{V}_{Air,Max}$ is the maximum air flow (m³/s)

HR is the Humidity Ratio (kg water/kg dry air)

$h_{ice to vapor}$ is the enthalpy of phase change from vapor to ice.

When the sensible capacity provided is greater than the sensible load requested from the zone energy balance, the coil fan speed is varied as described later for the condenser fan. The latent load and amount of water condensed from the air are scaled accordingly.

The frost accumulation and defrost cycles are handled as described previously for walk-in coolers.

The net sensible heat impact on the zone is the difference between the coil's sensible cooling capacity and any energy added during that time step by heaters, fan motors, and defrost.

18.2.6 Detailed Refrigeration Systems

The detailed refrigeration system object (Refrigeration:System) is an alternative to the refrigeration compressor rack object (Refrigeration:CompressorRack). Either works in conjunction with the refrigerated case and walk-in objects (Refrigeration:Case and Refrigeration:WalkIn) to simulate the performance of a retail refrigeration system. The detailed system model differs from the compressor rack model in that it:

1. requires performance data for each compressor (see the RefrigerationCompressorCurves dataset),
2. requires condenser performance curves for air- and evaporative-cooled condensers,
3. explicitly calculates the amount of superheat available for reclaim in an optional air or water heating coil,
4. allows the suction temperature to rise when the case loads are less than the design loads, thus improving compressor efficiency,
5. allows the transfer of loads from one system to another, including cascade condensers and secondary systems typically used to reduce the amount of refrigerant inventory in the primary system, and mechanical subcoolers typically used to transfer a part of the refrigeration load from a lower-temperature system to a more efficient higher-temperature system,
6. allows the use of liquid suction heat exchangers which will improve the cycle efficiency for some refrigerants,

7. models three condenser fan types,
8. allows the user to keep track of refrigerant inventory,
9. does not assume that the compressor and condenser capacity is sufficient to meet the case loads, but carries unmet load over to the next time step,
10. provides optional suction piping heat gain for comparison to distribution piping heat gain for secondary systems. [Note, these piping heat gains are also reflected in the zone heat balance. This piping heat gain is not to be confused with the pressure change in the suction piping, even though this pressure change is typically expressed in terms of an change in the saturated suction temperature].

18.2.6.1 Refrigeration System Loads and Convergence

The refrigeration loads for refrigerated cases and walk-ins are added to provide the first value for the refrigeration load on a detailed system, as well as the evaporating temperature. (If there are no cases or walk-ins served directly by a system, that system is not solved until the energy transfer loads are available.) The user can also choose to include suction pipe heat gain as a load on the system. The performance of refrigeration compressors is dependent upon the condensing and evaporating temperatures. The calculation starts with an estimated condensing temperature, which is used to calculate the compressor power use.

$$\dot{Q}_{\text{Refrigeration}} = \sum \dot{Q}_{\text{case}} + \sum \dot{Q}_{\text{walkin}} (+ \sum \dot{Q}_{\text{PipeHeatGain}}) \quad (18.188)$$

$$\dot{Q}_{\text{System,Estimated}} = \dot{Q}_{\text{Refrigeration}} + P_{\text{Compressors,Estimated}} \quad (18.189)$$

These values are in turn used to determine the total heat rejection load on the condenser, which produces a new estimate for the condensing temperature. A few iterations are usually necessary to converge upon the final condensing temperature and compressor power for each time step for each system.

After each detailed refrigeration system has been solved, all energy transfers (subcoolers, secondary loops, and cascade condensers) among the systems are made.

$$\begin{aligned} \dot{Q}_{\text{Transfer}} &= \sum \dot{Q}_{\text{CascadeCondenser}} + \sum \dot{Q}_{\text{SecondaryLoop}} + \sum \dot{Q}_{\text{MechanicalSubcooler}} \\ \dot{Q}_{\text{Refrigeration}} &= \sum \dot{Q}_{\text{Case}} + \sum \dot{Q}_{\text{WalkIn}} + \sum \dot{Q}_{\text{Transfer}} + \sum \dot{Q}_{\text{PipeHeatGain}} \end{aligned} \quad (18.190)$$

This two step process is repeated twice to ensure that all the energy transfers among systems are balanced.

Suction piping heat gain is an optional element in the load calculation. Typically, the suction pipe heat gain is small compared to the other loads. However, when comparing DX systems to secondary systems, this portion of the total load can be very different. (Hinde, D., et al. 2009) To calculate the pipe heat gain load, the user must first calculate the U-value and area for the suction piping. The U-value is the total conductance from the inside skin coefficient to the outside skin coefficient. This value must be multiplied by the area to provide the “sum of the UA in W/C,” required in the input.

18.2.6.2 Compressor Energy Use

The compressor object (Refrigeration:Compressor) calculations start with the determination of the inlet (suction) and outlet (discharge) conditions. The suction pressure is defined by the saturated suction temperature (equal to the evaporating temperature in the refrigeration loads connected to the suction group) minus the pressure drop in the suction pipes. With proper design, this pressure drop typically corresponds to a saturated suction temperature drop of about 1°C. The saturated discharge pressure is defined by the condensing temperature plus the pressure drop in the discharge pipes. With proper design, this discharge pipe pressure drop typically corresponds to a saturated discharge temperature increase of about 0.5°C (ASHRAE 2006a). These two temperatures are then used with the manufacturer's performance curves for each compressor. The performance curves are defined in ARI Standard 540 and take the following form (ARI 2004):

$$\begin{aligned} X &= C_1 + C_2(S) + C_3(D) + C_4(S^2) + C_5(SD) + C_6(D^2) + C_7(S^3) + C_8(DS^2) + C_9(SD^2) + C_{10}(D^3) \\ S &= T_{evap} - 1. \\ D &= T_{condense} + 0.5 \end{aligned} \tag{18.191}$$

where:

X can represent power input or cooling capacity (W)

C is the compressor performance coefficient (be sure to see the IO Reference guide because the Energy Plus input order for this equation does not match this ARI form)

S is the saturation temperature corresponding to the suction pressure (°C)

D is the saturation temperature corresponding to the discharge pressure (°C)

T_{evap} is the evaporating temperature (°C).

The rated values for the cooling capacity and power consumption from the manufacturer include a specified amount of subcooling before the thermal expansion valve and a certain amount of superheat in the suction gas. Adjustments must be made to these rated values to reflect the actual subcooling and superheat conditions. Actual subcooling is determined by the condenser's rated subcooling and by the subcooling provided by optional subcoolers. The actual superheat is determined by the refrigerated case superheat (usually set to ensure that there is no liquid in the suction lines leading to the compressors), set here at 4°C, and the effect from any optional subcoolers (ASHRAE 2006b). These various state points are shown in Figure 18.17.

Once the corrected capacity is calculated for each compressor, the compressors are dispatched one at a time until the system load is met. The last compressor dispatched is assumed to run at full load for the fraction of the time step necessary to meet the load. That is, the model neglects compressor cycling losses at part-load conditions. Using the state point identification from Figure 18.17, these corrections are shown in the following equations. If the capacity available from all the compressors is less than the sum of the case loads for that time period, the unmet load is accumulated to be met in succeeding time steps. If this accumulated unmet load becomes too great, a warning message is generated.

$$\begin{aligned} Cap_{corrected} &= \frac{\rho_{1b}}{\rho_{1c}} \times \frac{h_{1b}-h_4}{h_{1c}-h_{4c}} Cap_{rated} \\ \dot{m} &= \frac{Cap_{corrected}}{h_{1b}-h_4} \end{aligned} \tag{18.192}$$

where:

\dot{m} is the mass flow rate of refrigerant (kg/s)

Figure 18.17: State Points and Energy Flows for Detailed Refrigeration System

ρ is the density (kg/m³)

h is the enthalpy (J/kg)

Cap is the refrigeration capacity of an individual compressor (W).

Compressor performance can also be improved by allowing the suction pressure to rise whenever the sum of the loads on the refrigerated cases served by the compressors is less than the design load. The calculation of the maximum allowable evaporator temperature is described in “Variable Evaporator Temperature” in the discussion of Refrigeration Cases.

18.2.6.3 Two-Stage Compression Systems

In addition to the single-stage compression refrigeration system illustrated above, two-stage compression systems can be modeled. For low temperature applications where the pressure ratio between the low- and high-pressure sides of the system could be 1:10 or more, it may be beneficial to utilize two stages of compressions (Evans 2008). Two smaller compressors in series have a smaller displacement and usually operate more efficiently than one large compressor that covers the entire pressure range from the evaporator to the condenser. This is especially true in ammonia refrigeration systems due to the large amount of superheating that occurs during the compression process (ASHRAE 2009b).

Between the two stages of compression, an intercooler is used to cool the discharge gas exiting the low-stage compressor before it enters the high-stage compressor. The cooling is performed within the intercooler by refrigerant at an intermediate pressure. The degree to which intercooling reduces the power requirement of a refrigeration cycle depends on the refrigerant which is being used as well as the temperature lift between the evaporator and the condenser.

Several methods of two-stage compression and intercooling have been used. For large industrial refrigeration systems, typical of ammonia systems used in refrigerated warehouses, both shell-and-coil intercooling (Figure 18.18) and flash intercooling (Figure 18.19) are used. The two stages of compression in these systems may be performed by separate low- and high-stage compressors or with a compound compressor containing both the low and high stages within the same compressor body.

For two-stage compression systems with intercooling, there is an optimum intermediate pressure that minimizes the total power consumption of the system. In the case of an ideal intercooler in which the refrigerant gas enters the high-stage compressor at the same temperature as it enters the low-stage compressor, the minimum compressor work is achieved using the same pressure ratio across both compressors (Baek et al. 2005). Typically, the optimum intermediate pressure is approximated as the geometric mean pressure of the system as follows:

$$P_{intercooler} = \sqrt{(P_{evaporator})(P_{condenser})} \quad (18.193)$$

where $P_{intercooler}$ is the pressure within the intercooler shell, $P_{evaporator}$ is the evaporating pressure and $P_{condenser}$ is the condensing pressure.

The low-stage compressors operate between the evaporator pressure and the intercooler pressure while the high-stage compressors operate between the intercooler pressure and the condensing pressure. The performance of both the low-stage and high-stage compressors are modeled using the compressors’ performance curves defined by ARI Standard 540 (ARI 2004), as discussed previously in the “Compressor Energy Use” section. In addition, capacity corrections are applied to the compressor performance curves to account for deviations between the actual operating conditions and the rated conditions.

Figure 18.18: Two-Stage Compression System with a Shell-and-Coil Intercooler.

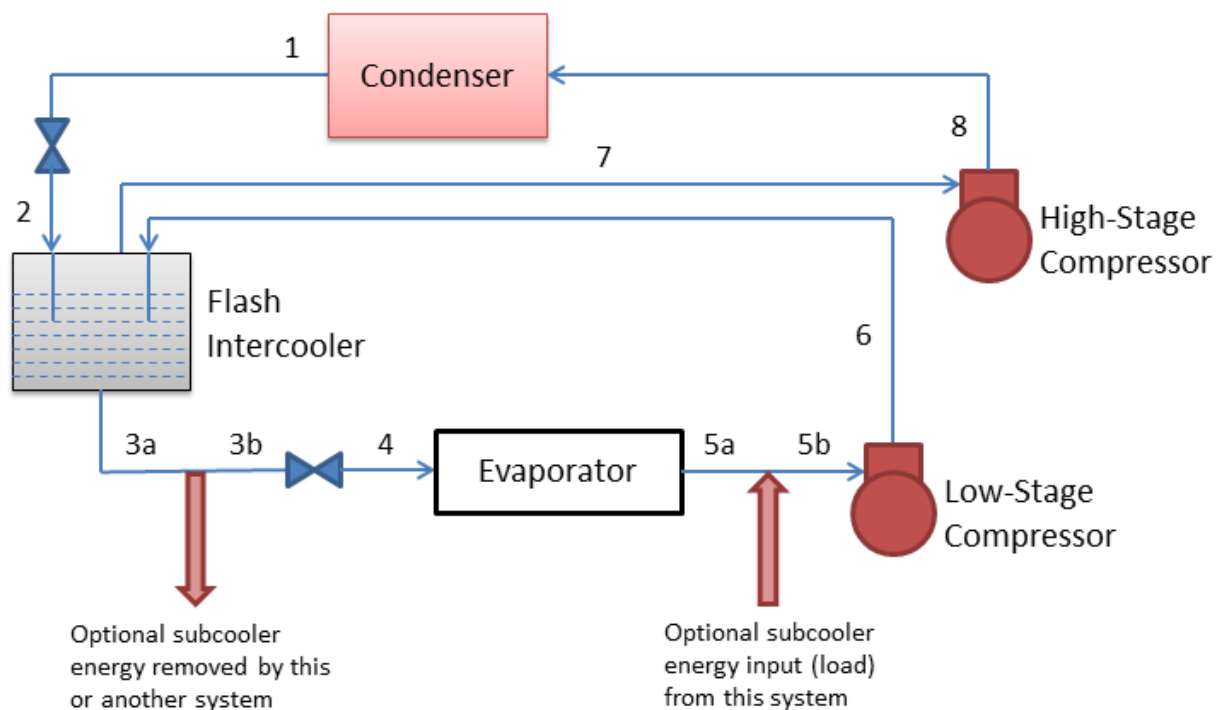

Figure 18.19: Two-Stage Compression System with a Flash Intercooler.

Referring to Figure 18.18 for a two-stage system with a shell-and-coil intercooler, the performance of the intercooler is modeled with a “Shell-and-Coil Intercooler Effectiveness”, defined as follows:

$$\eta = \frac{T_4 - T_{5a}}{T_4 - T_3} \quad (18.194)$$

where η is the shell-and-coil intercooler effectiveness, T_4 is the inlet temperature of the liquid refrigerant at Location 4, T_{5a} is the outlet temperature of the liquid refrigerant at Location 5a, and T_3 is the saturated refrigerant temperature within the intercooler shell. Valid values for the effectiveness range from 0.0 to 1.0. An effectiveness of zero indicates that no heat is transferred from the refrigerant in the shell-side of the intercooler to the liquid refrigerant in the coil-side of the the intercooler, and thus, there is no change in the temperature of the liquid refrigerant from Location 4 to Location 5a. An effectiveness of 1.0 indicates that the temperature of the liquid exiting the coil-side of the intercooler at Location 5a is equal to the temperature of the saturated refrigerant in the shell-side of the intercooler. The user may specify a value for the intercooler effectiveness and a default value of 0.8 is used if no value is specified. Furthermore, it is assumed that saturated vapor refrigerant exits the shell-and-coil intercooler at Location 9.

For the flash intercooler shown in Figure 18.19, it is assumed that saturated liquid exits the intercooler at Location 3a and saturated vapor refrigerant exits the intercooler at Location 7.

The two-stage compression refrigeration system may include an optional mechanical subcooler or liquid-suction subcooler. These subcoolers cool the liquid refrigerant which exits the intercooler before the refrigerant enters the thermal expansion valve. Further details regarding the modeling of mechanical and liquid-suction subcoolers may be found in the “Subcoolers” section.

18.2.6.4 Condenser Performance

Only one condenser is allowed per system. However, multiple refrigeration systems can reject heat through the same condenser. If a single condenser is used by multiple refrigeration systems, the code will iterate just as it does for loads transferred between systems to ensure that the total load on the condenser is accounted for in determining the saturated condensing temperature.

The condenser can be modeled as dry air cooling, wet evaporative cooling, water loop cooling, or cascade cooling. (The detailed system can not be used for a compressor rack discharging heat into a conditioned zone.) The condenser performance is modeled to determine: (1) the condensing temperature and enthalpy of the refrigerant entering the refrigerated cases attached to the suction group, both of which will influence the efficiency of the compressors, (2) auxiliary power consumption for fans and pumps, and (3) water consumption for evaporative and water-cooled condensers.

EnergyPlus can simulate waste heat being reclaimed from a detailed refrigeration system for use by refrigerant-to-air and refrigerant-to-water heating coils. (Refer to objects Coil:Heating:Desuperheater and Coil:WaterHeating:Desuperheater for a complete description of how these coils are modeled.) Heat reclaimed from the detailed refrigeration system is limited to the portion of the rejected heat in the superheat region. Using the state point nomenclature from Figure 18.17, this value is calculated by the detailed compressor and condenser models each time step as follows:

$$\dot{Q}_{AvailableSuperheat} = \dot{m} (h_{2a} - h_{2b}) \quad (18.195)$$

Heat reclaimed for hot gas or hot brine defrost is not limited to the superheat range. However, if an excessive amount of the system rejected heat is diverted for that purpose, a warning is issued

advising the user to increase the diversity of the defrost schedules.

The total heat rejection load on the condenser is the sum of the case and walk-in loads, any transfer loads (e.g., mechanical subcooler or secondary system (see object Refrigeration:SecondarySystem)) on the system(s), and the total compressor power. The condenser load is reduced by any heat reclaimed by desuperheating coils for HVAC or water heating purposes and hot gas or hot brine defrost. If a secondary system or cascade condenser is served by the system(s) using this condenser, any defrost heat rejection credits from loads on the secondary system are assigned to this condenser.

$$\dot{Q}_{Rejected} = \sum \dot{Q}_{System} - \sum \dot{Q}_{Reclaimed} \quad (18.196)$$

where:

$\dot{Q}_{Rejected}$ is the heat rejected by the condenser (W)

$\sum \dot{Q}_{Reclaimed}$ is the sum of all the heat reclaimed by desuperheater coils and hot gas and hot brine defrost (W).

Depending upon the condenser type, the heat rejection environment is set to the ambient conditions, conditions corresponding to a defined outside air node (sometimes used to represent condensers located above ground level) or zone node, to a temperature specified for a water-cooled condenser, or according to the evaporating temperature for a higher-temperature loop (used for cascade condensers).

The enthalpy of the condensed refrigerant leaving the condenser is equal to:

$$h_{condenser,out} = h_{sat,liquid}(T_{condense}) - c_{p,sat,liquid}(T_{condense}) \cdot \Delta T_{RatedSubcooling} \quad (18.197)$$

where:

$h_{condenser,out}$ is the enthalpy leaving the condenser (J/kg)

$h_{sat,liquid}$ is the enthalpy of saturated liquid at the condensing temperature (J/kg)

$c_{p,sat,liquid}$ is the specific heat of saturated liquid at the condensing temperature (J/kg-°C)

$\Delta T_{RatedSubcooling}$ is the amount of subcooling included in condenser rated heat rejection (°C).

A minimum condensing temperature is specified for the detailed refrigeration system, and is usually required to maintain acceptable thermal expansion valve performance. When the calculated condensing temperature is less than this minimum, the air flow for air and evaporative-cooled condensers is reduced to reduce the condenser capacity and maintain the required condensing temperature.

18.2.6.4.1 Air-Cooled Condensers

The heat rejection capacity of a dry air-cooled condenser object (Refrigeration:Condenser:AirCooled) is directly proportional to the difference between the condensing temperature and the drybulb temperature for the heat rejection environment. The manufacturers typically provide the performance data, at one standard atmosphere, in a linear relationship between heat rejection and temperature difference. A correction factor is applied to account for the variation in air density with elevation (Carrier 1999).

$$\begin{aligned} H_{rejRated} &= C_1 + C_2 (T_{condenser} - T_{drybulb}) \\ H_{rejRated,corrected} &= H_{rejRated} (1 - (7.17E - 5 \times Elevation)) \end{aligned} \quad (18.198)$$

where:

$H_{rej}H_{rejRated}$ is the manufacturer’s rated heat rejected by the condenser (W)

C_1 is the intercept taken from manufacturer’s condenser performance data (W)

C_2 is the coefficient taken from the manufacturer’s condenser performance data (W/°C)

$T_{condense}$ is the condensing temperature (°C)

$T_{drybulb}$ is the drybulb temperature for the local environment (°C)

Elevation is the local elevation (m)

The manufacturer’s form of performance data is used internally to define the condensing temperature as a function of the heat rejection load.

$$T_{condense} = T_{drybulb} + \left(\frac{H_{rej} - C_1}{C_2} \right) \div (1 - 7.17E - 5 \times Elevation) \quad (18.199)$$

This calculated condensing temperature is then compared to the minimum condensing temperature allowed for that system. If necessary, the air flow to the condenser is reduced to maintain the condensing temperature at or above that minimum value.

18.2.6.4.2 Condenser Fan Energy Use

Condenser fan power for air-cooled condensers is determined by the type of fan control, fixed, variable speed, or two-speed. For all three fan control types, the fan power is set equal to the rated fan power whenever the calculated condensing temperature is greater than or equal to the minimum allowed condensing temperature. If the calculated temperature is less than the minimum allowed, the condenser air flow must be reduced. The reduced rated capacity is calculated using the previous equation for $H_{rejRated}$ with the specified minimum condensing temperature. (Note, the minimum condensing temperature is often determined by the expansion valve performance, and is therefore input with the system description, not with the condenser description.) The air flow for the reduced condenser capacity is:

$$\begin{aligned} H_{rej} &\propto \text{AirVelocity}^N \\ \text{Air Velocity} &\propto H_{rej}^{1/N} \\ \text{Air Volume Ratio} &= \left(\frac{H_{rej}}{H_{rejRated}} \right)^{1/N} \end{aligned} \quad (18.200)$$

where N is 0.633 for turbulent air flow over cylinders (ASHRAE 2005).

The Air Volume Ratio is limited by a minimum value, which may be specified by the user. The default for this value is 0.2.

Four fan curves are built into the condenser fan model to represent four types of fan control, as shown in Figure 18.20. (Lawrence Berkeley Laboratory and Resource Dynamics, April 2003)

For a fixed-speed fan, the air flow is reduced through either the use of dampers or by cycling the fan on and off.

For a cycling fan, the power variation with air flow volume is approximately linear above the minimum air volume ratio as shown in the following equation for the option “FixedLinear”:

$$P_{CondFan} = (\text{Air Volume Ratio})P_{CondFan,design} \quad (18.201)$$

where:

$P_{CondFan}$ is the output variable “Refrigerated Case Condenser Fan Electric Power [W]”, not allowed to exceed the design condenser fan power

$P_{CondFan,design}$ is the design condenser fan power (W).

Figure 18.20: Condenser fan power curve options

For a fixed speed fan with damper (corresponding to the option “Fixed”), the shape of the power fraction curve is as shown above, and calculated using:

$$P_{CondFan} = (Air\ Volume\ Ratio)e^{(1-Air\ Volume\ Ratio)}P_{CondFan,design} \quad (18.202)$$

For an ideal variable speed fan, the power is proportional to the cube of the air flow. To reflect non-ideal real systems, an exponent of 2.5 is used as shown in the following equation:

$$P_{CondFan} = (Air\ Volume\ Ratio)^{2.5}P_{CondFan,design} \quad (18.203)$$

For a two-speed fan, the fan power is varied as for a constant speed fan with dampers for Air Volume Ratios greater than or equal to 0.6. For lower Air Volume Ratios, which correspond to a half-speed fan setting, the power is reduced to the variable fan power value at that point and then varied as for damper control below Air Volume Ratios (AVR) of 0.6.

$$P_{CondFan} = \begin{cases} (AVR) (e^{(1-AVR)}) P_{CondFan,Design} & \text{if } AVR \geq 0.6 \\ \left(\frac{AVR+0.4}{2^{2.5}}\right) (e^{(1-AVR)}) P_{CondFan,Design} & \text{if } AVR < 0.6 \end{cases} \quad (18.204)$$

For a water cooled condenser, there is no fan load at the condenser (i.e., the water/refrigerant heat exchanger). Any fan load would be related to and accounted for at the heat rejection object (e.g., cooling tower)

18.2.6.4.3 Evaporative-Cooled Condensers

The input object Refrigeration:Condenser:EvaporativeCooled allows using evaporative cooling rather than dry air cooling which will allow for more efficient condenser heat rejection based on the entering air approaching the wet-bulb temperature rather than the dry-bulb temperature. Analyses under the International Energy Agency’s (IEA) Heat Pumping Programme Annex 26 indicates that this measure can improve refrigeration system efficiency by up to 10% (IEA 2003). The basin heater energy and water pumping power consumption for evaporative condensers in the detailed refrigeration system is modeled as described for the Refrigeration:CompressorRack. Just as for air-dried condensers, an elevation correction is needed to adjust for the variation in density of the air. This correction factor was derived by combining the barometric pressure correction from ARI 490 and a standard correlation for barometric pressure as a function of elevation (ARI 2008, NASA 1976).

$$\begin{aligned} Hrej_{Rated,Corrected} &= Hrej_{Rated} [1 + k_1 BP_{std} (1 - e^{(A \times Elev)})] \\ A &= \frac{g_0 M_0}{R^* T_b} = -0.00012 m^{-1} \end{aligned} \quad (18.205)$$

where

k_1 is 0.0023 for pressure stated in kPa, (ARI 2008)

BP_{std} is the standard atmosphere at rating conditions (101.0 kPa)

g_0 is the gravitational constant (9.80665 m/s²)

R^* is the universal gas constant (8.31432E3 N-m/kmol-K)

M_0 is the molar mass of air (28.9644 kg/kmol)

T_b is the standard temperature (288.15 K).

Although based upon an exponential relationship, the resulting correction is very nearly linear within the range of elevations found upon dry land, so the following form of correction is used:

$$Hrej_{Rated,Corrected} = Hrej_{Rated} \times (1 - 3.07E - 5 \times Elevation) \quad (18.206)$$

To calculate the condensing temperature for an evaporative cooled condenser, it is necessary to provide the manufacturer's performance data. The manufacturers typically provide this data as a table of condensing temperature as a function of both entering wet-bulb temperature and the ratio of the heat rejected to the rated heat rejected. This data can be well represented, as shown in Figure 18.21, by a regression of the form:

$$(T_{condense} - T_{wetbulb}) = C_1 + C_2 HRCF + \frac{C_3}{HRCF} + C_4 T_{wetbulb} \quad (18.207)$$

or:

$$T_{condense} = C_1 + C_2 HRCF + \frac{C_3}{HRCF} + (1 + C_4) T_{wetbulb} \quad (18.208)$$

Where:

$$HRCF = \frac{Hrej_{Rated}}{Hrej} \quad (18.209)$$

C_1 , C_2 , C_3 , and C_4 are coefficients determined by regression from manufacturer's data.

Figure 18.21 shows a comparison between this equation form, which produced an adjusted R^2 of 0.998 and a maximum residual of 0.7°C , for one manufacturer of evaporative condensers. Data from two other manufacturers showed similar agreement with this parameterization.

Figure 18.21: Comparison of the condensing temperature predicted by four-factor equation to manufacturer's data

Again, the condensing temperature is not allowed to fall below the system's minimum allowed condensing temperature. Just as with an air-cooled condenser, the air flow through the condenser is controlled to maintain this minimum condensing temperature and the air velocity reduction is a function of the decreased capacity (Manske, 1999). For an evaporative condenser, relevant capacity is not the amount of heat rejected, but the rated capacity at that reduced air flow. That decreased rated capacity must first be calculated based upon the specified minimum condensing temperature. Using Equation 18.208, the specified condensing temperature is used to calculate the reduced HRCF, which is used with the current heat rejection to calculate the “reduced Rated Heat Rejection”.

$$0 = C_2 \times HRCF^2 + ([C_1 + C_4 T_{wetbulb} - ((T_{condenser} - T_{wetbulb}))] \times HRCF + C_3 \quad (18.210)$$

$$Reduced\ Rated\ Heat\ Rejection = HRCF \times Hrej \quad (18.211)$$

$$Air\ Volume\ Ratio = \left(\frac{Reduced\ Rated\ Heat\ Rejection}{Hrej_{Rated}} \right)^{1/N} \quad (18.212)$$

where N = exponent for evaporative condensers, set to 0.76 (Manske, 1999).

The water consumption for an evaporative condenser is calculated based upon the air flow rate, the total heat rejection, and the heat rejection environment. The amount of water consumption also includes the amount of water that is purged to reduce the concentration of contaminants. The purge water is estimated as proportional to the heat rejection, at a rate of 5.0E-10 m³/s per Watt of heat rejection (B.A.C., 2007). (This value, which corresponds to 3 gal./min. per 100 tons, is slightly more conservative than the value quoted by ASHRAE, 2004.) For the compressor racks, the condenser effectiveness was input as a function of the environmental wetbulb temperature. For the detailed evaporative condenser, the input data instead describes the capacity as a function of environmental conditions and loading. From that data, the water evaporation is calculated using the effectiveness corresponding to a fully loaded condenser. When the condenser is operating outside the bounds of the manufacturer's data, the effectiveness is limited to a maximum value of 0.9.

$$\begin{aligned} \eta &= \frac{Hrej}{\dot{V}_{air,rated} \rho_{air} (h_{Tcondense,sat} - h_{air,in})} \\ h_{air,out} &= h_{air,in} + \eta (h_{Tcondense,sat} - h_{air,in}) \\ T_{air,out} &= T_{saturated}(h_{air,out}, P_{barometric}) \\ \dot{V}_{evaporation} &= \frac{AirVolumeRatio \cdot \dot{V}_{air,rated} \cdot \rho_{air,dry} \cdot (\omega_{air,out} - \omega_{air,in})}{\rho_{water}} \\ \dot{V}_{makeup} &= \dot{V}_{evaporation} + \dot{V}_{purge} \end{aligned} \quad (18.213)$$

where:

$h_{Tcondense,sat}$ is the enthalpy of saturated air at the calculated condensing temperature

$h_{air,out}$ is the enthalpy of the air leaving the condenser

$h_{air,in}$ is the enthalpy of the inlet air, psychrometric function of inlet air drybulb temperature and humidity ratio

$\dot{V}_{air,rated}$ is the rated volumetric air flow for the evaporative condenser (input value) m³/s

ρ_{air} is the density of air evaluated at environmental conditions

$\rho_{air,dry}$ is the density of dry air evaluated at environmental temperature

$T_{air,out}$ is the air temperature leaving the condenser, psychometric function of saturated air at the enthalpy leaving the condenser and the barometric pressure

$\dot{V}_{evaporation}$ is the volumetric rate of water evaporation in the condenser (m^3/s)

$\omega_{air,out}$ is the humidity ratio ($\text{kg}_{water}/\text{kg}_{dry air}$) of the air leaving the condenser, psychometric function of $T_{air,out}$ and the barometric pressure

$\omega_{air,in}$ is the humidity ratio ($\text{kg}_{water}/\text{kg}_{dry air}$) of the air at environmental conditions

ρ_{water} is the density of water evaluated at the environmental wetbulb temperature (kg/m^3)

\dot{V}_{purge} is the volumetric rate of water purged in the condenser (m^3/s)

\dot{V}_{makeup} is the volumetric rate of water makeup in the condenser (m^3/s).

The source of the makeup water may be specified as a water storage tank. If not specified, the makeup water is assumed to come from the building mains (Ref. Water Mains Temperatures).

An evaporative condenser can be scheduled, using the Evaporative Condenser Availability Schedule described previously, so that it operates in a dry mode for a portion of the year. This is important in climates subject to freezing weather in order to avoid excessive ice formation on the condenser surfaces and surroundings. (The Availability Schedule is the correct way to model the use of evaporative condensers in cold climates. However, some users may take a single input description and use it to model a building with a refrigeration system in a variety of climates. To avoid modeling the use of evaporative coolers in freezing weather, the code includes a cutout to switch to dry operation whenever the outdoor drybulb temperature drops below 4°C .) Dry operation can also reduce water use when the dry heat rejection capacity of the equipment is sufficient to meet the load during times of the year when the outside drybulb temperature is reduced. In dry operation, the condenser heat rejection capacity is approximately one third of the rated wetted heat rejection capacity (Manske, 2000). In dry operation, the condensing temperature is estimated by using the same four-factor equation, but using the air drybulb temperature instead of the wetbulb temperature and using the reduced heat rejection capacity factor.

$$\begin{aligned} HRCF_{dryoperation} &= \frac{HRCF_{wetoperation}}{3.0} \\ T_{condense,dryoperation} &= C_1 + C_2 HRCF_{dryoperation} + \frac{C_3}{HRCF_{dryoperation}} + (1 + C_4) T_{drybulb} \end{aligned} \quad (18.214)$$

18.2.6.4.4 Water-Cooled Condensers

If the condenser heat rejection is specified as water cooled (input object Refrigeration:Condenser:WaterCooled), the model uses the same algorithms described above for Refrigeration Compressor Racks. The condensing temperature is set equal to the inlet water temperature plus an approach temperature equal to the difference between the rated values for water inlet temperature and condensing temperature.

18.2.6.4.5 Cascade Condensers

A cascade condenser joins two full detailed refrigeration systems; that is, both systems joined by the cascade condenser have loads, compressor(s), and a condenser, as shown in Figure 18.22.

The input object, Refrigeration:Condenser:Cascade, allows the use of a higher temperature refrigeration system (primary system) to serve as a heat rejection sink for a lower temperature refrigeration system (secondary system). The selection of the condensing temperature represents a trade-off in performance between the primary system absorbing the heat rejection and the secondary system rejecting heat. (Lee et al., 2006) If the condensing temperature control type is ‘fixed,’ then the secondary system condensing temperature is held constant at the temperature specified for

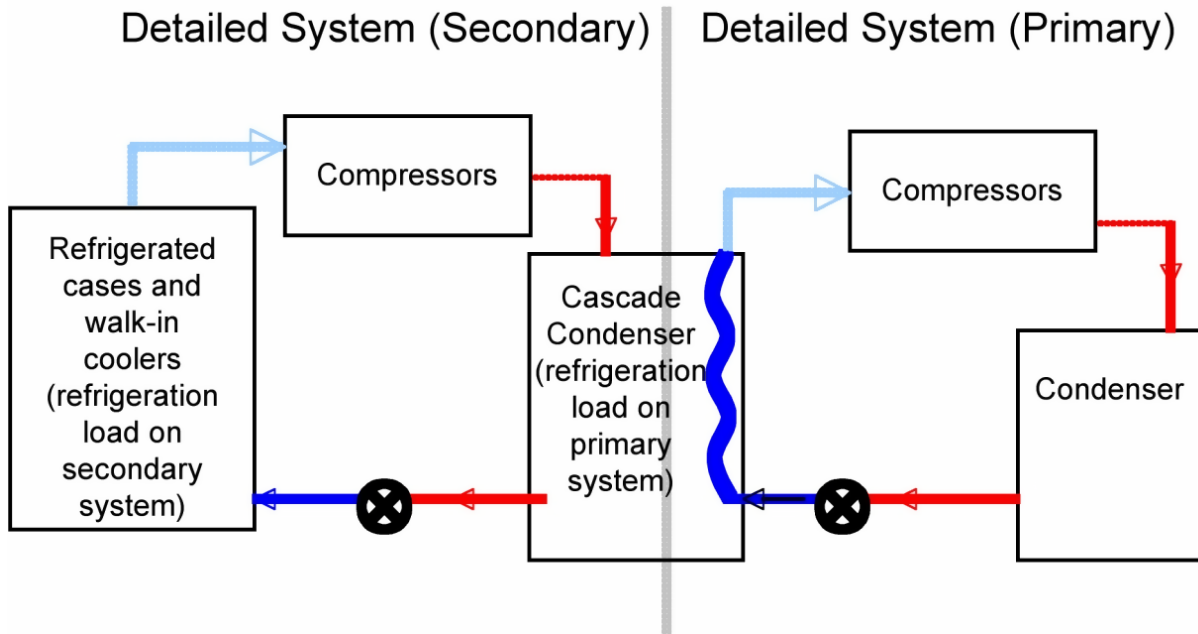

Figure 18.22: A cascade condenser is used to reject heat from a low-temperature detailed refrigeration system to a higher-temperature detailed refrigeration system

that cascade condenser (which should be greater than or equal to the secondary system's specified minimum condensing temperature). If the condensing temperature control type is 'float', the condensing temperature is allowed to float according to the minimum required evaporating temperature for other loads served by the primary system.

For fixed control:

$$T_{condense} = T_{condense,rated} \quad (18.215)$$

For floating control:

$$T_{condense} = \Delta T_{approach} + T_{evap,min} \quad (18.216)$$

where:

$T_{condense,rated}$ is the rated condensing temperature for the cascade condenser ($^{\circ}\text{C}$)

$\Delta T_{approach}$ is the rated approach temperature difference for the cascade condenser ($\Delta^{\circ}\text{C}$)

$T_{evap,min}$ is the evaporating temperature required to meet other loads on the primary system ($^{\circ}\text{C}$).

The approach temperature difference (the difference between the condensing and evaporating temperatures) in the cascade condenser, is held constant at the rated value. That is, the approach temperature difference is not varied according to the load on the condenser.

For cases and walk-ins served by cascade condensers, energy needed for hot brine or hot gas defrost is reclaimed from the primary system. The refrigeration load the cascade condenser places upon the primary system is classified as a 'transfer load', because it transfers load from one system to another. This load is the sum of all case and walk-in loads served by the secondary system, any suction piping heat gains on the secondary loop, plus the secondary loop's compressor power. The

same name (Ref. Refrigeration:Condenser:Cascade, field “Name”) used to identify the condenser in the secondary loop is used to identify the transfer load on the primary system.

$$\dot{Q}_{\text{Cascade}} = \sum \dot{Q}_{\text{Case}} + \sum \dot{Q}_{\text{Walkin}} + \sum \dot{Q}_{\text{Compressor}} \left(+ \sum \dot{Q}_{\text{PipeHeatGain}} \right) \quad (18.217)$$

where:

\dot{Q}_{Cascade} is the total refrigeration load the cascade condenser places upon the primary system (W)

\dot{Q}_{Case} is the case load on the secondary loop (W)

\dot{Q}_{Walkin} is the walk-in load on the secondary loop (W)

$\dot{Q}_{\text{Compressor}}$ is the power input to a compressor on the secondary loop (W)

$\dot{Q}_{\text{PipeHeatGain}}$ is the heat gain in secondary loop suction pipe (W).

Even though a cascade condenser is considered to be a part of a secondary loop, that loop is described with the Refrigeration:System object, not with the object, Refrigeration:SecondarySystem, described below.

18.2.6.5 Subcoolers

Subcooler objects (Refrigeration:Subcooler) reduce the temperature of the liquid refrigerant after it leaves the condenser and before it reaches the thermal expansion valve, corresponding to state point, 3b, on Figure 18.17. The detailed refrigeration system permits the use of two type of subcoolers, mechanical and liquid suction. A mechanical subcooler is used to transfer refrigeration load from a lower-temperature system to a higher-temperature system. For example, the compressors that are used to provide cooling for dairy products could be used to subcool the refrigerant in another system that is serving frozen food cases. For the system providing the cooling, the mechanical subcooler acts like another refrigerated case load. For the system receiving the cooling, the mechanical subcooler reduces the enthalpy of the refrigerant from point 3a to point 3b on Figure 18.17, and thus reduces the required refrigerant flow rate. Mechanical subcooler performance is defined by the controlled temperature of the subcooled liquid as follows:

$$\begin{aligned} \dot{Q} &= \dot{m} C_p (T_{3a} - T_{\text{control}}) \\ h_{3b} &= h_{3a} - C_{p,\text{liquid}} (T_{3a} - T_{\text{control}}) \end{aligned} \quad (18.218)$$

where:

\dot{Q} is the subcooler load (W)

\dot{m} is the mass flow rate of refrigerant (kg/s)

$C_{p,\text{liquid}}$ is the specific heat of saturated liquid at the condensing temperature, (J/kg·°C)

T_{control} is the control temperature specified for the mechanical subcooler (°C)

h is the enthalpy (J/kg).

A liquid suction heat exchanger (LSHX) subcooler uses the cold gas exiting the refrigerated cases to subcool the condensed liquid refrigerant in the same system. Depending upon the shape of the refrigerant’s saturation curve and the operating condensing and evaporating temperature, this can save significant energy by reducing the required refrigerant flow (ASHRAE 2006a). (This model neglects the pressure drop through the suction side of the heat exchanger, although this pressure drop will cause the compressor to operate at a lower suction pressure.) A liquid suction heat exchanger is defined by specifying the design values for: inlet liquid temperature, inlet vapor temperature, and liquid temperature change. A liquid suction heat exchanger subcooler will also

increase the superheat of the gas returning to the compressor, as shown by the difference between state points 1a and 1b in Figure 18.17:

$$\begin{aligned}
 \eta_{LSHX} &= \frac{\Delta T_{Design}}{T_{LiquidDesign} - T_{VaporDesign}} \\
 \dot{Q} &= \dot{m} C_{p,liquid} \eta_{LSHX} (T_{3a} - T_{1a}) \\
 T_{1b} &= T_{1a} + \frac{\dot{Q}}{\dot{m} C_{p,vapor}} \\
 h_{3b} &= h_{3a} - \frac{\dot{Q}}{\dot{m}}
 \end{aligned} \tag{18.219}$$

where:

η_{LSHX} is the subcooler effectiveness

$C_{p,vapor}$ is the specific heat of saturated vapor at the evaporating temperature (J/kg·°C)

ΔT_{Design} is the design liquid temperature difference (°C)

$T_{LiquidDesign}$ is the design liquid inlet temperature (°C)

$T_{VaporDesign}$ is the design vapor inlet temperature (°C).

If a system is subcooled by both a mechanical subcooler and a liquid subcooler, the liquid subcooler will follow the mechanical subcooler and those points labeled ‘3a’ in the liquid suction equations would correspond to the points labeled ‘3b’ in the mechanical subcooler equations, that is, the inlet of the LSHX would be the outlet of the mechanical subcooler.

Any one system can be cooled (i.e., have energy removed between points ‘3a’ and ‘3b’) by at most one liquid suction heat exchanger and one mechanical subcooler. However, a system can provide cooling to multiple mechanical subcoolers. For example if a building had one high temperature refrigeration system (perhaps cooling fresh produce) and three low temperature systems (perhaps cooling frozen foods and meat), each of the three low temperature systems could include a mechanical subcooler with the refrigeration energy for all three absorbed by the one high-temperature system. For the compressors and condenser on the high-temperature system, these three mechanical subcoolers would represent a load very similar to that of the refrigerated cases served by that system.

18.2.6.6 Suction Piping Heat Gains

Suction piping heat gain is an optional element in the load calculation. Typically, the suction pipe heat gain is small compared to the other loads. However, when comparing DX systems to secondary systems, this portion of the total load can be very different. (Hinde, D., et al. 2009) To include the suction pipe heat gain load, the user must first calculate the U-value and outer surface area for the suction piping. The U-value is the total conductance from the inside skin coefficient, through the pipe insulation, to the outside skin coefficient. This value must be multiplied by the external surface area of the pipe insulation to provide the sum of the UA required in the input. These piping heat gains are also reflected in the zone heat balance.

$$\dot{Q}_{PipeHeatGain} = \sum UA(T_{zone} - T_{SaturatedSuction}) \tag{18.220}$$

where:

$\dot{Q}_{PipeHeatGain}$ is the heat load on the detailed refrigeration system due to suction pipe heat gains (W)

$\sum UA$ is the sum of the product of the conductance times the surface area for the suction piping (W/°C).

18.2.7 Secondary Refrigeration Systems

The object, `Refrigeration:SecondarySystem`, is used to model systems that do not have compressors, but have a circulating pump and a heat exchanger (called the secondary evaporator) where evaporating refrigerant in the primary loop absorbs heat rejected by the secondary loop. The purpose of the secondary refrigeration system model is to determine: the refrigerating load placed upon the primary system via the Secondary Evaporator, the required evaporating temperature in the Secondary Evaporator, any heat recovered for defrost purposes, and the total pump power.

If your secondary loop includes compressors and a cascade condenser, do NOT use a `Refrigeration:SecondarySystem` object. Use a `Refrigeration:System` object with a `Refrigeration:Condenser:Cascade` object and list that condenser as a transfer load in the input description of the primary system.

In the secondary loop shown in Figure 18.23, the secondary evaporator serves to chill a brine or glycol solution (single phase) that in turn chills the refrigeration loads on the secondary loop. In Figure 18.24, the secondary evaporator serves as a condenser for a refrigerant that has been partially vaporized (two-phase) while circulating through the refrigeration loads on the secondary loop. Every secondary system includes a refrigeration load made up of refrigerated cases and/or walk-ins, a heat exchanger (called the Secondary Evaporator), and circulating pump(s). The loop performance at any one time step is determined by the effectiveness of the heat exchanger, the refrigeration load, and the pumping power needed to meet that load. The fluid temperature entering the cases and walk-ins is maintained at a set value.

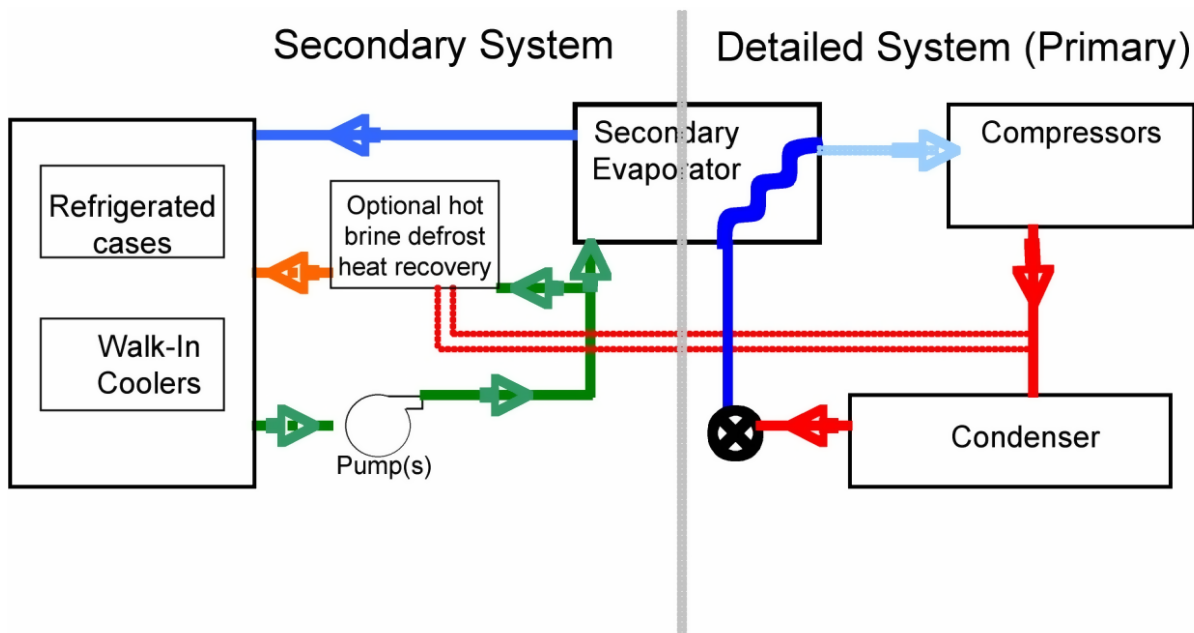

Figure 18.23: Secondary loop with brine or glycol solution circulation

For both types of secondary loops, the primary refrigeration system absorbs the load by providing cold refrigerant that evaporates in the secondary evaporator. We classify this secondary load as a ‘transfer load’ because it transfers load from one ‘system’ to another. (Cascade condenser loads are also considered transfer loads.) Just as with any DX refrigeration evaporator, the variable load from the secondary system is served by varying the primary system refrigerant flow to the

Figure 18.24: Secondary loop with liquid-overfeed refrigerant circulation

evaporator side of the secondary evaporator. Unmet load will be carried over to the next time step anytime the load on the secondary condenser/evaporator exceeds the rated capacity for the specified temperatures. (A warning will be generated if the total unmet energy grows excessively large.) The main differences between the single-phase secondary loop model and the two-phase secondary loop model lie in the definition and performance of the secondary evaporator and the way input data is processed to define evaporator capacity.

For a brine system, the secondary loop capacity is matched to the case and walk-in load by varying the brine flow rate. (*Throughout this section, ‘brine’ will be used when referring to the secondary loop heat transfer fluid for systems where the secondary circulating fluid remains in the liquid state.*) When selecting the brine loop design parameters, it is important to consider the performance trade-off between pumping energy and the temperature difference, or range, in the heat exchanger. The circulating fluid selection is also critical in determining the performance of brine loop, with large variations caused by differences in viscosity and density (which impact pumping power requirements) and specific heat (which determines the required fluid flow rate). (Kazachki, G. S., and Hinde, D. K., 2006, Faramarzi, R. T., and Walker, D. H. 2004, ASHRAE. 2006c)

For a secondary loop to accommodate a two-phase secondary coolant, additional hardware is required and the system control mode changes. A separator/receiver is required to separate the wet mixture of liquid and gas returning from the refrigeration load, as shown in Figure 18.24. (In the following discussion, we will refer to the secondary fluid in a liquid-overfeed system as CO_2 .) In Figure 18.25, which focuses in on the secondary loop alone, the gaseous CO_2 moves via thermosiphon effect to the secondary evaporator, where heat is absorbed by the primary system to condense the CO_2 , which then returns via gravity flow to the separator/receiver. The liquid CO_2 is pulled from the bottom of the separator/receiver and pumped to the load. The term ‘liquid overfeed ratio’ refers to the ratio of the total pumped mass flow rate (at the point labeled “1” on Figure 18.25) of CO_2 to the mass rate of CO_2 evaporated at the load (vapor portion of the flow at the point labeled “5” on Figure 18.25). With a variable flow rate (obtained with either a variable-speed pump or multiple constant-speed pumps), the liquid overfeed ratio is maintained at or above the specified value. With

a constant flow rate (obtained by specifying a single constant-speed pump), the liquid overfeed ratio will vary to match the capacity of the variable refrigeration load. (Hinde et al 2009) Even though a greater amount of CO₂ is circulated than is evaporated, the pumping power requirements are still much less than those for a single-phase secondary coolant.

Figure 18.25: Thermodynamic cycle for a liquid overfeed secondary loop

If the defrost type for any of the cases or walk-ins on the secondary loop is ‘HotBrine’ or ‘HotGas’, the defrost energy is assumed to come from the hot compressed gas leaving the compressors on the primary system, as shown in Figure 18.23 and Figure 18.24. (Minea, V. 2007) Therefore, the amount of heat rejected by the condenser for that primary system is reduced by the amount needed for defrost. Some research has shown that the defrost times for cases and walk-ins defrosted using hot brine can be significantly shorter than defrost times for electric or hot gas. (Terrell, W. J. Jr., 1999) The user should consider this factor when describing the input data for cases and walk-ins served by a secondary loop.

18.2.7.1 Secondary Evaporator in a Single-Phase Secondary Loop (Brine or Glycol Loop)

For a single-phase secondary system, the heat exchanger effectiveness is calculated based upon the input rating data, which includes the evaporating temperature, approach and range temperature differences, and heat exchanger capacity. The rated capacity for the heat exchanger can be specified by either providing the capacity in Watts, or the rated mass flow rate. The density and specific heat both correspond to those properties at the average temperature of the heat exchange fluid within the secondary loop heat exchanger.

These variables are specified by the chiller manufacturer at rated conditions:

$\Delta T_{Approach}$ is the approach temperature difference ($^{\circ}\text{C}$)

ΔT_{Range} is the range temperature difference ($^{\circ}\text{C}$)

$T_{EvapDesign}$ is the heat exchanger evaporating temperature ($^{\circ}\text{C}$)

$Flow_{RatedVolume}$ is the brine flow rate through the heat exchanger (kg/s)

$Capacity_{Rated}$ is the heat exchanger cooling capacity (W).

The rated conditions are used to calculate:

$$T_{BrineOutRated} = T_{EvapDesign} + \Delta T_{Approach} \quad (18.221)$$

$$T_{BrineInRated} = T_{BrineOutRated} + \Delta T_{Range} \quad (18.222)$$

$$\eta = Capacity_{Rated} / (Flow_{RatedMass} * C_{pBrine} * (T_{BrineInRated} - T_{EvapDesign})) \quad (18.223)$$

$$T_{BrineAverage} = (T_{BrineOutRated} + T_{BrineInRated}) / 2 \quad (18.224)$$

If the capacity is specified and the flow rate is not, then the flow rate is calculated as:

$$Flow_{RatedMass} = Capacity_{Rated} / (C_{pBrine} * \Delta T_{Range}) \quad (18.225)$$

$$Flow_{RatedVol} = Flow_{RatedMass} / \rho_{Brine} \quad (18.226)$$

If the flow rate is specified and the capacity is not, the capacity is calculated as:

$$Flow_{RatedMass} = Flow_{RatedVol} * \rho_{Brine} \quad (18.227)$$

$$Capacity_{Rated} = Flow_{RatedMass} * C_{pBrine} * \Delta T_{Range} \quad (18.228)$$

Where:

η is the heat exchanger effectiveness (dimensionless and less than one)

$T_{BrineInRated}$ is the heat exchanger brine inlet temperature at rated conditions (°C)

$T_{BrineOutRated}$ is the heat exchanger brine outlet temperature at rated conditions (°C)

$T_{BrineAverage}$ is the average brine temperature in the heat exchanger (°C)

$Flow_{RatedMass}$ is the brine flow rate through the heat exchanger (kg/s)

$Flow_{RatedVol}$ is the brine flow rate through the heat exchanger (m³/s)

C_{pBrine} is the brine specific heat (J/kg-°C)

ρ_{Brine} is the brine density (kg/m³).

After the heat exchanger effectiveness has been calculated, the value for the heat exchanger design brine flow rate is compared to the design flow rate for the secondary loop pump(s). The maximum flow rate in the loop is limited to the smaller of these two values. The heat transfer capacity corresponding to this maximum flow rate is then calculated and compared to the rated heat exchanger capacity. The maximum load on the heat exchanger is limited to the lesser of these two values, the rated heat exchanger capacity or the capacity corresponding to the maximum loop flow rate.

$$Flow_{MaxVol} = Minimum(Flow_{RatedVol}, Flow_{RatedPumpVol}) \quad (18.229)$$

$$Capacity_{AtMaxVolFlow} = Flow_{MaxVol} * \eta * (C_{pBrine} * Density_{Brine}) * (T_{BrineInRated} - T_{EvapDesign}) \quad (18.230)$$

$$Capacity_{Max} = Minimum(Capacity_{Rated}, Capacity_{AtMaxVolFlow}) \quad (18.231)$$

where:

$Flow_{MaxVol}$ is the maximum loop volume flow, limited by either the pump rating or the heat exchanger rating (m^3/s)

$Capacity_{AtMaxVolFlow}$ is the secondary loop capacity corresponding to the maximum loop flow rate (W)

$Capacity_{Max}$ is the maximum secondary evaporator capacity (W).

18.2.7.2 Secondary Evaporator in a Two-Phase Secondary Loop (Liquid-Overfeed Loop, e.g., CO₂)

For a two-phase system, the secondary evaporator effectiveness is not calculated. Both the evaporating and condensing sides of the heat exchanger are assumed to operate at fixed temperatures. If the capacity of the secondary evaporator is not input, it will be calculated as the sum of the rated loads plus the rated pump power.

$$\begin{aligned} Capacity_{Rated} &= \text{Input} \quad \text{or:} \\ Capacity_{Rated} &= \sum \dot{Q}_{Case} + \sum \dot{Q}_{WalkIn} + Power_{Pump} \\ Capacity_{Max} &= Capacity_{Rated} \end{aligned} \quad (18.232)$$

If the flow rate through the evaporator is not input, it will be calculated based upon the input value for the Circulating Rate.

$$Flow_{RatedVol} = \frac{\sum \dot{Q}_{Case} + \sum \dot{Q}_{WalkIn} + Power_{Pump}}{\rho_{Liquid} \Delta h_{fg}} \quad (18.233)$$

Where:

ρ_{Liquid} is the liquid density (kg/m^3)

Δh_{fg} is the heat of vaporization (J/kg).

18.2.7.3 Secondary Loop Distribution Piping and Receiver Shell Heat Gains

Distribution piping and receiver shell heat gains are optional elements in the load calculation. Typically, the distribution pipe and receiver shell heat gains are small compared to the other loads. However, when comparing direct expansion systems to secondary systems, this portion of the total load can be very different. (Hinde, D., et al. 2009) To calculate the pipe heat gain load, the user must first calculate the U-value and area for the distribution piping. The U-value is the total conductance from the inside skin coefficient to the outside skin coefficient. This value must be multiplied by the piping external surface area to provide the sum of the UA required in the input. Note that these piping and receiver shell heat gains are also reflected in the zone heat balance, similar to the zone cooling credits provided by refrigerated cases.

$$\dot{Q}_{PipeHeatGain} = \sum UA(T_{zone} - T_{BrineAverage}) \quad (18.234)$$

where:

$\dot{Q}_{PipeHeatGain}$ is the heat load on the secondary loop due to pipe heat gains, output variable “Refrigeration Secondary Loop Pipe Heat Gain Rate” (W)

$\sum UA$ is the sum of the product of the conductance times the surface area for the piping ($W/^\circ C$).

The receiver shell heat gains are calculated in the same manner.

18.2.7.4 Secondary Loop Pumping Power and Secondary Loop Load

Pump ratings are typically given in the form of curves. The input values for the pumps should correspond to the full-load design conditions, with respect to fluid viscosity, density, and temperature, as well as pressure drop. For these conditions, the user provides either the total pump power or the total head, as well as the flow rate. *These values must be representative of the selected heat transfer fluid at the average loop operating temperature and pressure.* If the pump head at design conditions is specified, the pump power is calculated as:

$$Power_{PumpRated} = Flow_{RatedPumpVol} * Head_{Rated} / (Efficiency_{PumpImpeller} * Efficiency_{PumpMotor}) \quad (18.235)$$

where:

$Power_{PumpRated}$ is the total pumping power for the secondary loop at rated conditions (W)

$Head_{Rated}$ is the pressure drop through the entire secondary loop circulation at rated conditions, including at the pumps, the chiller, supply and return piping, and through the case and walk-in coils (pipes are typically sized to produce a total head ranging from 0.25E6 to 0.3E6 Pa (ASHRAE 2006c) (Pa)

$Efficiency_{PumpImpeller}$ is the pump impeller efficiency

$Efficiency_{PumpMotor}$ is the pump motor efficiency.

The pump impeller efficiency is assumed to be 78%. (ASHRAE 2006c) The pump motor efficiency is assumed to be 85%. (ITT 2009) If a semi-hermetic motor is specified, all the pump power is translated to heat within the fluid. The total heat load placed upon the loop by the pumps is therefore:

$$\dot{Q}_{Pump} = Power_{PumpRated} * Ratio_{PowerToHeat} \quad (18.236)$$

where:

\dot{Q}_{Pump} is the total heat load placed upon the secondary loop by the pumps (W)

$Ratio_{PowerToHeat}$ is the ratio of total motor energy rejected to the circulating fluid to the total pump power used (input by the user, suggest 1.0 for semi-hermetic motors and 0.85 for others).

A variable speed pump can be modeled by providing a cubic curve for pump power as a function of the ratio of total flow needed to the total flow specified at full load design conditions.

$$\dot{Q}_{Pump} = [A(LF_{Pump})^3 + B(LF_{Pump})^2 + C(LF_{Pump}) + D] \times Power_{PumpRated} \times Ratio_{PowerToHeat} \quad (18.237)$$

where LF_{Pump} is the ratio of total flow needed to the total flow specified at full load design conditions.

The user may also specify multiple constant-speed pumps. Multiple pumps, or pump staging, are often used to reduce the total pumping power requirements while still providing the capacity and constant pressure drop needed to meet peak design loads. (Faramarzi, R. T., and Walker, D. H. 2004) When multiple pumps are specified, the flow rate provided by one pump is compared to the flow rate needed to meet the refrigeration load on the loop during that time step. If that flow rate is insufficient, another pump is added, and the process is continued until the needed flow rate is met or all the pumps are included. The incremental power for each pump is added to determine the total pump power for the loop. Each pump is assumed to operate at full load if it is needed at all. A bypass is assumed to carry any fluid flow not needed to meet the load. An iterative solution

is required for the total pump load on the heat exchanger because the flow rate is determined by the load, which includes the pump power that is determined by the necessary flow rate. For the first estimate, the pump power load is assumed to be zero.

$$\begin{aligned}
 \dot{Q}_{Refrigeration} &= \sum \dot{Q}_{Case} + \sum \dot{Q}_{WalkIn} \\
 \dot{Q}_{TotalSecondary} &= \dot{Q}_{Refrigeration} + \dot{Q}_{Pump} + \sum \dot{Q}_{Pipe \text{ and Receiver Shell heat gains}} \\
 FlowNeeded &= \frac{\dot{Q}_{TotalSecondary}}{\eta C_{p,Brine} \rho_{Brine} (T_{BrineOutRated} - T_{evap})}
 \end{aligned} \tag{18.238}$$

where:

$\dot{Q}_{Refrigeration}$ is the output variable “Refrigeration Secondary Loop Load Heat Transfer Rate” (W)

$\dot{Q}_{TotalSecondary}$ is the total load the secondary loop transfers to the primary system, output variable “Refrigeration Secondary Loop Total Heat Transfer Rate” (W)

\dot{Q}_{Pump} is the pump power, function of $Flow_{Needed}$, output variable “Refrigeration Secondary Loop Pump Electric Power” (W)

$Flow_{Needed}$ is the flow rate needed to meet the loop refrigeration load, , output variable “Refrigeration Secondary Loop Volume Flow Rate” (m³/s).

The needed flow rate is used to determine the number of pumps required and the total pumping power, which produces a new estimate for the total load. A few iterations converge upon the final secondary loop load for each time step. The total load on the heat exchanger is therefore the sum of the refrigeration loads, any pipe heat gains, and the portion of the pump power that is absorbed by the circulating fluid.

18.2.8 Transcritical CO₂ Refrigeration System

The Refrigeration:TranscriticalSystem object allows users to model detailed transcritical carbon dioxide (CO₂) booster refrigeration systems used in supermarkets. The object allows for modeling either a single stage system with medium-temperature loads or a two stage system with both medium- and low-temperature loads.

The input objects required to model a detailed transcritical CO₂ refrigeration system include the following:

- One Refrigeration:TranscriticalSystem object,
- At least one refrigeration load object which may include any combination of the following:
 - Refrigeration:Case,
 - Refrigeration:WalkIn,
 - Refrigeration:CaseAndWalkInList (may include both cases and/or walk-in cooler names),
- At least one Refrigeration:Compressor object (multiple compressors are entered using a Refrigeration:CompressorList),
- One Refrigeration:GasCooler:AirCooled object,

Output variables are available to describe the total heat exchange between all the refrigeration objects and the zones containing these objects.

At least one refrigeration load object must be defined which may be one of two types of loads, including a refrigerated display case and a walk-in cooler, (Ref. Refrigeration:Case, and Refrigeration:WalkIn). If multiple loads are served by the same system, the user should use the refrigerated case and walk-in list object available to assign all cases and walk-ins cooled directly by this system (Ref. Refrigeration:CaseAndWalkInList).

The name of at least one compressor must be defined and a list object is available if the system is served by more than one compressor (Ref. Refrigeration:Compressor and Refrigeration:CompressorList).

Heat is rejected to the outdoors via an air-cooled gas cooler (Ref. Refrigeration:GasCooler:AirCooled).

The Refrigeration:TranscriticalSystem object coordinates the energy flows between the other refrigeration objects and is used to set system parameters.

The inputs for the refrigeration system object, in addition to the names of the other refrigeration objects described above, include a name for this system, the minimum condensing temperature, and the refrigeration system working fluid. Optional input fields are also provided for users seeking to keep track of refrigerant inventory and suction pipe heat gains.

18.2.8.1 Transcritical CO₂ Refrigeration Cycles

Transcritical CO₂ refrigeration cycles are characterized by a subcritical evaporation process and a supercritical “gas cooling” process. In the subcritical evaporation process which occurs in the evaporator, the CO₂ changes phase from a liquid and vapor mixture to a superheated vapor. In doing so, the CO₂ absorbs heat, thereby creating the cooling effect. This process is similar to the evaporation process in a standard vapor-compression refrigeration cycle.

After the CO₂ exits the evaporator and is compressed into the supercritical region, the CO₂ gas is cooled. This gas cooling process differs from the condensation process which occurs in the standard vapor-compression refrigeration system. In the standard refrigeration cycle, the refrigerant vapor is first desuperheated and then condensed to a liquid in the condenser. In the transcritical CO₂ cycle, a “gas cooler” rather than a condenser is used to cool the supercritical CO₂ from the compressor discharge temperature to the expansion device inlet temperature. No condensation occurs in this process. Rather, the temperature and density of the CO₂ continuously changes from that at the compressor discharge to that at the expansion device inlet.

EnergyPlus is capable of modeling the transcritical booster refrigeration cycle. Figure 18.26 shows a schematic of the booster cycle while Figure 18.27 shows the corresponding pressure-enthalpy (p - H) diagram of the booster cycle.

Carbon dioxide exits the gas cooler at Location 1 and passes through the suction line heat exchanger, exiting at Location 2, during which the refrigerant is cooled by the suction gas. An intermediate expansion occurs between Locations 2 and 3, and saturated CO₂ enters the receiver. Saturated liquid CO₂ exits the receiver at Location 6, which is then expanded and fed to the medium-temperature loads (between Locations 7 and 8) and the low-temperature loads (between Locations 9 and 10). Saturated vapor CO₂ exits the receiver bypass at Location 4 and is expanded to the medium-temperature pressure level at Location 5. Carbon dioxide vapor exiting the low temperature loads is compressed to the medium-temperature pressure level (Location 10 to 11). The CO₂ from the discharge of the low pressure compressors, the outlet of the medium-temperature loads and the outlet of the receiver bypass are then combined at Location 13. The CO₂ suction gas

Figure 18.26: Schematic of the Transcritical CO₂ Booster Refrigeration Cycle.

Figure 18.27: Pressure-Enthalpy (*p-H*) Diagram for the Transcritical CO₂ Booster Refrigeration Cycle.

then passes through the suction line heat exchanger where the refrigerant is heated, exiting at Location 14. The carbon dioxide is finally compressed to the gas cooler pressure level at Location 15 and heat is rejected to the surroundings in the gas cooler between Locations 15 and 1.

18.2.8.2 CO₂ Compressor Performance Modeling

To model the performance of the CO₂ compressors during subcritical and transcritical operation, cubic polynomials are used to curve fit manufacturers' performance data. This technique is similar to that described in AHRI Standard 540 (AHRI 2004). For subcritical operation, the power consumption and cooling capacity of a CO₂ compressor is a function of the saturated suction temperature, t_{ss} (°C), and the saturated discharge temperature, t_{sd} (°C), as follows:

$$z = C_1 + C_2 t_{ss} + C_3 t_{sd} + C_4 t_{ss}^2 + C_5 t_{ss} t_{sd} + C_6 t_{sd}^2 + C_7 t_{ss}^3 + C_8 t_{ss}^2 t_{sd} + C_9 t_{ss} t_{sd}^2 + C_{10} t_{sd}^3 \quad (18.239)$$

where z is either power consumption (W) or cooling capacity (W) and C_x are the corresponding correlation coefficients.

For transcritical operation, the power consumption (in Watts) of a CO₂ compressor, W , is a function of the saturated suction temperature and the gas cooler pressure, p_{gc} (Pa), as follows (Ge and Tassou 2011):

$$W = C_1 + C_2 t_{ss} + C_3 p_{gc} + C_4 t_{ss}^2 + C_5 t_{ss} p_{gc} + C_6 p_{gc}^2 + C_7 t_{ss}^3 + C_8 t_{ss}^2 p_{gc} + C_9 t_{ss} p_{gc}^2 + C_{10} p_{gc}^3 \quad (18.240)$$

The cooling capacity (in Watts) of a transcritical CO₂ compressor, Q , is a function of the saturated suction temperature and the gas cooler outlet enthalpy, h_{go} (J/kg), as follows (Ge and Tassou 2011):

$$Q = C_1 + C_2 t_{ss} + C_3 h_{go} + C_4 t_{ss}^2 + C_5 t_{ss} h_{go} + C_6 h_{go}^2 + C_7 t_{ss}^3 + C_8 t_{ss}^2 h_{go} + C_9 t_{ss} h_{go}^2 + C_{10} h_{go}^3 \quad (18.241)$$

The correlation coefficients, C_x , are obtained either directly from CO₂ compressor manufacturers or from cubic curve fits performed on their published CO₂ compressor performance data. For convenience, correlation coefficients for CO₂ compressors from several manufacturers have been included in the EnergyPlus refrigeration compressor coefficient database.

The rated values for the cooling capacity and power consumption from the manufacturer include a specified amount of subcooling before the thermal expansion valve and a certain amount of superheat in the suction gas. Adjustments must be made to these rated values to reflect the actual subcooling and superheat conditions. Actual subcooling is determined by the condenser's rated subcooling and by the subcooling provided by optional subcoolers. The actual superheat is determined by the refrigerated case superheat (usually set to ensure that there is no liquid in the suction lines leading to the compressors), set here at 10°C, and the effect from any optional subcoolers. See the section, "Detailed Refrigeration Systems", for a description of the compressor corrections.

Once the corrected capacity is calculated for each compressor, the compressors are dispatched one at a time until the system load is met. The last compressor dispatched is assumed to run at full load for the fraction of the time step necessary to meet the load. That is, the model neglects compressor cycling losses at part-load conditions. If the capacity available from all the compressors is less than the sum of the case loads for that time period, the unmet load is accumulated to be met in succeeding time steps. If this accumulated unmet load becomes too great, a warning message is generated.

18.2.8.3 Gas Cooler Performance

Only one gas cooler is allowed per transcritical refrigeration system. However, multiple refrigeration systems can reject heat through the same gas cooler. Currently, only air-cooled gas coolers are modeled. The gas cooler performance is modeled to determine the gas cooler pressure, gas cooler outlet temperature and outlet enthalpy of the refrigerant, and the auxiliary power consumption for the fans.

18.2.8.3.1 Optimal Gas Cooler Pressure for Transcritical CO₂ Cycles

When the compressor discharge conditions are such that the CO₂ is in the supercritical region, then the high-side operating pressure is independent of the gas cooler exit temperature (Sawalha 2008). Thus, for a given gas cooler exit temperature, there is an optimum pressure to achieve the maximum coefficient of performance (COP). Figure 18.28 illustrates the variation in COP of a transcritical CO₂ cycle with discharge pressure at different gas cooler exit temperatures.

Several researchers have developed correlations to determine the optimum gas cooler pressure in CO₂ refrigeration systems (Chen and Gu 2005; Ge and Tassou 2011; Kauf 1998; Liao and Zhao 2000; Sawalha 2008). Using a similar curve-fitting procedure, the following optimum gas cooler pressure correlations are used in EnergyPlus:

$$p_{gc} = \begin{cases} 7.5 \times 10^6 & \text{if } T_{amb} < 27^\circ\text{C} \\ 2.3083 \times 10^5 T_{amb} + 1.190 \times 10^6 & \text{if } T_{amb} \geq 27^\circ\text{C} \end{cases} \quad (18.242)$$

Figure 18.28: COP of CO₂ Transcritical Cycle vs. Discharge Pressure at Different Gas Cooler Exit Temperatures (Sawalha 2008).

where p_{gc} is the optimum gas cooler pressure (Pa) and T_{amb} (°C) is the ambient temperature surrounding the gas cooler. The corresponding gas cooler exit temperature, T_{gco} (°C), is determined as follows:

$$T_{gco} = T_{amb} + \Delta T_{approach} \quad (18.243)$$

where $\Delta T_{approach}$ is the approach temperature of the gas cooler, defined as the difference between the gas cooler exit temperature and the entering ambient air temperature.

During transcritical operation, the gas cooler outlet pressure is not allowed to fall below 7.5×10^6 Pa to ensure proper operation.

18.2.8.3.2 Condensing Temperature and Pressure for Subcritical Operation

During subcritical operation, the gas cooler behaves as a condenser and the condensing pressure is allowed to float with the ambient conditions. The condensing temperature, T_{cond} (°C), is determined according to the following:

$$T_{cond} = \begin{cases} T_{cond,min} & \text{if } T_{amb} \leq T_{cond,min} - \Delta T \\ T_{amb} + \Delta T & \text{if } T_{cond,min} - \Delta T < T_{amb} \leq T_{trans} - \Delta T \\ T_{trans} & \text{if } T_{trans} - \Delta T < T_{amb} < T_{trans} \\ T_{sat,P=7.2MPa} & \text{if } T_{trans} \leq T_{amb} < 30.978 \end{cases} \quad (18.244)$$

where T_{amb} is the ambient temperature (°C), ΔT is the temperature difference between the condensing temperature and the ambient temperature (°C), $T_{cond,min}$ is the minimum allowable condensing temperature (°C), and T_{trans} is the ambient air transition temperature between subcritical and transcritical operation (°C). The condensing pressure, P_{cond} (Pa), is determined as the saturation pressure corresponding to the condensing temperature.

18.2.8.3.3 Gas Cooler Fan Energy Use

Gas cooler fan power for air-cooled gas coolers is determined by the type of fan control, which can either be fixed, variable speed, or two-speed. For all three fan control types, the gas cooler fan energy is calculated in the same fashion as that for air-cooled condensers, as described in the section, “Detailed Refrigeration Systems”.

18.2.8.4 Suction Line Heat Exchanger

The performance of the transcritical CO₂ booster system can be enhanced by using a suction line heat exchanger. As shown in Figure 18.26, the suction gas entering the heat exchanger at location 13 is used to cool the refrigerant after it leaves the gas cooler at location 1. The performance of this heat exchanger is modeled with the heat exchanger effectiveness, ε :

$$\varepsilon = \frac{h_{14} - h_{13}}{h_{T_1,P_{13}} - h_{13}} = \frac{h_1 - h_2}{h_{T_1,P_{13}} - h_{13}} \quad (18.245)$$

where h_1 , h_2 , h_{13} , and h_{14} are the enthalpies of carbon dioxide at the respective locations in the refrigeration cycle, as shown in Figure 18.26 and Figure 18.27, and $h_{T_1,P_{13}}$ is the enthalpy of carbon dioxide evaluated at temperature T_1 and pressure P_{13} .

In EnergyPlus, the value of the suction line heat exchanger effectiveness, ε , is specified by the user as an input, and the enthalpies at the exit of the heat exchanger, h_2 and h_{14} , are determined

from the definition of heat exchanger effectiveness given above. In EnergyPlus, the default value of heat exchanger effectiveness is 0.4.

Thermodynamic Properties of CO₂

Modeling of transcritical CO₂ booster refrigeration cycles requires the thermodynamic properties of CO₂ in the saturated (liquid and vapor), superheated and supercritical regions. The refrigerant properties database within EnergyPlus includes saturated, superheated and supercritical thermodynamic data for CO₂, including temperature, pressure, density, enthalpy and specific heat.

18.3 Setpoint Managers

18.3.1 Overview

Setpoint Managers are one of the high-level control constructs in EnergyPlus. A Setpoint Manager is able to access data from any of the HVAC system nodes and use this data to calculate a setpoint (usually a temperature setpoint) for one or more other HVAC system nodes. Setpoints are then used by Controllers as a goal for their control actions.

Setpoint managers are executed at the start of each HVAC time step, and they reside outside the HVAC system iteration loops. Thus, the Setpoint Managers are executed once per HVAC time step, and they use previous time step information (except for zone load) to calculate their setpoints.

All temperatures in the following descriptions are in degrees C, loads are in Watts, mass flow rates are in kg/s.

18.3.2 Scheduled

The input object SetpointManager:Scheduled provides the simplest setpoint manager that allows the user to specify a seasonal (or other) scheduled reset, for example, of the supply air temperature setpoint.

$$T_{set} = T_{sched} \quad (18.246)$$

where T_{set} is the supply air temperature setpoint and T_{sched} is the current value (°C) from the user input temperature schedule. In this case, T_{set} will be applied to the node or nodes specified in the input object SetpointManager:Scheduled. There are a number of other types of setpoints that can be set, by choosing different control variables in the object, including:

1. Maximum temperature of fluid at node (°C)
2. Minimum temperature of fluid at node (°C)
3. Humidity ratio of fluid at node (kg water/ kg dry air)
4. Maximum humidity ratio of fluid at node (kg water/ kg dry air)

5. Minimum humidity ratio of fluid at node (kg water/ kg dry air)
6. Mass flow rate of fluid at node (kg/s)
7. Maximum mass flow rate of fluid at node (kg/s)
8. Minimum mass flow rate of fluid at node (kg/s)

18.3.3 Outdoor Air Reset

The input object SetpointManager:OutdoorAirReset provides a setpoint manager that places a setpoint temperature on a system node according to the outdoor air temperature using a reset strategy. The user defines a reset rule for this strategy by specifying two setpoint temperatures at two outside drybulb temperatures. Generally the lower setpoint temperature is matched with the higher outdoor air drybulb temperature and the higher setpoint temperature is matched with the lower outdoor air drybulb temperature. The user can specify two reset rules and schedule their usage. A schedule value of 1 indicates use of the 1st rule; 2 indicates use of the 2nd. This setpoint manager can be used to place a setpoint temperature on air loop and plant loop system nodes.

IF $SchedVal = 2$:

$$T_{out,low} = T_{2,out,low} \quad (18.247)$$

$$T_{out,high} = T_{2,out,high} \quad (18.248)$$

$$T_{set,atOAlow} = T_{2,set,atOAlow} \quad (18.249)$$

$$T_{set,atOAhigh} = T_{2,set,atOAhigh} \quad (18.250)$$

Otherwise:

$$T_{out,low} = T_{1,out,low} \quad (18.251)$$

$$T_{out,high} = T_{1,out,high} \quad (18.252)$$

$$T_{set,atOAlow} = T_{1,set,atOAlow} \quad (18.253)$$

$$T_{set,atOAhigh} = T_{1,set,atOAhigh} \quad (18.254)$$

The parameter T_{set} is determined as per the following pseudo code:

If $T_{out,low} < T_{out,high}$ then

 If $T_{out} \leq T_{out,low}$ then

$T_{set} = T_{set,atOAlow}$

 If $T_{out} \geq T_{out,high}$ then

$T_{set} = T_{set,atOAhigh}$

 Otherwise

$T_{set} = T_{set,atOAlow} - ((T_{out} - T_{out,low}) / (T_{out,high} - T_{out,low})) \cdot (T_{set,atOAlow} - T_{set,atOAhigh})$

End If
 Otherwise
 $T_{set} = 0.5(T_{set,atOAlow} + T_{set,atOAhigh})$
 End IF

T_{set} will be applied to the node or nodes specified in the *SetpointManager:OutdoorAirReset* object input.

18.3.4 Single Zone Reheat Heating and Cooling

The input object *SetpointManager:SingleZone:Reheat* provides a setpoint manager that is used to implement a variable supply air setpoint temperature in which the setpoint is varied each timestep to meet the heating or cooling load in a control zone. The manager operates in the following manner.

$$T_{set} = T_z + \dot{Q}_z / (C_{p,air} \cdot \dot{m}_z) \quad (18.255)$$

where T_z is the control zone temperature, \dot{Q}_z is the zone load (greater than zero for heating, less than zero for cooling), \dot{m}_z is the zone supply air mass flow rate, and $C_{p,air}$ is the specific heat of air. If \dot{m}_z is very small ($\leq .001$ kg/s) T_{set} is set equal to $T_{set,min}$ if the control zone has a cooling load and to $T_{set,max}$ if the control zone has a heating load. $T_{set,min}$ is the user specified minimum setpoint and $T_{set,max}$ is the user specified maximum setpoint. T_{set} will be applied to the node or nodes specified in the *SetpointManager:SingleZone:Reheat* object input.

18.3.5 Single Zone Heating Only

The input object *SetpointManager:SingleZone:Heating* provides a model that detects the control zone load to meet the current heating setpoint (Report Variable “Zone Predicted Sensible Load to Heating Setpoint Heat Transfer Rate [W]”, zone inlet node flow rate, and zone node temperature, and calculates a setpoint temperature for the supply air that will satisfy the zone heating load for the control zone. “Zone Predicted Sensible Load to Heating Setpoint Heat Transfer Rate [W]” > 0 indicates a heating load. The following rules are applied:

- If there is no zone heating load, then the setpoint is set at the specified minimum supply air temperature.
- If there is a zone heating load and the zone supply mass flow rate is less than 0.001 kg/s, then the setpoint is set at the specified maximum supply air temperature.
- If there is a zone heating load and the zone supply mass flow rate is greater than 0.001 kg/s, then the setpoint is set calculated as follows:

$$SetPoint = ZoneTemp + ZoneLoadtoHeatSP / (CpAir * ZoneMassFlow) \quad (18.256)$$

where:

SetPoint is the setpoint temperature applied to the specified setpoint node(s)

ZoneTemp is the current zone temperature

ZoneLoadtoHeatSP is the zone heating load (Report Variable "Zone Predicted Sensible Load to Heating Setpoint Heat Transfer Rate [W]")

CpAir is the specific heat of zone supply air

ZoneMassFlow is the zone supply air mass flow rate.

18.3.6 Single Zone Cooling Only

The input object SetpointManager:SingleZone:Cooling provides a model that detects the control zone load to meet the current cooling setpoint (Report Variable "Zone Predicted Sensible Load to Cooling Setpoint Heat Transfer Rate [W]", zone inlet node flow rate, and zone node temperature, and calculates a setpoint temperature for the supply air that will satisfy the zone cooling load for the control zone. "Zone Predicted Sensible Load to Cooling Setpoint Heat Transfer Rate [W]" < 0 indicates a cooling load. The following rules are applied:

- If there is no zone cooling load, then the setpoint is set at the specified maximum supply air temperature.
- If there is a zone cooling load and the zone supply mass flow rate is less than 0.001 kg/s, then the setpoint is set at the specified minimum supply air temperature.
- If there is a zone cooling load and the zone supply mass flow rate is greater than 0.001 kg/s, then the setpoint is set calculated as follows:

$$SetPoint = ZoneTemp + ZoneLoadtoCoolSP / (CpAir * ZoneMassFlow) \quad (18.257)$$

where:

SetPoint is the setpoint temperature applied to the specified setpoint node(s)

ZoneTemp is the current zone temperature

ZoneLoadtoCoolSP is the zone cooling load (Report Variable "Zone Predicted Sensible Load to Cooling Setpoint Heat Transfer Rate [W]")

CpAir is the specific heat of zone supply air

ZoneMassFlow is the zone supply air mass flow rate.

18.3.7 Single Zone Minimum Humidity

The input object SetpointManager:SingleZone:Humidity:Minimum provides a model where the zone moisture load from ZoneTempPredictorCorrector (via DataZoneEnergyDemands) is used to calculate the minimum/maximum supply air humidity ratio needed to meet minimum/maximum zone relative humidity requirement. For the Max setpoint manager is currently used in Controller:WaterCoil, when the control variable "TemperatureAndHumidityRatio". A negative MoistureLoad means a dehumidification load for the coil controller. This could be used for any system.

18.3.8 Single Zone Maximum Humidity

The input object `SetpointManager:SingleZone:Humidity:Maximum` provides a setpoint manager that allows the control of high air humidity levels in a single zone. This setpoint manager, used in conjunction with object `ZoneControl:Humidistat`, detects the air humidity level in a single control zone and uses air/moisture mass balances to calculate the supply air humidity ratio needed to maintain the zone relative humidity at or below a given setpoint. The calculated supply air humidity ratio is then entered as a setpoint on a designated supply air stream node. A dehumidification component placed upstream of this node can then use the humidity ratio setpoint to control its moisture removal rate (e.g. desiccant dehumidifiers). In the case of a chilled water coil which is used for both temperature and high humidity control, this setpoint manager works in conjunction with a `Controller:WaterCoil` object to determine the minimum supply air temperature required to meet both the temperature (sensible) and humidity (latent) load in the control zone. (Ref: `Controller:WaterCoil`).

18.3.8.1 Model Description

The user must input the required information according to the IO Reference Manual (ref: `SetpointManager:SingleZone:Humidity:Maximum`). Specific inputs include an object name, control variable (`HumidityRatio`), name of the schedule defining the maximum relative humidity for the control zone, setpoint node name or list, and the zone air node name associated with the control zone (ref: `ZoneHVAC:EquipmentConnections`). The schedule name must refer to a valid schedule type (range 0-1) and contain values of fractional relative humidity.

This setpoint manager first converts the desired relative humidity setpoint for the control zone to humidity ratio based on the control zone dry-bulb temperature, the scheduled maximum relative humidity setpoint and outdoor barometric pressure.

$$\omega_{sp} = \text{PsyWFnTdbRhPb}(T_{db}, RH_{sp}, P) \quad (18.258)$$

where:

ω_{sp} is the humidity ratio setpoint (kg H₂O/kg air)

`PsyWFnTdbRHPb` is an EnergyPlus psychrometric function, returns humidity ratio as a function of dry-bulb temperature, relative humidity, and barometric pressure

T_{db} is the dry-bulb temperature in the control zone (°C)

RH_{sp} is the maximum relative humidity setpoint

P is the outdoor barometric pressure (Pa).

The model then calculates the supply air humidity ratio required to reduce the control zone relative humidity to the desired level. Using the humidity ratio setpoint (ω_{sp}) calculated above,

$$\omega_{sa} = \omega_{sp} + \frac{\dot{Q}_l}{\dot{m}} \quad (18.259)$$

where:

ω_{sa} is the maximum supply air humidity ratio setpoint (kg H₂O/kg air)

\dot{Q}_l is the control zone latent load calculated by `Zone Control:Humidistat` (kg H₂O/s)

\dot{m} is the control zone mass flow rate (kg/s).

All setpoint managers are executed at the beginning of the simulation time step. Therefore, the calculated setpoint is based on the resulting control zone air temperature and air mass flow rate for the previous simulation time step.

The maximum supply air humidity ratio setpoint is placed on the node(s) specified in the input for this object (using node property Humidity Ratio Maximum).

18.3.9 Mixed Air

The input object SetpointManager:MixedAir provides a setpoint manager that takes an already established setpoint (usually the supply air outlet node setpoint temperature), subtracts the supply fan heat gain, and applies the result as the setpoint temperature at the mixed air node (or any other node the user specifies).

$$T_{set} = T_{set,ref} - (T_{fan,outlet} - T_{fan,inlet}) \quad (18.260)$$

When inputs of optional fields, Cooling Coil Inlet Node Name, Cooling coil Outlet Node Name, and Minimum Temperature at Cooling Coil Outlet Node, are provided, the setpoint temperature at the mixed air node is given below based on supply fan placement and reference node location:

Blow through placement:

$$T_{set} = \max(T_{set,ref}, T_{min}) - (T_{coil,outlet} - T_{coil,inlet}) - (T_{fan,outlet} - T_{fan,inlet}) \quad (18.261)$$

Draw through placement:

When the reference node is the cooling coil outlet node:

$$T_{set} = \max(T_{set,ref}, T_{min}) - (T_{coil,outlet} - T_{coil,inlet}) \quad (18.262)$$

When the reference node is the unitary system outlet node:

$$T_{set} = \max(T_{set,ref} - (T_{fan,outlet} - T_{fan,inlet}), T_{min}) - (T_{coil,outlet} - T_{coil,inlet}) \quad (18.263)$$

18.3.10 Outdoor Air Pretreat

The input object SetpointManager:OutdoorAirPretreat provides a setpoint manager that is meant to be used in conjunction with an OutdoorAir:Mixer. The outdoor air pretreat setpoint manager is used to establish a temperature or humidity ratio setpoint in the outdoor air stream flowing into the outdoor air stream node of an outdoor air mixer. This setpoint manager determines the required setpoint in the outdoor air stream to produce the reference setpoint in the mixed air stream after mixing with return air. For example, if the temperature setpoint at the mixed air node is 15C, the return air temperature is 20C, and the outdoor air flow fraction is 0.5, the outdoor air pretreat setpoint would be set to 10C. This setpoint manager references four user-specified nodes to obtain the following values:

- Reference setpoint node – desired mixed flow condition = RefNodeSetPoint
- Mixed air stream node – mixed air flow rate = MixedOutNodeMassFlowRate
- Outdoor air stream node – outdoor air flow rate = OAINodeMassFlowRate
- Return air stream node – return air condition = ReturnInValue

The following calculations are used to determine the new setpoint value (SetPoint):

$$OAFraction = OAINodeMassFlowRate / MixedOutNodeMassFlowRate \quad (18.264)$$

$$SetPoint = ReturnInValue + (RefNodeSetPoint - ReturnInValue) / OAFraction \quad (18.265)$$

Depending on the specified control variable type, the setpoints and conditions may be humidity ratio (max or min) or temperature. Note that zero is not allowed as the computed setpoint humidity ratio, because zero is used as a special value to indicate that no humidification or dehumidification is needed. If the reference humidity ratio setpoint value is zero, the zero value will be passed directly to the setpoint Node(s).

18.3.11 Warmest Zone Supply Air Reset

The input object SetpointManager:Warmest provides a setpoint manager that attempts to establish a supply air setpoint that will meet the cooling load of the zone needing the coldest air at the maximum zone supply air flowrate. The algorithm loops over all the zones that the system can cool and calculates

$$T_{set,z} = T_z + \dot{Q}_z / (C_{p,air} \cdot \dot{m}_{z,max}) \quad (18.266)$$

Note that for cooling $\dot{Q}_z < 0$. The lowest $T_{set,z}$ is chosen as T_{set} . T_{set} is constrained to be less than or equal to the maximum setpoint temperature (user input) and greater than or equal to the minimum setpoint temperature (user input). If the sum of the zone cooling loads is very small, the setpoint temperature is set to the maximum. T_{set} will be applied to the node or nodes specified in the SetpointManager:Warmest object input.

18.3.12 Coldest Zone Supply Air Reset

The input object SetpointManager:Coldest provides a setpoint manager that attempts to establish a supply air setpoint that will meet the heating load of the zone needing the warmest air at the maximum zone supply air flowrate. The algorithm loops over all the zones that the system can heat and calculates

$$T_{set,z} = T_z + \dot{Q}_z / (C_{p,air} \cdot \dot{m}_{z,max}) \quad (18.267)$$

Note that for heating $\dot{Q}_z > 0$. The highest $T_{set,z}$ is chosen as T_{set} . T_{set} is constrained to be less than or equal to the maximum setpoint temperature (user input) and greater than or equal to the minimum setpoint temperature (user input). If the sum of the zone heating loads is very small, the setpoint temperature is set to the minimum. T_{set} will be applied to the node or nodes specified in the SetpointManager:Coldest object input.

18.3.13 Return Air Bypass Flow

The input object `SetpointManager:ReturnAirBypassFlow` provides a setpoint manager that sets the air flow rate in a bypass duct such that when the bypassed and non-bypassed air are mixed the resultant air stream will be at the user-specified setpoint temperature.

The user specifies the desired setpoint temperature T_{set} through a input temperature schedule. This temperature is modified to account for any potential fan heat gain:

$$T_{set,mod} = T_{set} - (T_{loop,out} - T_{mixer,out}) \quad (18.268)$$

Here $T_{loop,out}$ is the temperature at the air loop outlet node and $T_{mixer,out}$ is the temperature at the outlet node of the bypass – nonbypass air mixer. Depending on the system configuration these may be the same node. Then

$$\dot{m}_{bypass} = (\dot{m}_{tot} \cdot T_{set,mod} - \dot{m}_{nonbypass} \cdot T_{nonbypass}) / T_{bypass} \quad (18.269)$$

where \dot{m}_{tot} is the total supply air flowrate in kg/s sent to the zones, $\dot{m}_{nonbypass}$ is the nonbypassed air flowrate (the conditioned air), $T_{nonbypass}$ is the corresponding temperature just before mixing with the bypassed air, and T_{bypass} is the temperature of the bypassed (unconditioned) air. The resulting \dot{m}_{bypass} is the mass flow rate setpoint for the bypass air branch.

18.3.14 Warmest Temp Flow

The input object `SetpointManager:WarmestTemperatureFlow` provides a setpoint manager that attempts to establish a supply air setpoint that will meet the cooling load of the zone needing the coldest air at the maximum zone supply air flowrate. The supply air temperature setpoint is established by `SetpointManager:WarmestTemperatureFlow` using one of two strategies: ‘Temp First’ sets the supply air temperature to the highest temperature that will meet the cooling load of the coolest zone at minimum cfm. ‘Flow First’ sets the supply air temperature to the highest temperature that will meet the cooling load of the warmest zone at maximum cfm. ‘Temp First’ gives higher priority to reducing fan energy whereas ‘Flow First’ gives higher priority to reducing chiller energy.

The algorithm loops over all the zones that the system can cool and calculates according to strategy:

Temp First:

$$T_{set,z} = T_z + \frac{\dot{Q}_z}{C_{p,air} \dot{m}_{z,min}} \quad (18.270)$$

Flow First:

$$T_{set,z} = T_z + \frac{\dot{Q}_z}{C_{p,air} \dot{m}_{z,max}} \quad (18.271)$$

where $\dot{m}_{z,min}$ is the minimum air flow rate to the zone produced by reducing the capacity of the supply fan or by reducing the opening of the damper in the terminal box, if present, and $\dot{m}_{z,max}$ is the design air flow rate to the zone.

Note that for cooling $\dot{Q}_z < 0$. The lowest $T_{set,z}$ is chosen as T_{set} . T_{set} is constrained to be less than or equal to the maximum setpoint temperature (user input) and greater than or equal to

the minimum setpoint temperature (user input). If the unconstrained value of T_{set} is less than the minimum setpoint temperature and there are no VAV terminal boxes, the fan capacity is increased so as to meet the zone cooling loads with the constrained value of T_{set} :

$$\dot{m}_{fan} = \sum_z \dot{m}_{z,min} = \sum_z \dot{Q}_z / [C_{p,air} \cdot (T_{set} - T_z)] \quad (18.272)$$

This is more likely to occur in the ‘Temp First’ case. If the sum of the zone cooling loads is very small, the setpoint temperature is set to the maximum. T_{set} will be applied to the node or nodes specified in the SetpointManager:WarmestTemperatureFlow object input.

18.3.15 Multizone Heating Average

The input object SetpointManager:MultiZone:Heating:Average provides a setpoint manager that attempts to establish a supply air heating setpoint that will meet the heating load of multiple zones served by an HVAC air loop. The algorithm aggregates the predicted heating loads for all controlled zones served by an air loop (i.e., zones that have a thermostat object), and calculates the multizone average supply air heating setpoint temperature as follows:

IF ($\dot{Q}_{Zj} > 0$) THEN

$$\overline{T_{SP}} = \overline{T_Z} + \left(\frac{\sum_{j=1}^{NumControlZones} \dot{Q}_{Zj}}{\sum_{j=1}^{NumControlZones} \dot{m}_{Zj} \cdot C_{p_j}} \right) \quad (18.273)$$

END IF

$$\overline{T_Z} = \left(\sum_{j=1}^{TotZones} \dot{m}_{Zj} \cdot C_{p_j} \cdot T_{Zj} \right) / \left(\sum_{j=1}^{TotZones} \dot{m}_{Zj} \cdot C_{p_j} \right) \quad (18.274)$$

where:

$\overline{T_{SP}}$ is the average supply air setpoint temperature (°C)

$NumControlZones$ is the number of controlled zones (i.e., zones that contain thermostat objects) served by the air loop

\dot{Q}_{Zj} is the sensible heating load required to reach the zone air temperature setpoint for the j^{th} controlled zone at current time step (W)

\dot{m}_{Zj} is the air mass flow rate being supplied by the air loop to the j^{th} controlled zone, lagged by one HVAC simulation time step (kg/s)

C_{p_j} is the specific heat of supply air for the j^{th} controlled zone (J/kg-K)

T_{Zj} is the air node temperature for the j^{th} controlled zone (°C)

$\overline{T_Z}$ is the average zone air node temperature weighted by the heat capacity rate of the supply air streams for the controlled zones served by the air loop (°C)

$TotZones$ is the total number of zones served by the air loop.

Note that for heating $\dot{Q}_{Zj} > 0$. The average supply air setpoint temperature $\overline{T_{SP}}$ is constrained to be less than or equal to the maximum setpoint temperature (user input) and greater than or equal to the minimum setpoint temperature (user input). If the sum of the zone sensible heating loads is extremely small (i.e., no heating load), the setpoint temperature is set to the minimum. $\overline{T_{SP}}$ will be

applied to the setpoint node or nodes specified in the SetpointManager:MultiZone:Heating:Average object.

18.3.16 Multizone Cooling Average

The input object SetpointManager:MultiZone:Cooling:Average provides a setpoint manager that attempts to establish a supply air cooling setpoint that will meet the cooling load of multiple zones served by an HVAC air loop. The algorithm aggregates the predicted cooling loads for all controlled zones served by an air loop (i.e., zones that have a thermostat object), and calculates the multizone average supply air cooling setpoint temperature as follows:

IF ($\dot{Q}_{Zj} < 0$) THEN

$$\overline{T_{SP}} = \overline{T_Z} + \left(\frac{\sum_{j=1}^{NumControlZones} \dot{Q}_{Zi}}{\sum_{j=1}^{NumControlZones} \dot{m}_{Zi} \cdot Cp_j} \right) \quad (18.275)$$

END IF

$$\overline{T_Z} = \left(\sum_{j=1}^{TotZones} \dot{m}_{Zj} \cdot Cp_j \cdot T_{Zj} \right) / \left(\sum_{j=1}^{TotZones} \dot{m}_{Zj} \cdot Cp_j \right) \quad (18.276)$$

Note that for cooling $\dot{Q}_{Zj} < 0$. The average supply air setpoint temperature $\overline{T_{SP}}$ is constrained to be less than or equal to the maximum setpoint temperature (user input) and greater than or equal to the minimum setpoint temperature (user input). If the sum of the zone sensible cooling loads is extremely small (i.e., no cooling load), the setpoint temperature is set to the maximum. $\overline{T_{SP}}$ will be applied to the setpoint node or nodes specified in the SetpointManager:MultiZone:Cooling:Average object.

18.3.17 Multizone Minimum Humidity Average

The input object SetpointManager:MultiZone:MinimumHumidity:Average provides a setpoint manager that attempts to establish a supply air minimum humidity ratio setpoint that will meet the humidification load of multiple zones served by an HVAC air loop. This setpoint manager, used in conjunction with object ZoneControl:Humidistat, detects the air humidity level for all controlled zones served by an air loop (i.e., zones that have a humidistat object with a humidifying setpoint schedule), and uses moisture mass balances to calculate the average supply air minimum humidity ratio setpoint as follows:

IF ($\dot{Q}_{lZj} > 0$) THEN

$$\overline{\omega_{SP}} = \overline{\omega_Z} + \frac{\sum_{j=1}^{NumControlZones} \dot{Q}_{l,Zj}}{\sum_{j=1}^{NumControlZones} \dot{m}_{Zj}} \quad (18.277)$$

END IF

$$\bar{\omega}_Z = \frac{\sum_{j=1}^{TotZones} \dot{m}_{Zj} \omega_{Zj}}{\sum_{j=1}^{TotZones} \dot{m}_{Zj}} \quad (18.278)$$

where:

$\bar{\omega}_{SP}$ is the average supply air minimum humidity ratio setpoint (kg H₂O/kg air)

$NumControlZones$ is the number of controlled zones (i.e., zones that contain humidistat objects with humidifying setpoint schedule) served by the air loop

\dot{Q}_{lZj} is the latent (humidification) load required to reach the zone air humidifying setpoint for the j^{th} controlled zone at current time step (kg H₂O/s)

\dot{m}_{Zj} is the air mass flow rate being supplied by the air loop to the j^{th} controlled zone, lagged by one HVAC simulation time step (kg/s)

ω_{Zj} is the air node humidity ratio for the j^{th} controlled zone (kg H₂O/kg air)

$\bar{\omega}_Z$ is the average zone air node humidity ratio weighted by supply air mass flow rate for the controlled zones served by the air loop (kg H₂O/kg air)

$TotZones$ is the total number of zones served by the air loop.

Note that a positive latent load means humidification is required. The average supply air minimum humidity ratio setpoint $\bar{\omega}_{SP}$ is constrained to be less than or equal to the maximum setpoint humidity ratio (user input) and greater than or equal to the minimum setpoint humidity ratio (user input). If the sum of the zone latent humidification loads is extremely small (i.e., no humidification load), the humidity ratio setpoint is set to the minimum. $\bar{\omega}_{SP}$ will be applied to the setpoint node or nodes specified in the SetpointManager:MultiZone:MinimumHumidity:Average object. A humidification component (e.g., an electric humidifier) placed upstream of this node can then use the humidity ratio setpoint to control its moisture addition rate.

All setpoint managers are executed at the beginning of the simulation time step. Therefore, the calculated setpoint is based on the resulting zone air node humidity ratios and supply air mass flow rates for the previous simulation time step.

18.3.18 Multizone Maximum Humidity Average

The input object SetpointManager:MultiZone:MaximumHumidity:Average provides a setpoint manager that attempts to establish a supply air maximum humidity ratio setpoint that will meet the dehumidification load of multiple zones served by an HVAC air loop. This setpoint manager, used in conjunction with object ZoneControl:Humidistat, detects the air humidity level for all controlled zones served by an air loop (i.e., zones that have a humidistat object with a dehumidifying setpoint schedule), and uses moisture mass balances to calculate the average supply air maximum humidity ratio as follows:

IF ($\dot{Q}_{lZj} < 0$) THEN

$$\bar{\omega}_{SP} = \bar{\omega}_Z + \frac{\sum_{j=1}^{NumControlZones} \dot{Q}_{l,Zj}}{\sum_{j=1}^{NumControlZones} \dot{m}_{Zj}} \quad (18.279)$$

END IF

$$\overline{\omega_Z} = \frac{\sum_{j=1}^{TotZones} \dot{m}_{Zj} \omega_{Zj}}{\sum_{j=1}^{TotZones} \dot{m}_{Zj}} \quad (18.280)$$

Note that a negative latent load means dehumidification is required. The average supply air maximum humidity ratio setpoint $\overline{\omega_{SP}}$ is constrained to be less than or equal to the maximum setpoint humidity ratio (user input) and greater than or equal to the minimum setpoint humidity ratio (user input). If the sum of the zone latent dehumidification loads is extremely small (i.e., no dehumidification load), the humidity ratio setpoint is set to the maximum. $\overline{\omega_{SP}}$ will be applied to the setpoint node or nodes specified in the SetpointManager:MultiZone:MaximumHumidity:Average object. A dehumidification component (e.g., an desiccant dehumidifier) placed upstream of this node can then use the humidity ratio setpoint to control its moisture removal rate. In the case of a chilled water coil which is used for both temperature and high humidity control, this setpoint manager works in conjunction with a Controller:WaterCoil object to determines the minimum supply air temperature required to meet both the temperature (sensible) and humidity (latent) load in the control zone (ref: Controller:WaterCoil).

18.3.19 MultiZone Minimum Humidity Supply Air Reset

The input object SetpointManager:MultiZone:Humidity:Minimum provides a setpoint manager that attempts to establish a supply air minimum humidity ratio setpoint that will meet the humidification load of zone with the critical humidification requirement at each time step served by an HVAC air loop at the zone actual supply air mass flow rate. This setpoint manager, used in conjunction with object ZoneControl:Humidistat, detects the air humidity level for all controlled zones served by an air loop (i.e., zones that have a humidistat object with a humidifying setpoint schedule), and uses moisture mass balances to calculate the supply air minimum humidity ratio setpoint. The algorithm loops over all the zones that the system can humidify and calculates the setpoint based on a zone with the highest humidity ratio setpoint requirement as follows:

IF ($\dot{Q}_{lZj} > 0$) THEN

$$\omega_{SP\ Zj} = \omega_{Zj} + \dot{Q}_{lZj} / \dot{m}_{Zj} \quad (18.281)$$

END IF

$$\omega_{SP\ Zj} = MAX(\omega_{SP\ Zj}, \omega_{SP\ Min}) \quad (18.282)$$

$$\omega_{SP} = MIN(\omega_{SP\ Zj}, \omega_{SP\ Max}) \quad (18.283)$$

where:

ω_{SP} is the supply air humidity ratio setpoint (kg/kg)

\dot{Q}_{lZj} is the latent load required to reach the zone air setpoint for the j^{th} controlled zone at current time step (kg H₂O/s)

\dot{m}_{Zj} is the actual mass flow rate supplied by the air loop to the j^{th} controlled zone, (kg/s)

ω_{Zj} is the air node humidity ratio for the j^{th} controlled zone (kg/kg)

$\omega_{SP\ Zj}$ is the supply air humidity ratio setpoint for the j^{th} controlled zones (kg/kg)

$\omega_{SP\ Min}$ is the user-specified supply air minimum humidity ratio setpoint (kg/kg)

$\omega_{SP\ Max}$ is the user-specified supply air maximum humidity ratio setpoint (kg/kg).

Note that a positive latent load means humidification is required. The supply air minimum humidity ratio setpoint ω_{SP} is constrained to be less than or equal to the maximum setpoint humidity ratio (user input) and greater than or equal to the minimum setpoint humidity ratio (user input). If the humidification load for all zones in the air loop is extremely small (i.e., no humidification load), the humidity ratio setpoint is set to the user input minimum value. ω_{SP} will be applied to the setpoint node or nodes specified in the SetpointManager:MultiZone:Humidity:Minimum object. A humidification component (e.g., an electric humidifier) placed upstream of this node can then use the humidity ratio setpoint to control its moisture addition rate.

18.3.20 MultiZone Maximum Humidity Supply Air Reset

The input object SetpointManager:MultiZone:Humidity:Maximum provides a setpoint manager that attempts to establish a supply air maximum humidity ratio setpoint that will meet the dehumidification load of the zone with the critical dehumidification requirement at each time step served by an HVAC air loop at the zone actual supply air mass flow rate. This setpoint manager, used in conjunction with object ZoneControl:Humidistat, detects the air humidity level for all controlled zones served by an air loop (i.e., zones that have a humidistat object with a dehumidifying setpoint schedule), and uses moisture mass balances to calculate the supply air maximum humidity ratio setpoint. The algorithm loops over all the zones that the system can dehumidify and calculates the setpoint based on a zone with the lowest humidity ratio setpoint requirement as follows:

IF ($\dot{Q}_{lZj} < 0$) THEN

$$\omega_{SP\ Zj} = \omega_{Zj} + \dot{Q}_{lZj} / \dot{m}_{Zj} \quad (18.284)$$

END IF

$$\omega_{SP\ Zj} = MAX(\omega_{SP\ Zj}, \omega_{SP\ Min}) \quad (18.285)$$

$$\omega_{SP} = MIN(\omega_{SP\ Zj}, \omega_{SP\ Max}) \quad (18.286)$$

Note that a negative latent load means dehumidification is required. The supply air maximum humidity ratio setpoint ω_{SP} is constrained to be less than or equal to the maximum setpoint humidity ratio (user input) and greater than or equal to the minimum setpoint humidity ratio (user input). If the dehumidification load for all zones in the air loop is extremely small (i.e., no dehumidification load), the humidity ratio setpoint is set to the user input maximum value. ω_{SP} will be applied to the setpoint node or nodes specified in the SetpointManager:MultiZone:Humidity:Maximum object. A dehumidification component (e.g., an desiccant dehumidifier) placed upstream of this node can then use the humidity ratio setpoint to control its moisture removal rate. In the case of a chilled water coil which is used for both temperature and high humidity control, this setpoint manager works in conjunction with a Controller:WaterCoil object to determines the minimum supply air temperature required to meet both the temperature (sensible) and dehumidification (latent) load in the control zone (ref: Controller:WaterCoil).

18.3.21 Follow Outdoor Air Temperature

The input object SetpointManager:FollowOutdoorAirTemperature provides a setpoint manager that is used to place a temperature setpoint on a system node that is derived from the current outdoor air environmental conditions. The outdoor air conditions are obtained from the weather information during the simulation.

```
IF (ReferenceTemperatureType = OutdoorWetBulb)
    Setpoint = OutdoorWetBulbTemp + OffSet
ELSEIF (ReferenceTemperatureType = OutdoorDryBulb)
    Setpoint = OutdoorDryBulbTemp + OffSet
ENDIF
Setpoint = MAX(Setpoint, MinSetPoint)
Setpoint = MIN(Setpoint, MaxSetPoint)
```

MinSetPoint, MaxSetPoint and OffSet are specified by the user as the input in object Setpoint-Manager:FollowOutdoorAirTemperature.

18.3.22 Follow System Node Temperature

The input object SetpointManager:FollowSystemNodeTemperature provides a temperature setpoint on a system node that is derived from the current temperatures at a separate system node. The current value of the temperature at a reference node are obtained and used to generate setpoint on a second system node. If the reference node is also designated to be an outdoor air (intake) node, then this setpoint manager can be used to follow outdoor air conditions that are adjusted for altitude.

```
IF (ReferenceTemperatureType = NodeWetBulb)
    Setpoint = NodeWetbulbTemp + OffSet
ELSEIF (ReferenceTemperatureType = NodeDryBulb)
    Setpoint = NodeDrybulbTemp + OffSet
ENDIF
Setpoint = MAX(Setpoint, MinSetPoint)
Setpoint = MIN(Setpoint, MaxSetPoint)
```

MinSetPoint, MaxSetPoint and OffSet are specified by the user as the input in object Setpoint-Manager:FollowSystemNodeTemperature.

18.3.23 Follow Ground Temperature

The input object SetpointManager:FollowGroundTemperature provides a temperature setpoint on a system node that is derived from a current ground temperature. The ground temperatures are specified in different Site:GroundTemperature:* objects and used during the simulation. This setpoint manager is primarily intended for condenser or plant loops using some type of ground heat exchanger.

```
IF (ReferenceGroundTemperatureObjectType = BuildingSurface)
    Setpoint = GroundTemp + OffSet
ELSEIF (ReferenceGroundTemperatureObjectType = Shallow)
    Setpoint = GroundTemp_Surface + OffSet
ELSEIF (ReferenceGroundTemperatureObjectType = Deep)
```

```

    Setpoint = GroundTemp_Deep + OffSet
ELSEIF (ReferenceTGroundTemperatureObjectType = FCfactorMethod)
    Setpoint = GroundTemp_FC + OffSet
ENDIF
Setpoint = MAX(Setpoint, MinSetPoint)
Setpoint = MIN(Setpoint, MaxSetPoint)

```

where:

- GroundTemp is the current ground temperature (Ref: Site:GroundTemperature:BuildingSurface)
(C)
GroundTemp_Surface is the current surface ground temperature (Ref: Site:GroundTemperature:Shallow)
(C)
GroundTemp_Deep = Current deep ground temperature (Ref: Site:GroundTemperature:Deep)
(C)
GroundTemp_FC = Current ground temperature defined F or C factor method (Ref: Site:GroundTemperature:FCfactorMethod) (C)
MinSetPoint, MaxSetPoint and OffSet are specified by the user as the input in object Setpoint-Manager:FollowGroundTemperature.

18.3.24 Condenser Entering Water Temperature Reset

The object resets the condenser entering water temperature to the optimal cooling tower water set point temperature that will result in minimum net energy consumption for the chiller and cooling tower plant. This chiller-tower optimization scheme uses one curve to determine the optimum condenser entering water temperature for a given time step and two other curves to place limit conditions on the “optimized” set point value. The optimized condenser entering water temperature may not be valid every timestep then will be limited algorithmically by two boundary curves. The first of these boundary curves is given by:

$$MinDsnWB = C1 + C2 * OaWb + C3 * WPLR + C4 * TwrDsnWB + C5 * NF \quad (18.287)$$

where:

$C1-C5$ are the curve coefficients

$OaWb$ is the outside air wetbulb for current timestep (°C)

$TwrDsnWB$ is the tower design inlet Air Wet-Bulb Temperature (°C)

$WPLR$ is the weighted PLR which is equal to ChillerCoolingLoadThisTimestep / NominalChillerCapacity

NF is the normalized condenser water flow per unit of tower capacity ($m^3/W\cdot s$) which is equal to Design Tower Flow Rate / Design Tower Capacity (*typically at $5.382E-8 m^3/s$, i.e., 3 gpm/ton*)

$MinDsnWB$ is compared against the design tower wetbulb. This curve is usually a function of Weighted PLR and NF . So if NF is constant at $5.382E-8 m^3/s$ (3 gpm/ton), the curve can be depicted as follows:

The second boundary curve is given by:

$$MinActualWb = C1 + C2 * MinDsnWB + C3 * WPLR + C4 * TwrDsnWB + C5 * NF \quad (18.288)$$

Figure 18.29: Minimum Tower Design Wet Bulb Boundary Condition

where:

$C1-C5$ are the curve coefficients

$MinDsnWB$ is from first boundary equation ($^{\circ}C$)

$TwrDsnWB$ is the tower design inlet Air Wet-Bulb Temperature ($^{\circ}C$)

$WPLR$ is the weighted PLR which is equal to $ChillerCoolingLoadThisTimestep / NominalChillerCapacity$

NF is the normalized condenser water flow per unit of tower capacity ($m^3/W-s$) which is equal to Design Tower Flow Rate / Design Tower Capacity (typically at $5.382E-8 m^3/s$, i.e., 3 gpm/ton)

$MinActualWb$ is compared against this time step's outside air wet bulb. This curve is usually a function of $MinDesignWB$, $WeightedRatio$ and $TwrDesignWB$. So if $TwrDesignWB$ is constant at $25.6^{\circ}C$ ($78^{\circ}F$), and $NF = 5.382E-8 m^3/s$ (3 gpm/ton), the curve can be depicted as follows:

Figure 18.30: Minimum Wet Bulb Boundary Condition

The Optimized Condenser Entering Water Temperature is calculated with this equation:

$$OptCondEntTemp = C1 + C2 * OaWb + C3 * WPLR + C4 * TwrDsnWB + C5 * NF \quad (18.289)$$

where:

$C1-C5$ are curve coefficients

$OaWB$ is at this timestep's outside air wetbulb ($^{\circ}C$)

$TwrDsnWB$ is the tower design inlet Air Wet-Bulb Temperature ($^{\circ}C$)

$WPLR$ is the weighted PLR which is equal to $\text{ChillerCoolingLoadThisTimestep} / \text{NominalChillerCapacity}$

NF is the normalized condenser water flow per unit of tower capacity ($\text{m}^3/\text{W-s}$) which is equal to $\text{Design Tower Flow Rate} / \text{Design Tower Capacity}$ (typically $5.382\text{E-}8 \text{ m}^3/\text{s}$, i.e., 3 gpm/ton)

A graph of the curve can be seen in Figure 18.31.

Figure 18.31: Optimum EWT vs PLR & OaWb

The optimized condenser entering water temperature is calculated but is not necessarily used each timestep. If OptCondEntTemp does not fall within the bounds established by MinDsnWB and MinActualWb , then the value from the Default Condenser Entering Water Temperature Schedule is used for the Condenser Entering Water Set Point instead.

18.3.24.1 Special Note for Multiple Towers

This control scheme is available for multiple towers by following two steps:

- Use average tower conditions in the curves for the independent variables related to the towers
- Make sure the setpoint is applied to either the condenser supply outlet node or use a node list to apply it to each tower outlet node

18.3.25 Ideal Condenser Entering Water Temperature Reset

The object determines a “near-optimal” condenser water entering set point at each time step that will result in minimum net energy consumption for the chiller and cooling tower plant. The “ideal”

chiller-tower optimization scheme uses a search algorithm to find the ideal optimal setpoint at a given timestep. This requires resimulating HVAC systems at each timestep until finding an “optimal” condenser water entering setpoint (OptSetpoint) which gives the minimum total chiller, cooling tower, chilled water pump and condenser water pump power consumption (TEC). The OptSetpoint falls between realistic minimum and maximum boundaries, which are set by the user. The minimum boundary is determined based on the minimum lift (user input) and evaporator leaving water temperature. The maximum boundary is specified by the user. It is assumed that a single minimum point exists between these boundaries. The following steps are used to find “optimal” setpoint:

1. Set an initial setpoint value for the iteration to a user-defined maximum condenser entering water temperature (Toptset_1) and calculate TEC.
2. Decrease the setpoint value by 1°C ($\text{Toptset}_2 = \text{Toptset}_1 - 1^\circ\text{C}$) and calculate TEC.
3. Compare the TEC in Step 1 (TEC_1) and TEC in Step 2 (TEC_2), i.e., ($\text{dTEC}_1 = \text{TEC}_1 - \text{TEC}_2$).
4. If dTEC_1 is negative, stop the iteration and set the “optimal” setpoint to Toptset_1 .
5. If dTEC_1 is positive, Decrease the setpoint value by 1°C and calculate TEC. Compare the TECs and repeat this step (i.e., $\text{dTEC}_N = \text{TEC}_N - \text{TEC}_{N+1}$) until either Toptset_{N+1} reaches to the minimum boundary value or dTEC_N becomes negative.
6. If Toptset_N reaches to the minimum boundary value and still dTEC_N is positive, set the “optimal” setpoint to Toptset_{N+1} .
7. If TEC_N becomes negative, decrease Toptset_{N-1} by 0.2°C and calculate TEC. Compare the TECs and repeat this step (i.e., $\text{dTEC}_M = \text{TEC}_M - \text{TEC}_{M+1}$) until dTEC_M becomes negative. Then set the “optimal” setpoint to Toptset_{M+1} .

18.3.26 Plant Return Water Control Setpoint Reset

The input objects:

- SetpointManager:ReturnTemperature:ChilledWater, and
- SetpointManager:ReturnTemperature:HotWater

allow for controlling the temperature of the water (or a different fluid defined for the plant) that is returning back to the plant supply equipment. In a typical chilled water loop configuration, this is essentially controlling the temperature of the water entering the chiller. In a typical hot water loop configuration, this is essentially controlling the temperature of the water entering the boiler.

The target return temperature can be specified by:

- providing a constant value to use throughout the simulation, or
- scheduling the value to vary through the simulation (which then allows custom EMS overriding of the scheduled value), or
- using a separate setpoint manager to set the setpoint on the return node itself, which is then retrieved by this reset manager.

18.3.26.1 Operation

The setpoint manager senses conditions on two named nodes, which should correspond to a central plant's supply side inlet and outlet nodes, the return and supply nodes, respectively. The temperature and flow rate information is used in a series of calculations in order to determine a setpoint to specify on the supply outlet node which will in turn provide the target desired return temperature on the supply inlet node. The calculations are summarized for a chilled water loop here:

1. Use the current supply and demand temperatures to calculate an average temperature for property calculation: $C_p = f(T_{avg}) = f\left(\frac{T_{ret} + T_{sup}}{2}\right)$
2. Calculate the current loop demand using: $\dot{Q} = \dot{m} * C_p * (T_{ret} - T_{sup})$
3. Assuming that this load will be the same moving forward, we can calculate what supply temperature we should target in order to meet the desired return temperature.
4. So retrieve the current target return temperature, $T_{ret,target}$, either from a schedule or constant value.
5. Then calculate the supply temperature setpoint using: $T_{sup,sp} = T_{ret,target} - \frac{\dot{Q}}{\dot{m}C_p}$
6. Constrain the value to user-specified limiting min/max values

For a chilled water loop, the user-specified minimum is the default setpoint used in cases of no-load or negative-load. In a hot-water loop the user-specified maximum is used for these situations. Also, in a hot-water loop the sign of the demand will be reversed.

18.3.26.2 Key control note

The setpoint will be reset at the beginning of a system time step, and remain that way through that time step. The setpoint is calculated based on the latest known value of loop demand and loop flow rate. If the demand and flow rate remain the same for the currently calculated time step, the loop will maintain control well. However, if either changes, there will be a lag effect while the loop attempts to maintain control. Consider the following plot shown in Figure 18.32.

Throughout the day, the heat addition (green line) to the loop increases. Each time it increases, there is a small period of time where the loop attempts to regain control of the return temperature. The setpoint is only reset at the beginning of the system time step, so as the plant converges within a single time step, the load will vary and the return temperature may not be exactly on target.

This is not necessarily a big problem. However, some users may be especially interested in very tight control of the return temperature. This can be done very easily by simply reducing the simulation time step. For example, in the following plot (see Figure 18.33, the time step was reduced from 10 minutes to 1 minute.

With the smaller time step, the reporting frequency is higher. But more importantly, with the smaller time step, the setpoint can be corrected much more often. Because of this, the return temperature regains control much quicker than with the larger time step.

However, these examples are for a jagged demand profile full of discontinuous step changes in loop demand. As a final example, this return water temperature control is applied to the large office reference building chilled water loop. This is shown in Figure 18.34

Figure 18.32: Setpoint Manager Reset for Return Control Plot 1

Figure 18.33: Setpoint Manager Reset for Return Control Plot 2

Figure 18.34: Setpoint Manager Reset for Return Control Plot 3

Note the control is working properly, maintaining a return temperature around the target of 12 degrees where possible. Since the load profile is a typical -smooth- profile, the control is also much smoother. This should be a good representation of the capabilities of this setpoint manager.

For jagged load profiles, if tight control is highly important, choosing a smaller timestep (~1 minute) is recommended. For normal building profiles, the typical range of timesteps (~15 minute) should be fully satisfactory.

18.4 Solar Collectors

Solar collectors are devices that convert solar energy into thermal energy by raising the temperature of a circulating heat transfer fluid. The fluid can then be used to heat water for domestic hot water usage or space heating. Flat-plate solar collectors using water as the heat transfer fluid, Integral-Collector Storage solar collectors using water and unglazed transpired solar collectors using air are currently the only types of collector available in EnergyPlus.

18.4.1 Flat-Plate Solar Collectors

The input object `SolarCollector:FlatPlate:Water` provides a model for flat-plate solar collectors that are the most common type of collector. Standards have been established by ASHRAE for the performance testing of these collectors (ASHRAE 1989; 1991) and the Solar Rating and Certification Corporation (SRCC) publishes a directory of commercially available collectors in North America (SRCC 2003).

The EnergyPlus model is based on the equations found in the ASHRAE standards and Duffie and Beckman (1991). This model applies to glazed and unglazed flat-plate collectors, as well as banks of tubular, i.e. evacuated tube, collectors.

18.4.1.1 Solar and Shading Calculations

The solar collector object uses a standard EnergyPlus surface in order to take advantage of the detailed solar and shading calculations. Solar radiation incident on the surface includes beam and diffuse radiation, as well as radiation reflected from the ground and adjacent surfaces. Shading of the collector by other surfaces, such as nearby buildings or trees, is also taken into account. Likewise, the collector surface can shade other surfaces, for example, reducing the incident radiation on the roof beneath it.

18.4.1.2 Thermal Performance

The thermal efficiency of a collector is defined as the ratio of the useful heat gain of the collector fluid versus the total incident solar radiation on the gross surface area of the collector.

$$\eta = \frac{(q/A)}{I_{solar}} \quad (18.290)$$

where:

q is the useful heat gain

A is the gross area of the collector

I_{solar} is the total incident solar radiation.

Notice that the efficiency η is only defined for $I_{solar} > 0$.

An energy balance on a solar collector with double glazing shows relationships between the glazing properties, absorber plate properties, and environmental conditions.

$$\frac{q}{A} = I_{solar} \tau_{g1} \tau_{g2} \alpha_{abs} - \frac{T_{abs}^4 - T_{g2}^4}{R_{rad}} - \frac{T_{abs} - T_{g2}}{R_{conv}} - \frac{T_{abs} - T_{air}}{R_{cond}} \quad (18.291)$$

where:

τ_{g1} is the transmittance of the first glazing layer

τ_{g2} is the transmittance of the second glazing layer

α_{abs} is the absorptance of the absorber plate

R_{rad} is the radiative resistance from absorber to inside glazing

R_{conv} is the convective resistance from absorber to inside glazing

R_{cond} is the conductive resistance from absorber to outdoor air through the insulation

T_{abs} is the temperature of the absorber plate

T_{g2} is the temperature of the inside glazing

T_{air} is the temperature of the outdoor air.

The equation above can be approximated with a simpler formulation as:

$$\frac{q}{A} = F_R [I_{solar}(\tau\alpha) - U_L(T_{in} - T_{air})] \quad (18.292)$$

where:

F_R is an empirically determined correction factor

$(\tau\alpha)$ is the product of all transmittance and absorptance terms

U_L is the overall heat loss coefficient combining radiation, convection, and conduction terms

T_{in} is the inlet temperature of the working fluid.

Substituting this into Equation 18.290,

$$\eta = F_R(\tau\alpha) - F_R U_L \frac{(T_{in} - T_{air})}{I_{solar}} \quad (18.293)$$

A linear correlation can be constructed by treating $F_R(\tau\alpha)$ and $-F_R U_L$ as characteristic constants of the solar collector:

$$\eta = c_0 + c_1 \frac{(T_{in} - T_{air})}{I_{solar}} \quad (18.294)$$

Similarly, a quadratic correlation can be constructed using the form:

$$\eta = c_0 + c_1 \frac{(T_{in} - T_{air})}{I_{solar}} + c_2 \frac{(T_{in} - T_{air})^2}{I_{solar}} \quad (18.295)$$

Both first- and second-order efficiency equation coefficients are listed in the *Directory of SRCC Certified Solar Collector Ratings*.

18.4.1.3 Incident Angle Modifiers

As with regular windows the transmittance of the collector glazing varies with the incidence angle of radiation. Usually the transmittance is highest when the incident radiation is normal to the glazing surface. Test conditions determine the efficiency coefficients for normal incidence. For off-normal angles, the transmittance of the glazing is modified by an *incident angle modifier* coefficient.

$$K_{\tau\alpha} = \frac{(\tau\alpha)}{(\tau\alpha)_n} \quad (18.296)$$

Additional testing determines the incident angle modifier as a function of incident angle θ . This relationship can be fit to a first-order, linear correlation:

$$K_{\tau\alpha} = 1 + b_0 \left(\frac{1}{\cos \theta} - 1 \right) \quad (18.297)$$

or a second-order, quadratic correlation:

$$K_{\tau\alpha} = 1 + b_0 \left(\frac{1}{\cos \theta} - 1 \right) + b_1 \left(\frac{1}{\cos \theta} - 1 \right)^2 \quad (18.298)$$

The incident angle modifier coefficients b_0 and b_1 are usually negative, although some collectors have a positive value for b_0 . Both first- and second-order incident angle modifier equation coefficients are listed in the *Directory of SRCC Certified Solar Collector Ratings*.

The SRCC incident angle modifier equation coefficients are only valid for incident angles of 60 degrees or less. Because these curves can be valid yet behave poorly for angles greater than 60 degree, the EnergyPlus model cuts off collector gains for incident angles greater than 60 degrees.

For flat-plate collectors, the incident angle modifier is generally symmetrical. However, for tubular collectors the incident angle modifier is different depending on whether the incident angle is parallel or perpendicular to the tubes. These are called bi-axial modifiers. Some special flat-plate collectors may also exhibit this asymmetry. The current model cannot yet handle two sets of incident angle modifiers. In the meantime it is recommended that tubular collectors be approximated with caution using either the parallel or perpendicular correlation.

Incident angle modifiers are calculated separately for sun, sky, and ground radiation. The net incident angle modifier for all incident radiation is calculated by weighting each component by the corresponding modifier.

$$K_{\tau\alpha,net} = \frac{I_{beam}K_{\tau\alpha,beam} + I_{sky}K_{\tau\alpha,sky} + I_{gnd}K_{\tau\alpha,gnd}}{I_{beam} + I_{sky} + I_{gnd}} \quad (18.299)$$

For sky and ground radiation the incident angle is approximated using Brandemuehl and Beckman's equations:

$$\theta_{sky} = 59.68 - 0.1388\phi + 0.001497\phi^2 \quad (18.300)$$

$$\theta_{ground} = 90.0 - 0.5788\phi + 0.002693\phi^2 \quad (18.301)$$

where ϕ is the surface tilt in degrees.

The net incident angle modifier is then inserted into the useful heat gain Equation 18.292:

$$\frac{q}{A} = F_R [I_{solar}K_{\tau\alpha,net}(\tau\alpha)_n - U_L(T_{in} - T_{air})] \quad (18.302)$$

Equation 18.293 is also modified accordingly.

$$\eta = F_RK_{\tau\alpha,net}(\tau\alpha)_n - F_RU_L \frac{(T_{in} - T_{air})}{I_{solar}} \quad (18.303)$$

18.4.1.4 Outlet Temperature

Outlet temperature is calculated using the useful heat gain q as determined by Equation 18.302, the inlet fluid temperature T_{in} , and the mass flow rate available from the plant simulation:

$$\frac{q}{A} = \dot{m}c_p(T_{out} - T_{in}) \quad (18.304)$$

where:

\dot{m} is the fluid mass flow rate through the collector

c_p is the specific heat of the working fluid.

Solving for T_{out} ,

$$T_{out} = T_{in} + \frac{q}{\dot{m}c_pA} \quad (18.305)$$

If there is no flow through the collector, T_{out} is the stagnation temperature of the fluid. This is calculated by setting the left side of Equation 18.302 to zero and solving for T_{in} (which also equals T_{out} for the no flow case).

18.4.2 Integral-collector-storage (ICS) Solar Collector

Solar collectors with integral storage unit models use `SolarCollector:IntegralCollectorStorage` object, and the characteristics parameter inputs of this collector are provided by the `SolarCollectorPerformance:IntegralCollectorStorage` object. This model is based on detailed Energy Balance equations of solar collectors that integrates storage in it. This model has two options to represent the collector bottom outside boundary conditions: `AmbientAir`, and `OtherSideConditionsModel`. `AmbientAir` simply applies outside air temperature using combined convection and radiation conductance, and the `OtherSideConditionsModel` applies combined radiation and convection models that exists in a naturally ventilated cavity to represent the collector bottom outside boundary condition. The latter boundary condition accounts for the shading of the collector on the underlying surface, hence, the ICS collector can be assumed as an integral part of the building envelope. Schematic diagram of a rectangular ICS solar collector is shown in Figure 18.35 below:

Figure 18.35: Schematic diagram of rectangular Integrated Collector Storage unit

18.4.2.1 Solar and Shading Calculations

The solar collector object uses a standard EnergyPlus surface in order to take advantage of the detailed solar and shading calculations. Solar radiation incident on the surface includes beam and diffuse radiation, as well as radiation reflected from the ground and adjacent surfaces. Shading of the collector by other surfaces, such as nearby buildings or trees, is also taken into account. Likewise, the collector surface shades the roof surface beneath it, hence no direct solar radiation incident on the roof surface. The collector and the roof outside boundary conditions should be specified as `OtherSideConditionModel` to account for solar collector shading impact on the roof surface.

18.4.2.2 Mathematical Model

The integral-collector-storage (ICS) solar collector is represented using two transient energy balance equations shown below. These equations represent the energy balance equation for the absorber plate, and the water in the collector.

$$m_p C_p \frac{dT_p}{dt} = A \cdot [(\tau\alpha)_e \cdot I_t - h_{pw} (T_p - T_w) - U_t (T_p - T_a)] \quad (18.306)$$

$$m_w C_w \frac{dT_w}{dt} = A \cdot [h_{pw} (T_p - T_w) - U_b (T_w - T_{OSC}) - U_s (T_w - T_a)] - \dot{m}_w C_w (T_w - T_{wi}) \quad (18.307)$$

where:

$m_p C_p$ is the thermal capacity of the absorber surface, J/°C

A is the collector gross area, m²

$(\tau\alpha)_e$ is the transmittance-absorptance product of the absorber plate and cover system

I_t is the total solar irradiation (W/m²)

h_{pw} is the convective heat transfer coefficient from absorber plate to water (W/m²-K)

U_t is the overall heat loss coefficient from absorber to the ambient air (W/m²-K)

T_p is the absorber plate average temperature (°C)

T_w is the collector water average temperature (°C)

T_a is the ambient air temperature (°C)

$m_w C_{pw}$ is the thermal capacity of the water mass in the collector (J/°C)

U_s is the area-weighted conductance of the collector side insulation (W/m²-K)

U_b is the conductance of the collector bottom insulation (W/m²-K)

T_{osc} is the outside temperature of bottom insulation determined from the other side condition model (°C)

T_{wi} is the entering makeup or mains water temperature (°C)

$\dot{m}_w C_w$ is the water capacity flow through the collector (W/°C).

The other side condition model boundary condition represented by the T_{osc} , allows us to apply a realistic outside boundary condition for a collector mounted on a building roof. This also accounts for the shading impact of the collector on the under-laying surface (roof). On the other hand if ambient air boundary condition is specified, then the collector does not shade the underlying surface it is mounted on.

The two energy balance equation can be written as non-homogeneous first order DE with constant coefficients. The initial conditions for these equations are the absorber plate average temperature and the collector water average temperature at previous time steps.

$$\frac{dT_p}{dt} = a_1 T_p + a_2 T_w + a_3 \quad (18.308)$$

$$\frac{dT_w}{dt} = b_1 T_p + b_2 T_w + b_3 \quad (18.309)$$

$$a_1 = -(A \cdot h_{pw} + A \cdot U_t) / (m_p \cdot C_p) \quad (18.310)$$

$$a_2 = A \cdot h_{pw} T_w / (m_p \cdot C_p) \quad (18.311)$$

$$a_3 = A \cdot (\tau\alpha)_e \cdot I_t + A \cdot U_t T_a \quad (18.312)$$

$$b_1 = A \cdot h_{pw} T_p / (m_w \cdot C_w) \quad (18.313)$$

$$b_2 = -(A \cdot h_{pw} + A \cdot U_b + A \cdot U_s + \dot{m}_w C_w) \quad (18.314)$$

$$b_3 = (A \cdot U_b T_{osc} + A \cdot U_s T_a + \dot{m}_w C_w T_{wi}) \quad (18.315)$$

The two coupled first order differential equation are solved analytically. Auxiliary equation of the the coupled homogeneous differential equation is given by:

$$\lambda^2 - (a_1 + b_2) + (a_1 b_2 - a_2 b_1) = 0 \quad (18.316)$$

This auxiliary quadratic equation has always two distinct real roots (λ_1 and λ_2) hence the solution of the homogeneous equation is exponential, and the general solutions of the differential equations are given by:

$$T_p = c_1 e^{\lambda_1 t} + c_2 e^{\lambda_2 t} + A \quad (18.317)$$

$$T_w = r_1 c_1 e^{\lambda_1 t} + r_2 c_2 e^{\lambda_2 t} + B \quad (18.318)$$

The constant terms A and B are the particular solution of the non-homogeneous differential equations, the coefficients of the exponential terms (c_1 , c_2 , r_1 , and r_2) are determined from the initial conditions of the absorber and collector water temperatures (T_{p0} , T_{w0}) and are given by:

$$r_1 = (\lambda_1 - a_1)/a_2; \quad r_2 = (\lambda_2 - a_1)/a_2 \quad (18.319)$$

$$A = (-a_3 b_2 + b_3 a_2)/(a_1 b_2 - b_1 a_2); \quad B = (-a_1 b_3 + b_1 a_3)/(a_1 b_2 - b_1 a_2) \quad (18.320)$$

$$c_1 = (r_2 T_{p0} - T_{w0} - r_2 A + B)/(r_2 - r_1); \quad c_2 = (T_{w0} - r_1 T_{p0} + r_1 A - B)/(r_2 - r_1) \quad (18.321)$$

18.4.2.3 Thermal Network Model:

The thermal network model requires energy balance for each of the collector covers as well. The heat balance equation of the collector covers is assumed to obey steady state formulation by ignoring their thermal mass. The thermal-network representation of the ICS collector is shown in Figure 18.36. Also, the heat balance at each cover surface requires knowledge of the amount of solar fraction absorbed, which is determined from the ray tracing analysis. For the thermal network model shown above the overall top heat loss coefficient is determined from combination of the resistances in series as follows:

$$U_t = [R_1 + R_2 + R_3]^{-1} \quad (18.322)$$

or

$$U_t = \left[\frac{1}{h_{c,c1-a} + h_{r,c1-a}} + \frac{1}{h_{c,c2-c1} + h_{r,c2-c1}} + \frac{1}{h_{c,p-c2} + h_{r,p-c2}} \right]^{-1} \quad (18.323)$$

The convection and radiation heat transfer coefficients in equation above are calculated based on temperatures at the previous time step and determined as described in the *Heat Transfer Coefficients* section.

Figure 18.36: Thermal network diagram for ICS Solar Collector

Collector Cover Heat Balance

Ignoring the thermal mass of the collector cover, a steady state heat balance equations are formulated for each cover that allow us to determine cover temperatures. The cover surface heat balance representation is shown in Figure 18.37 below.

The steady state cover heat balance equation is given by:

$$q_{LWR,1} + q_{CONV,1} + q_{solar,abs} + q_{LWR,2} + q_{CONV,2} = 0 \quad (18.324)$$

Linearizing the longwave radiation exchange and representing the convection terms using the classical equation for Newton's law of cooling, the equations for the temperatures of covers 1 and 2 are given by:

$$T_{c1} = \frac{\alpha_{c1} I_t + h_{r,c1-a} T_a + h_{c,c1-a} T_a + h_{r,c2-c1} T_{c2} + h_{c,c2-c1} T_{c2}}{h_{r,c1-a} + h_{c,c1-a} + h_{r,c2-c1} + h_{c,c2-c1}} \quad (18.325)$$

$$T_{c2} = \frac{\alpha_{c2} I_t + h_{r,c2-c1} T_{c1} + h_{c,c2-c1} T_{c1} + h_{r,p-c2} T_p + h_{c,p-c2} T_p}{h_{r,c2-c1} + h_{c,c2-c1} + h_{r,p-c2} + h_{c,p-c2}} \quad (18.326)$$

where:

α_c is the weighted average solar absorptance of covers 1 and 2

Figure 18.37: Collector Cover Surface Heat Balance

$h_{r,c1-a}$ is the adjusted radiation heat transfer coefficient between cover 1 and the ambient air ($\text{W/m}^2\text{-K}$)

$h_{c,c1-a}$ is the convection heat transfer coefficient between cover 1 and the ambient ($\text{W/m}^2\text{-K}$)

$h_{r,c2-c1}$ is the radiation heat transfer coefficient between covers 1 and 2 ($\text{W/m}^2\text{-K}$)

$h_{c,c2-c1}$ is the convection heat transfer coefficient between covers 1 and 2 ($\text{W/m}^2\text{-K}$)

$h_{r,p-c2}$ is the radiation heat transfer coefficient between covers 2 and the absorber plate ($\text{W/m}^2\text{-K}$)

$h_{c,p-c2}$ is the convection heat transfer coefficient between covers 2 and the absorber plate ($\text{W/m}^2\text{-K}$)

$q_{LWR,1}$ is the longwave radiation exchange flux on side 1 of the collector cover (W/m^2)

$q_{CONV,1}$ is the convection heat flux on side 1 of the collector cover (W/m^2)

$q_{LWR,2}$ is the longwave radiation exchange flux on side 2 of the collector cover (W/m^2)

$q_{CONV,2}$ is the convection heat flux on side 2 of the collector cover (W/m^2)

$q_{solar,abs}$ is the net solar radiation absorbed by the collector cover (W/m^2)

R is the thermal resistance for each section along the heat flow path ($\text{m}^2\text{K/W}$).

18.4.2.4 Other Side Condition Model

ICS Solar Collectors are commonly mounted on building heat transfer surfaces hence the collectors shade the underlying heat transfer surface and require a unique boundary condition that reflects the air cavity environment created between the bottom of the collector surface and the underlying surface. The other side condition model that allows us to estimate the other side temperature, T_{osc} , can be determined based on steady state heat balance using the known collector water temperature at the previous time step.

Ignoring thermal mass of the collector bottom insulation, steady state surface heat balance can be formulated on the outer plane of the collector bottom surface facing the cavity as shown in Figure 18.38. The heat balance equation on the outer plane of the collector bottom surface is given by:

$$q_{cond} + q_{conv,cav} + q_{rad,cav} = 0 \quad (18.327)$$

Figure 18.38: Illustration for Other Side Condition Model

Substituting the equations for each term in the above equation yields:

$$U_L (T_w - T_{osc}) + h_{c,cav} (T_{a,cav} - T_{osc}) + h_{r,cav} (T_{so} - T_{osc}) = 0 \quad (18.328)$$

Simplifying yields the bottom insulation other side condition temperature:

$$T_{osc} = \frac{U_L T_w + h_{c,cav} T_{a,cav} + h_{r,cav} T_{so}}{U_L + h_{c,cav} + h_{r,cav}} \quad (18.329)$$

The cavity air temperature is determined from cavity air heat balance as follows:

$$T_{a,cav} = \frac{h_{c,cav} A T_{osc} + \dot{m}_{vent} C_p T_a + h_{c,cav} A T_{so}}{h_{c,cav} A + \dot{m}_{vent} C_p + h_{c,cav} A} \quad (18.330)$$

where:

$h_{r,cav}$ is the linearized radiation coefficient for underlying surface in the cavity (W/m²-K)

$h_{c,cav}$ is the convection coefficient for underlying surface in the cavity (W/m²-K)

T_{so} is the outside face temperature of the underlying heat transfer surface (°C)

\dot{m}_{vent} is the air mass flow rate due to natural ventilation (kg/s)

q_{cond} is the conduction heat flux through the insulation and bottom (W/m²)

$q_{conv,cav}$ is the convection heat flux between the collector bottom outside surface and the cavity air (W/m²)

$q_{rad,cav}$ is the longwave radiation exchange flux between the collector bottom outside surface and the outside surface of the underlying surface (W/m²).

The cavity air temperature is determined from the cavity air energy balance. The air heat balance requires the ventilated cavity air natural ventilation rates. The calculation of the ventilation rate is described elsewhere in this document. The SurfaceProperty:ExteriorNaturalVentedCavity, object is required to describe the surface properties, the characteristics of the cavity and opening for natural ventilation.

18.4.2.5 Heat Transfer Coefficients

The equations used to determine for the various heat transfer coefficients in the absorber and water heat balance equations are given below. The absorbed solar energy is transferred to the water by

convection. Assuming natural convection dominated heat transfer for a hot surface facing down and a cold surface facing down the following correlation for Nusselt number by Fujii and Imura (1972). The Nusselt number for hot surface facing down ward is given by:

$$Nu = 0.56(Gr \cdot Pr \cdot \cos\theta)^{1/5} \quad 10^5 < Gr \cdot Pr < 10^{11} \quad (18.331)$$

The Nusselt number for hot surface upward and cold surface facing down is given by:

$$Nu = 0.13(Gr \cdot Pr)^{1/3} \quad Gr \cdot Pr < 5.0 \times 10^8 \quad (18.332)$$

$$Nu = 0.16(Gr \cdot Pr)^{1/3} \quad Gr \cdot Pr > 5.0 \times 10^8 \quad (18.333)$$

$$Gr = g\beta_v (T_p - T_w) L_c^3 / \nu^2 \quad (18.334)$$

$$Pr = \nu / \alpha \quad (18.335)$$

$$T_r = T_p - 0.25 (T_p - T_w) \quad (18.336)$$

$$h_w = Nu \cdot k / L_c \quad (18.337)$$

where:

θ is the angle of inclination of the collector to the vertical (radians)

g is the gravitation force constant, 9.806 (m/s²)

T_r is the reference properties where the thermo-physical properties are calculated (°C)

L_c is the characteristic length for the absorber plate (m)

k is the thermal conductivity of water at reference temperature (W/m-K)

ν is the kinematic viscosity of water at reference temperature (m²/s)

α is the thermal diffusivity of water at reference temperature (m²/s)

β_v is the volumetric expansion coefficient (1/K) evaluated at T_v , $T_v = T_w + 0.25(T_p - T_w)$

Nu is the Nusselt number calculated for water properties at the reference temperature

Gr is the Grashof number calculated for water properties at the reference temperature

Pr is the Prandtl number calculated for water properties at the reference temperature.

The various radiation and convection heat transfer coefficients are given by the following equations. The convection heat transfer coefficients between the covers and the absorber plate are estimated from the empirical correlation for the Nusselt number for air gap between two parallel plates developed by Hollands et al. (1976) is:

$$Nu_a = 1 + 1.44 \left\{ 1 - \frac{1708(\sin 1.8\beta)^{1.6}}{Ra \cos \beta} \right\} \left\{ 1 - \frac{1708}{Ra \cos \beta} \right\} + \left\{ \left(\frac{Ra \cos \beta}{5830} \right)^{1/3} - 1 \right\} \quad (18.338)$$

$$h_c = Nu \cdot k / L \quad (18.339)$$

$$h_{rp-c2} = \frac{\sigma (T_p + T_{c2}) (T_p^2 + T_{c2}^2)}{1/\varepsilon_p + 1/\varepsilon_{c2} - 1} \quad (18.340)$$

$$h_{rc1-c2} = \frac{\sigma (T_{c1} + T_{c2}) (T_{c1}^2 + T_{c2}^2)}{1/\varepsilon_{c1} + 1/\varepsilon_{c2} - 1} \quad (18.341)$$

The long wave radiation exchange coefficients between the outer collector cover and the sky and ground referencing the ambient air temperature for mathematical simplification are given.

$$h_{rc1-s} = \frac{F_s \varepsilon_{c1} \sigma (T_{c1} + T_s) (T_{c1}^2 + T_s^2) (T_{c1} - T_s)}{(T_{c1} - T_a)} \quad (18.342)$$

$$h_{rc1-g} = \frac{F_g \varepsilon_{c1} \sigma (T_{c1} + T_g) (T_{c1}^2 + T_g^2) (T_{c1} - T_g)}{(T_{c1} - T_a)} \quad (18.343)$$

$$h_{cc1-a} = h_{cc1-s} + h_{cc1-g} \quad (18.344)$$

The convection heat transfer coefficient from the outer cover to the surrounding air is given by:

$$h_{cc1-a} = 2.8 + 3.0V_w \quad (18.345)$$

When the bottom surface boundary condition is AmbientAir, the combined conductance from the outer cover to the surrounding is calculated from the equation below (Duffie and Beckman, 1991).

$$h_{comb} = 5.7 + 3.8V_w \quad (18.346)$$

The overall loss coefficient through the bottom and side of the collector-storage is estimated as follows:

$$U_b = U_{Lb} (A_b/A) \quad (18.347)$$

$$U_s = \left[\frac{1}{U_{Ls} (A_s/A)} + \frac{1}{h_{comb}} \right]^{-1} \quad (18.348)$$

where:

ε_{c1} is the thermal emissivity of collector cover 1

ε_{c2} is the thermal emissivity of collector cover 2

F_s is the view factor from the collector to the sky

F_g is the view factor from the collector to the ground

T_{c1} is the temperature of collector cover 1, (K)

T_{c2} is the temperature of collector cover 2, (K)

T_s is the sky temperature, (K)

T_g is the ground temperature, (K)

k is the thermal conductivity of air (W/m K)

L is the air gap between the covers (m)

β is the inclination of the plates or covers to the horizontal (radians)

V_w is the wind speed (m/s)

U_{Lb} is the user specified bottom heat loss conductance (W/m²-K)

U_{Ls} is the user specified side heat loss conductance (W/m²-K)

A_b is the collector bottom heat transfer area (m²)

A_s is the collector side area (m^2)

h_{comb} is the combined conductance from the outer cover to the ambient air ($\text{W}/\text{m}^2\text{-K}$).

Transmittance-Absorptance Product

The transmittance-absorptance product of solar collector is determined using ray tracing method for any incident angle (Duffie and Beckman, 1991). This requires optical properties of the cover and absorber materials and the the transmittance-absorptance product for any incident angle is given by:

$$(\tau\alpha)_\theta = \frac{\tau\alpha}{1 - (1 - \alpha)\rho_d} \quad (18.349)$$

The transmittance of the cover system for single and two cover are given by:

$$\tau = \frac{1}{2} \left[\left(\frac{\tau_1 \cdot \tau_2}{1 - \rho_1 \rho_2} \right)_\perp + \left(\frac{\tau_1 \cdot \tau_2}{1 - \rho_1 \rho_2} \right)_\parallel \right] \quad (18.350)$$

$$\rho = \frac{1}{2} \left[\left(\rho_1 + \frac{\tau \cdot \rho_2 \cdot \tau_1}{\tau_2} \right)_\perp + \left(\rho_1 + \frac{\tau \cdot \rho_2 \cdot \tau_1}{\tau_2} \right)_\parallel \right] \quad (18.351)$$

The effective transmittance, reflectance and absorptance of a single cover are given by:

$$\tau = \frac{\tau_a}{2} \left\{ \frac{1 - r_\perp}{1 + r_\perp} \left[\frac{1 - r_\perp^2}{1 - (r_\perp \tau_a)^2} \right] + \frac{1 - r_\parallel}{1 + r_\parallel} \left[\frac{1 - r_\parallel^2}{1 - (r_\parallel \tau_a)^2} \right] \right\} \quad (18.352)$$

$$\rho = \frac{1}{2} \left\{ \left[r_\perp + \frac{(1 - r_\perp)^2 \tau_a^2 r_\perp}{1 - (r_\perp \tau_a)^2} \right] + \left[r_\parallel + \frac{(1 - r_\parallel)^2 \tau_a^2 r_\parallel}{1 - (r_\parallel \tau_a)^2} \right] \right\} \quad (18.353)$$

$$\alpha = \frac{(1 - \tau_a)}{2} \left\{ \left(\frac{1 - r_\perp}{1 - r_\perp \tau_a} \right) + \left(\frac{1 - r_\parallel}{1 - r_\parallel \tau_a} \right) \right\} \quad (18.354)$$

The transmittance of the cover system with absorption only considered t_a , is defined as:

$$\tau_a = \exp \left(-\frac{KL}{\cos \theta_2} \right) \quad (18.355)$$

$$\theta_2 = \sin^{-1} \left(\sin \theta_1 \cdot \frac{n_1}{n_2} \right) \quad (18.356)$$

The reflectance of un-polarized radiation on passing from medium 1 with reflective index n_1 to medium 2 with reflective index n_2 is given by:

$$r_\perp = \frac{\sin^2 (\theta_2 - \theta_1)}{\sin^2 (\theta_2 + \theta_1)} \quad (18.357)$$

$$r_\parallel = \frac{\tan^2 (\theta_2 - \theta_1)}{\tan^2 (\theta_2 + \theta_1)} \quad (18.358)$$

The sky and ground reflected diffuse radiations average equivalent incident angles are approximated by Brandemuehl and Beckman correlation (Duffie and Beckman, 1991) as follows:

$$\theta_{sd} = 59.68 - 0.1388\beta + 0.001497\beta^2 \quad (18.359)$$

$$\theta_{gd} = 90 - 0.5788\beta + 0.002693\beta^2 \quad (18.360)$$

where:

τ is the transmittance of the cover system

τ_1 is the transmittance of the cover 1

τ_2 is the transmittance of the cover 2

α is the absorptance of the absorber plate

ρ_d is the diffuse reflectance of the inner cover

L is the thickness of a cover material (m)

K is the extinction coefficient of a cover material (m^{-1})

θ_1 is the angle of incidence (degrees)

θ_2 is the angle of refraction (degrees)

r_{\perp} is the parallel component of reflected un-polarized radiation

r_{\parallel} is the perpendicular component of reflected un-polarized radiation

β is the slope of the collector (degrees)

θ_{sd} is the equivalent incident angle for sky diffuse solar radiation (degrees)

θ_{gd} is the equivalent incident angle for ground diffuse solar radiation (degrees).

The integral collector storage unit thermal performance parameters are calculated as follows:

$$Q_{delivered} = \dot{m}_w C_w (T_w - T_{wi}) \quad (18.361)$$

$$Q_{Stored} = m_w C_w \frac{dT_w}{dt} \quad (18.362)$$

$$Q_{SkinLoss} = A \cdot [U_t (T_p - T_w) + U_b (T_w - T_{OSC}) + U_s (T_w - T_a)] \quad (18.363)$$

$$\eta_{thermal} = \frac{m_w C_w \frac{dT_w}{dt} + \dot{m}_w C_w (T_w - T_{wi})}{A \cdot I_t} \quad (18.364)$$

18.4.4 Photovoltaic Thermal Flat-Plate Solar Collectors

Photovoltaic-Thermal solar collectors (PVT) combine solar electric cells and thermal working fluid to collect both electricity and heat. Although there are currently comparatively few commercial products, PVT research has been conducted for the past 30 years and many different types of collectors have been studied. Zondag (2008) and Charalambous et. al (2007) provide reviews of the PVT literature. Because PVT is much less commercially-mature, there are no standards or

rating systems such as for thermal-only, hot-water collectors. EnergyPlus currently has one simple model based on user-defined efficiencies.

The PVT models reuse the PV models for electrical production. These are described elsewhere in this document in the section on Photovoltaic Arrays-Simple Model

18.4.4.1 Simple PVT Thermal Model

The input object SolarCollector:FlatPlate:PhotovoltaicThermal provides a simple PVT model that is provided for quick use during design or policy studies. The user simply provides values for a thermal efficiency and the incident solar heats the working fluid. The model also includes a cooling mode for air-based systems where a user-provided surface emittance is used to model cooling of the working fluid to the night sky (water-based cooling will be made available once a chilled water storage tank is available). No other details of the PVT collector's construction are required as input data.

The simple model can heat either air or liquid. If it heats air, then the PVT is part of HVAC air system loop with air nodes connected to an air system. If it heats liquid, then the PVT is part of plant loop with nodes connected to a plant loop and the plant operating scheme determines flows.

Air-system-based PVT modeling include a modulating bypass damper arrangement. Control logic decides if the air should bypass the collector to better meet setpoint. The model requires a drybulb temperature setpoint be placed on the outlet node. The model assume the collector is intended and available for heating when the incident solar is greater than 0.3 W/m² and otherwise it is intended for cooling. The inlet temperature is compare to the setpoint on the outlet node to determine if cooling or heating are beneficial. If they are, then the PVT thermal models are applied to condition the air stream. If they are not beneficial, then the PVT is completely bypassed and the inlet node is passed directly to the outlet node to model a completely bypassed damper arrangement. A report variable is available for bypass damper status.

Plant-based PVT do not include a bypass (although one could be used in the plant loop). The collector requests its design flow rate but it otherwise relies on the larger plant loop for control.

When the PVT thermal collector is controlled to be “on,” in heating mode, and working fluid is flowing, the model calculates the outlet temperature based on the inlet temperature and the collected heat using the following equations.

$$Q_{therm} = A_{surf} \cdot f_{activ} \cdot G_T \cdot \eta_{thermal} \quad (18.365)$$

where:

Q_{therm} is the thermal energy collected (W)

A_{surf} is the net area of the surface (m²)

f_{activ} is the fraction of surface area with active PV/T collector

$\eta_{thermal}$ is the thermal conversion efficiency.

$$T_{out} = T_{in} + \frac{Q_{therm}}{\dot{m}c_p} \quad (18.366)$$

where:

T_{out} is the temperature of the working fluid leaving the PV/T

T_{in} is the temperature of the working fluid entering the PV/T

\dot{m} is the entire mass flow of the working fluid through the PV/T

c_p is the specific heat of the working fluid.

For air-based systems, the value of T_{out} is then compared to the temperature setpoint on the outlet node. If T_{out} exceeds the desired outlet temperature, $T_{set,out}$, then a bypass fraction is calculated to model a modulating bypass damper using:

$$f_{bypass} = \frac{(T_{set,out} - T_{out})}{(T_{in} - T_{out})} \quad (18.367)$$

When the PVT thermal collector is controlled to be “on,” in cooling mode, and working fluid is flowing, the model calculates the outlet temperature based on the inlet temperature and the heat radiated and convected to the ambient using a heat balance on the outside face of the collector:

$$\dot{m}c_p(T_{in} - T_{out}) = \dot{Q}_{LWR} + \dot{Q}_{conv} \quad (18.368)$$

where:

\dot{Q}_{LWR} is the net rate of long wavelength (thermal) radiation exchange with the air, night sky, and ground. See the section “External Longwave Radiation” in the Outside Surface Heat Balance, for full discussion of how this modeled in EnergyPlus using linearized radiation coefficients.

\dot{Q}_{conv} is the net rate of convective flux exchange with outdoor air. See the section “Exterior/External Convection” in the Outside Surface Heat Balance, for full discussion of how this modeled in EnergyPlus. The surface roughness is assumed to be “very smooth.”

The simple model assumes that the effective collector temperature, T_{col} , is the average of the working fluid inlet and outlet temperatures so that we can make the following substitution:

$$T_{out} = 2T_{col} - T_{in} \quad (18.369)$$

Substituting and solving for T_{col} we obtain the following model for collector temperatures during a (possible) cooling process :

$$T_{col} = \frac{2\dot{m}c_pT_{in} + A_{surf}f_{activ}(h_{r,gnd}T_{gnd} + h_{r,sky}T_{sky} + h_{r,air}T_{air} + h_{c,ext}T_{air})}{2\dot{m}c_p + A_{surf}f_{activ}(h_{r,gnd} + h_{r,sky} + h_{r,air} + h_{c,ext})} \quad (18.370)$$

Then the outlet temperature can be calculated and heat losses determined. However, the model allows only sensible cooling of the air stream and limits the outlet temperature to not go below the dewpoint temperature of the inlet.

PVT collectors have a design volume flow rate for the working fluid that is autosizable. For air-based systems used as pre-conditioners, the volume flow rate is sized to meet the maximum outdoor air flow rate. For water-based systems on the supply side of a plant loop, each of the PVT collectors are sized to the overall loop flow rate. For water-based systems on the demand side of a plant loop, the collectors are sized using a rule-of-thumb for typical flow rates per unit of collector area. This rule-of-thumb is based on a constant factor of $1.905 \times 10^{-5} \text{ m}^3/\text{s-m}^2$ that was developed by analyzing SRCC data set for conventional solar collectors (see data set SolarCollectors.idf) and averaging the ratio for all 171 different collectors.

18.4.5 Unglazed Transpired Solar Collectors

The input object `SolarCollector:UnglazedTranspired` provides a model for transpired collectors that are perhaps one of the most efficient ways to collect solar energy with demonstrated instantaneous efficiencies of over 90% and average efficiencies of over 70%. They are used for preheating outdoor air needed for ventilation and processes such as crop drying.

In *EnergyPlus*, an unglazed transpired solar collector (UTSC) is modeled as a special component attached to the outside face of a heat transfer surface that is also connected to the outdoor air path. A UTSC affects both the thermal envelope and the HVAC air system. From the air system's point of view, a UTSC is heat exchanger and the modeling needs to determine how much the device raises the temperature of the outdoor air. From the thermal envelope's point of view, the presence of the collector on the outside of the surface modifies the conditions experienced by the underlying heat transfer surfaces. *EnergyPlus* models building performance throughout the year and the UTSC will often be "off" in terms of forced airflow, but the collector is still present. When the UTSC is "on" there is suction airflow that is assumed to be uniform across the face. When the UTSC is "off" the collector acts as a radiation and convection baffle situated between the exterior environment and the outside face of the underlying heat transfer surface. We distinguish these two modes of operation as *active* or *passive* and model the UTSC component differently depending on which of these modes it is in.

18.4.5.1 Heat Exchanger Effectiveness

The perforated absorber plate is treated as a heat exchanger and modeled using a traditional effectiveness formulation. The heat exchanger effectiveness, ε_{HX} , is determined from correlations derived from small-scale experiments. Two correlations available in the literature are implemented in *EnergyPlus*. The first is based on research by Kutscher at the National Renewable Energy Laboratory. The second is based on the research by Van Decker, Hollands, and Brunger at the University of Waterloo. Because both correlations are considered valid, the choice of which correlation to use is left to the user.

18.4.5.2 Kutscher Correlation

Kutscher's (1994) correlation encompasses surface convection between the collector and the incoming outdoor air stream that occurs on the front face, in the holes, and along the back face of the collector. The correlation uses a Reynolds number based on the hole diameter as a length scale and the mean velocity of air as it passes through the holes as the velocity scale:

$$Re_D = \frac{V_h D}{\nu} \quad (18.371)$$

where:

V_h is the velocity through the holes (m/s)

D is the hole diameter (m)

ν is the kinematic viscosity of air (m²/s).

The correlation is a function of Reynolds number, hole geometry, the free stream air velocity, and velocity through the holes:

$$Nu_D = 2.75 \left[\left(\frac{P}{D} \right)^{-1.2} Re_D^{0.43} + 0.011 \sigma Re_D \left(\frac{U_\infty}{V_h} \right)^{0.48} \right] \quad (18.372)$$

where:

P is the pitch, or distance between holes (m)

D is the diameter of the holes (m)

σ is the porosity, or area fraction of the holes

V_h is the mean velocity of air passing through the holes (m/s)

U_∞ is the free stream velocity or the local wind speed (m/s).

The Nusselt number is formulated as:

$$Nu_D = \frac{U D}{k} \quad (18.373)$$

where:

U is the overall heat transfer coefficient based on log mean temperature difference (W/m²-K)

k is the thermal conductivity of air (W/m-K).

The heat exchanger effectiveness is:

$$\varepsilon_{HX} = 1 - e^{\left[-\frac{U A}{\dot{m} c_p} \right]} \quad (18.374)$$

Kutscher's relation was formulated for triangular hole layout, but based on Van Decker et al. (2001) we allow using the correlation for square hole layout and scale P by a factor of 1.6.

18.4.5.3 Van Decker, Hollands, and Brunger Correlation

Van Decker et. al. extended Kutscher's measurements to include a wider range of collector parameters including plate thickness, pitch, suction velocities, and square hole patterns. Their model formulation differs from Kutscher's in that the model was built up from separate effectiveness models for the front, back, and holes of the collector. Their published correlation is:

$$\varepsilon_{HX} = \left[1 - \left(1 + Re_s \text{Max} \left(1.733 Re_w^{-1/2}, 0.02136 \right)^{-1} \right) \right] \times \left[1 - \left(1 + 0.2273 Re_b^{1/2} \right)^{-1} \right] \\ \times e^{\left(-0.01895 \frac{P}{D} - \frac{20.62}{Re_D} \frac{t}{D} \right)} \quad (18.375)$$

where:

$$Re_s = \frac{V_s P}{v} \quad (18.376)$$

$$Re_w = \frac{U_\infty P}{v} \quad (18.377)$$

$$Re_b = \frac{V_h P}{v} \quad (18.378)$$

V_s is the average suction velocity across the front face of the collector (m/s)

t is the collector plate thickness (m).

18.4.5.4 Heat Exchanger Leaving Temperature

Using either of the correlations above allows determining the heat exchanger effectiveness from known values. By definition the heat exchanger effectiveness is also:

$$\varepsilon_{HX} = \frac{T_{a,HX} - T_{amb}}{T_{s,coll} - T_{amb}} \quad (18.379)$$

where:

$T_{a,HX}$ is the temperature of the air leaving the collector and entering the plenum (°C)

$T_{s,coll}$ is the temperature of the collector's absorber plate (°C)

T_{amb} is the temperature of the ambient outdoor air (°C).

By rewriting Equation 18.379 to solve for $T_{a,HX}$, we see that the temperature of the heated outdoor air entering the plenum can be determined once the collector surface temperature is known:

$$T_{a,HX} = \varepsilon_{HX} T_{s,coll} + (1 - \varepsilon_{HX}) T_{amb} \quad (18.380)$$

18.4.5.5 Collector Heat Balance

The collector is assumed to be sufficiently thin and high-conductivity so that it can be modeled using a single temperature (for both sides and along its area). This temperature $T_{s,coll}$ is determined by formulating a heat balance on a control volume that just encapsulates the collector surface. The heat balances are formulated separately for active and passive modes and are diagrammed in the following figure.

Observe that for the passive case, we do not use the heat exchanger relations to directly model the interaction of ventilating air with the collector. This is because these relations are considered to not apply when the UTSC is in passive mode. They were developed for uni-directional flow (rather than the balanced-in-and-out flow expected from natural forces) and for specific ranges of suction face velocity. Therefore, this heat transfer mechanism is handled using classical surface convection models (as if the collector was not perforated). (Air exchanges are modeled as ventilation in the plenum air heat balance but do not interact with the hole edges in the collector surface.)

When the UTSC is active, the heat balance on the collector surface control volume is:

$$q''_{\alpha sol} + q''_{LWR,Env} + q''_{conv,wind} - q''_{HX} + q''_{LWR,plen} + q''_{source} = 0 \quad (18.381)$$

where:

$q''_{\alpha sol}$ is absorbed direct and diffuse solar (short wavelength) radiation heat flux.

$q''_{LWR,Env}$ is net long wavelength (thermal) radiation flux exchange with the air and surroundings.

$q''_{conv,wind}$ is surface convection flux exchange with outdoor air under high wind and rain conditions. Note that this term is usually assumed to be zero in UTSC model development but we add the term to allow for deteriorated performance of the UTSC under poor conditions.

q''_{HX} is heat exchanger flux from collector to incoming outdoor air.

Figure 18.39: Transpired Collector Heat Balance

$q''_{LWR,plen}$ is net long wavelength (thermal) radiation flux exchange with the outside face of the underlying surface(s).

q''_{source} is a source/sink term that accounts for energy exported out of the control volume when the collector's absorber plate is a hybrid device such as a photovoltaic panel.

While the heat balance on the passive collector surface control volume is:

$$q''_{\alpha sol} + q''_{LWR,Env} + q''_{conv,Env} + q''_{LWR,plen} + q''_{conv,plen} + q''_{source} = 0 \quad (18.382)$$

where:

$q''_{conv,Env}$ is the surface convection flux exchange with outdoor air

$q''_{conv,plen}$ is the surface convection flux exchange with plenum air.

All terms are positive for net flux to the collector except the heat exchanger term, which is taken to be positive in the direction from collector to incoming air stream. Each of these heat balance components is introduced briefly below.

18.4.5.6 External SW Radiation

$q''_{\alpha sol}$ is calculated using procedures presented elsewhere in this manual and includes both direct and diffuse incident solar radiation absorbed by the surface face. This is influenced by location, surface facing angle and tilt, shading surfaces, surface face material properties, weather conditions, etc.

18.4.5.7 External LW Radiation

$q''_{LWR,Env}$ is a standard radiation exchange formulation between the surface, the sky, the ground, and the atmosphere. The radiation heat flux is calculated from the surface absorptivity, surface temperature, sky, air, and ground temperatures, and sky and ground view factors. Radiation is modeled using linearized coefficients.

18.4.5.8 External Convection

$q''_{conv,Env}$ is modeled using the classical formulation:

$$q''_{conv} = h_{co}(T_{air} - T_o) \quad (18.383)$$

where h_{co} is the convection coefficient. This coefficient will differ depending on whether or not the UTSC is active or passive. When the UTSC is passive, h_{co} is treated in the same way as an outside face with ExteriorEnvironment conditions. When the UTSC is active, the special suction airflow situation of a transpired collector during operation means that h_{co} is often zero because the suction situation can eliminate mass transport away from the collector. However when the winds are high, the strong turbulence and highly varying pressures can cause the suction flow situation to breakdown. Therefore, we include the $q''_{conv,wind}$ term in the heat balance and use a special coefficient $h_{c,wind}$ to model this lost heat transfer. In addition, when it is raining outside, we assume the collector gets wet and model the enhanced surface heat transfer using a large value for $h_{c,wind}$.

18.4.5.9 Heat Exchanger

q''_{HX} is modeled using the classical formulation:

$$q''_{HX} = \frac{\dot{m}c_p(T_{a,HX} - T_{amb})}{A} \quad (18.384)$$

where $T_{a,HX}$ is determined using correlations described above. When the UTSC is active, the air mass flow is determined from the operation of the outdoor air mixer component. When the UTSC is off, this term is zero.

18.4.5.10 Plenum LW Radiation

$q''_{LWR,plen}$ is a standard radiation exchange formulation between the collector surface and the underlying heat transfer surface located across the plenum. Radiation is modeled using linearized coefficients.

18.4.5.11 Plenum Convection

$q''_{conv,plen}$ is modeled using the classical formulation:

$$q''_{conv} = h_{cp}(T_{air} - T_o) \quad (18.385)$$

where h_{cp} is the convection coefficient. This coefficient is taken as zero when the UTSC is operating because of the suction airflow situation. When the UTSC is off, the value for h_{cp} is obtained from correlations used for window gaps from ISO (2003) standard 15099.

Substituting these models into Equation 18.381 and solving for $T_{s,coll}$ yields the following equation when the UTSC is active (“on”):

$$T_{s,coll} = \frac{\left(I_s\alpha + h_{r,atm}T_{amb} + h_{r,sky}T_{sky} + h_{r,gnd}T_{amb} + h_{r,plen}T_{so} + h_{c,wind}T_{amb} + \frac{\dot{m}c_p}{A}T_{amb} - \frac{\dot{m}c_p}{A}(1 - \varepsilon_{HX})T_{amb} + q''_{source}\right)}{\left(h_{r,atm} + h_{r,sky} + h_{r,gnd} + h_{r,plen} + h_{c,wind} + \frac{\dot{m}c_p}{A}\varepsilon_{HX}\right)} \quad (18.386)$$

and substituting into Equation 18.381 yields the following equation when the UTSC is passive (“off”):

$$T_{s,coll} = \frac{\left(I_s\alpha + h_{co}T_{amb} + h_{r,atm}T_{amb} + h_{r,sky}T_{sky} + h_{r,gnd}T_{amb} + h_{r,plen}T_{so} + h_{c,plen}T_{a,plen} + q''_{source}\right)}{\left(h_{co} + h_{r,air} + h_{r,sky} + h_{r,gnd} + h_{r,plen} + h_{c,plen}\right)} \quad (18.387)$$

where:

I_s is the incident solar radiation of all types (W/m²)

α is the solar absorptivity of the collector

$h_{r,atm}$ is the linearized radiation coefficient for the surrounding atmosphere (W/m²-K)

T_{amb} is the outdoor drybulb from the weather data, also assumed for ground surface (°C)

$h_{r,sky}$ is the linearized radiation coefficient for the sky (W/m²-K)

T_{sky} is the effective sky temperature (°C)

$h_{r,gnd}$ is the linearized radiation coefficient for the ground (W/m²-K)

$h_{r,plen}$ is the linearized radiation coefficient for the underlying surface (W/m²-K)

$h_{c,wind}$ is the convection coefficient for the outdoor environment when the UTSC is active and winds are high or it is raining (W/m²-K)

T_{so} is the temperature of the outside face of the underlying heat transfer surface (°C)

\dot{m} is the air mass flow rate when in active mode (kg/s)

c_p is the specific heat of air at constant pressure (J/kg-K)

A is the area of the collector (m²)

h_{co} is the convection coefficient for the outdoor environment (W/m²-K)

$h_{c,plen}$ is the convection coefficient for the surfaces facing the plenum (W/m²-K)

$T_{a,plen}$ is the air drybulb for air in the plenum and entering the outdoor air system (°C).

18.4.5.12 Plenum Heat Balance

The *plenum* is the volume of air located between the collector and the underlying heat transfer surface. The plenum air is modeled as well-mixed. The uniform temperature of the plenum air, $T_{a,plen}$, is determined by formulating a heat balance on a control volume of air as diagrammed below.

Note that we have formulated the control volumes with slight differences for the active and passive cases. For the active case, the suction air situation and heat exchanger effectiveness formulations dictate that the collector surface control volume encompass part of the air adjacent to both the front and back surfaces of the collector. However for the passive case, the collector surface control volume has no air in it and the plenum air control volume extends all the way to the surface of the collector.

When the UTSC is active, the heat balance on the plenum air control volume is:

$$\dot{Q}_{air} + \dot{Q}_{co} = 0 \quad (18.388)$$

where:

\dot{Q}_{air} is the net rate of energy added by suction air convecting through the control volume

\dot{Q}_{co} is the net rate of energy added by surface convection heat transfer with the underlying surface.

When the UTSC is passive, the heat balance on the plenum air control volume is:

$$\dot{Q}_{vent} + \dot{Q}_{co} + \dot{Q}_{c,coll} = 0 \quad (18.389)$$

where:

\dot{Q}_{vent} is the net rate of energy added from infiltration – where outdoor ambient air exchanges with the plenum air

$\dot{Q}_{c,coll}$ is the net rate of energy added by surface convection heat transfer with the collector.

Substituting into Equation 18.388 and solving for $T_{a,plen}$ yields the following equation for when the UTSC is active:

$$T_{a,plen} = \frac{(\dot{m}c_p T_{a,HX} + h_{c,plen} A T_{so})}{(\dot{m}c_p + h_{c,plen} A)} \quad (18.390)$$

And substituting into Equation 18.389 yields the following equation when the UTSC is passive:

$$T_{a,plen} = \frac{(h_{c,plen} A T_{so} + \dot{m}_{vent} c_p T_{amb} + h_{c,plen} A T_{s,coll})}{(h_{c,plen} A + \dot{m}_{vent} c_p + h_{c,plen} A)} \quad (18.391)$$

where \dot{m}_{vent} is the air mass flow from natural forces (kg/s).

Figure 18.40: Transpired Collector Plenum Air Heat Balance

The literature on UTSC does not appear to address the passive mode of operation and no models for \dot{m}_{vent} have been identified. Nevertheless, natural buoyancy and wind forces are expected to drive air exchange between the plenum and ambient and some method of modeling \dot{m}_{vent} is needed. Reasoning that the configuration is similar to single-side natural ventilation, we elect to use correlations for natural ventilation presented in Chapter 26 of the ASHRAE Handbook of Fundamentals (2001).

$$\dot{m}_{vent} = \rho V_{tot} \quad (18.392)$$

where:

ρ is the density of air (kg/m³)

$V_{tot} = V_{wind} + V_{thermal}$ is the total volumetric flow rate of air ventilating in and out of the plenum (m³/s)

$$V_{wind} = C_v A_{in} U_{\infty} \quad (18.393)$$

$$V_{thermal} = C_D A_{in} \sqrt{2g\Delta H_{NPL} (T_{a,plen} - T_{amb}) / T_{a,plen}} \quad (if \ T_{a,plen} > T_{amb}) \quad (18.394)$$

$$V_{thermal} = C_D A_{in} \sqrt{2g\Delta H_{NPL} (T_{amb} - T_{a,plen}) / T_{amb}} \quad (if \ T_{amb} > T_{a,plen} \text{ and } UTSC \text{ vertical}) \quad (18.395)$$

where:

C_v is the effectiveness of the openings that depends on opening geometry and the orientation with respect to the wind. ASHRAE HoF (2001) indicates values ranging from 0.25 to 0.6. In the UTSC model, this value is available for user input and defaulted to 0.25.

C_D is the discharge coefficient for the opening and depends on opening geometry. In the UTSC model, this value is available for user input and defaulted to 0.65.

Mass continuity arguments lead to modeling the area of the openings as one half of the total area of the holes, so we have:

$$A_{in} = \frac{A \sigma}{2} \quad (18.396)$$

g is the gravitational constant taken as 9.81 (m/s²).

ΔH_{NPL} is the height from midpoint of lower opening to the Neutral Pressure Level. This is taken as one-fourth the overall height of the UTSC if it is mounted vertically. For tilted collectors, the nominal height is modified by the sine of the tilt. If the UTSC is mounted horizontally (e.g. on the roof) then the ΔH_{NPL} is taken as the gap thickness of the plenum.

If the UTSC is horizontal and $T_{amb} > T_{a,plen}$, then $V_{thermal} = 0$ because this is a stable situation.

18.4.5.13 Underlying Heat Transfer Surface

The UTSC is applied to the outside of a heat transfer surface. This surface is modeled using the usual EnergyPlus methods for handling heat capacity and transients – typically the CTF method. These native EnergyPlus Heat Balance routines are used to calculate T_{so} . The UTSC model is coupled to the underlying surface using the OtherSideConditionsModel mechanism. The UTSC model provides values for $h_{r,plen}$, $T_{s,coll}$, $h_{c,plen}$, and $T_{a,plen}$ for use with the Heat Balance Model calculations for the outside face of the underlying surface (described elsewhere in this manual).

18.4.5.14 Solar and Shading Calculations

The transpired collector object uses a standard EnergyPlus surface in order to take advantage of the detailed solar and shading calculations. Solar radiation incident on the surface includes beam and diffuse radiation, as well as radiation reflected from the ground and adjacent surfaces. Shading of the collector by other surfaces, such as nearby buildings or trees, is also taken into account.

18.4.5.15 Local Wind Speed Calculations

The outdoor wind speed affects terms used in modeling UTSC components. The wind speed in the weather file is assumed to be measured at a meteorological station located in an open field at a height of 10 m. To adjust for different terrain at the building site and differences in the height of building surfaces, the local wind speed is calculated for each surface.

The wind speed is modified from the measured meteorological wind speed by the equation (ASHRAE 2001):

$$U_{\infty} = V_{met} \left(\frac{\delta_{met}}{z_{met}} \right)^{a_{met}} \left(\frac{z}{\delta} \right)^a \quad (18.397)$$

where:

z is the height of the centroid of the UTSC

z_{met} is the height of the standard meteorological wind speed measurement

a and δ are terrain-dependent coefficients. δ is the boundary layer thickness for the given terrain type. The values of a and δ are shown in the Table 18.3.

Table 18.3: Terrain-Dependent Coefficients (ASHRAE 2001).

Terrain	Description	Exponent, a	Layer Thickness, δ (m)
1	Flat, open country	0.14	270
2	Rough, wooded country	0.22	370
3	Towns and cities	0.33	460
4	Ocean	0.10	210
5	Urban, industrial, forest	0.22	370

The UTSC can be defined such that it has multiple underlying heat transfer surfaces. The centroid heights for each surface are area-weighted to determine the average height for use in the local wind calculation.

18.4.5.16 Convection Coefficients

UTSC modeling requires calculating up to three different coefficients for surface convection heat transfer. These coefficients are defined in the classic way by:

$$h_c = \frac{T_{air} - T_{surf}}{q''_{conv}} \quad (18.398)$$

First, h_{co} is the convection coefficient for the collector surface facing the outdoors when the UTSC is passive. It is modeled in exactly the same way as elsewhere in EnergyPlus and will depend on the user setting for Outside Convection Algorithm – Outside Surface Heat Balance entry elsewhere in this document.

Second, $h_{c,plen}$ is the convection coefficient for surfaces facing the plenum. This coefficient is applied to just the underlying surface's convection when the UTSC is active and to both the collector and the underlying surface when the UTSC is passive. When the UTSC is active, we use the convection correlation for forced air developed by McAdams (1954) as published by ASHRAE HoF (2001):

$$h_{c,plen} = 5.62 + 3.9V_p \quad (18.399)$$

where V_p is the mean velocity in the plenum determined from:

$$V_p = \frac{\dot{m}}{2\rho A_p} \quad (18.400)$$

and where A_p is the effective cross section area of the plenum perpendicular to the primary flow direction. When the UTSC is passive, we model the convection in the same way used in EnergyPlus to model air gaps in windows. These correlations vary by Rayleigh number and surface tilt and are based on the work of various research including Hollands et. al., Elsherbiny et. al., Wright, and Arnold. The formulations are documented in ISO (2003) standard 15099. For the UTSC implementation, the routines were adapted from Subroutine NusseltNumber in WindowManager.f90 (by F. Winkelmann), which itself was derived from Window5 subroutine “nusselt”.

Third, $h_{c,wind}$ is the convection coefficient used to degrade the UTSC performance under environmental conditions with high wind or rain. If the weather file indicates it is raining, then we set $h_{c,wind} = 1000.0$ which has the effect of making the collector the same temperature as ambient air. The heat exchanger effectiveness correlations described above account for a moderate amount of wind, but the correlations appear confined to the range 0 to 5.0 m/s. Therefore we set $h_{c,wind}$ equal to zero if U_∞ is ≤ 5.0 m/s. If U_∞ is > 5.0 m/s, then we use the McAdams correlation but with a reduced velocity magnitude:

$$h_{c,wind} = 5.62 + 3.9(U_\infty - 5.0) \quad (18.401)$$

18.4.5.17 Radiation Coefficients

UTSC modeling requires calculating up to four different linearized coefficients for radiation heat transfer. Whereas radiation calculations usually use temperature raised to the fourth power, this greatly complicates solving heat balance equations for a single temperature. Linearized radiation coefficients have the same units and are used in the same manner as surface convection coefficients and introduce very little error for the temperature levels involved.

The radiation coefficient, $h_{r,plen}$, is used to model thermal radiation between the collector surface and the outside face of the underlying heat transfer surface. We assume a view factor of unity. It is calculated using:

$$h_{r,plen} = \sigma_{SB} e_{coll} e_{so} \frac{(T_{s,coll}^4 - T_{so}^4)}{(T_{s,coll} - T_{so})} \quad (18.402)$$

where all temperatures are converted to Kelvin and:

σ_{SB} is the Stefan-Boltzmann constant

e_{coll} is the longwave thermal emittance of the collector

e_{so} is the longwave thermal emittance of the underlying heat transfer surface.

The three other coefficients, $h_{r,atm}$, $h_{r,sky}$, and $h_{r,gnd}$ are used elsewhere in EnergyPlus for the outside face surface heat balance and are calculated in the same manner as equation for UTSC collectors. [This is accomplished by calling subroutine InitExteriorConvectionCoeffs in the file HeatBalanceConvectionCoeffs.f90.]

18.4.5.18 Bypass Control

The UTSC is assumed to be arranged so that a bypass damper controls whether or not air is drawn directly from the outdoors or through the UTSC. The control decision is based on whether or not it will be beneficial to heat the outdoor air. There are multiple levels of control including an availability schedule, whether or not the outdoor air is cooler than the mixed air setpoint, or whether or not the zone air temperature is lower than a so-called free heating setpoint.

18.4.5.19 Sizing Warnings

Although the design of the transpired collector is left to the user, the program issues warnings when the suction airflow velocity falls outside the range 0.003 to 0.08 m/s.

18.4.5.20 Overall Efficiency

The overall thermal efficiency of the UTSC is a useful output report and is defined as the ratio of the useful heat gain of the entire system versus the total incident solar radiation on the gross surface area of the collector.

$$\eta = \frac{(\dot{Q}/A)}{I_{sc}} = \frac{\dot{m} c_p (T_{a,plen} - T_{amb})}{I_{sc} A} \quad (18.403)$$

where:

\dot{Q} is useful heat gain

I_{sc} is total incident solar radiation.

Note that the efficiency η is only defined for $I_{solar} > 0$. This efficiency includes heat recovered from the underlying wall and can exceed 1.0.

18.4.5.21 Collector Efficiency

The thermal efficiency of the collector is a useful output report and is defined as the ratio of the useful heat gain of the collector fluid versus the total incident solar radiation on the gross surface area of the collector.

$$\eta = \frac{\dot{m} c_p (T_{a,HX} - T_{amb})}{I_{sc} A} \quad (18.404)$$

Note that the efficiency η is only defined for $I_{solar} > 0$.

18.5 System Availability Managers

18.5.1 Overview

System availability managers, or *AvailabilityManagers*, are one of the high-level control constructs in EnergyPlus. An *AvailabilityManager* is able to access data from any of the HVAC system nodes and use this data to set flags telling a central air system or plant loop to turn on or off. Also, some of the *HVACZone:** components can use these same availability managers to turn their supply air fan on or off. Each type of availability manager encapsulates a specific high-level on-off control strategy. For instance, the input object *AvailabilityManager:NightVentilation* allows the user to specify a control strategy for pre-cooling the building with night-time ventilation.

Availability managers are contained in the program module *SystemAvailabilityManager*. The Availability managers are executed at the start of each HVAC time step by a call to *ManageSystemAvailability*, and they reside outside the HVAC system iteration loops. Thus, the availability managers are executed once per HVAC time step, and they use previous time step information to calculate their control actions.

If a given instance of an *AvailabilityManager* is specific to an *AirLoopHVAC* or to a *PlantLoop*, then in the input, each loop references its availability managers through a *AvailabilityManagerAssignmentList*. Once the data has been read in and processed, the *AvailabilityManager* data for each loop is stored in array *PriAirSysAvailMgr* in *DataAirLoop* (for *AirLoopHVAC*) and in array *PlantAvailMgr* in *DataPlant* for plant loops.

The availability status for each *AirLoopHVAC* (*PriAirSysAvailMgr*) is also passed to a zone equipment availability status array (*ZoneEquipAvail*) for possible use by the zones served by that air loop. This sets the availability for certain zone equipment which are assumed to operate in conjunction with the air loop. Specifically, the availability of zone exhaust fans (Ref. Fan:ZoneExhaust) and terminal unit fans (Ref. AirTerminal:SingleDuct:SeriesPIU: Reheat, AirTerminal:SingleDuct:ParallelPIU:Reheat, and AirTerminal:SingleDuct:VAV: Reheat:VariableSpeedFan), if specified in the input, will be the same as the corresponding *AirLoopHVAC* availability if an *AvailabilityManager* is specified. Other zone equipment are not affected by the *AirLoopHVAC* system availability managers (e.g., Window AC, PTAC and PTHP).

However, system availability managers can separately be specified for zone components (currently only allowed for Window AC, PTAC, PTHP, Unit Heater, Unit Ventilator, Zone Water to Air Heat Pump, Zone Terminal Unit (VRF), Standalone Energy Recovery Ventilator, Outdoor Air Unit, Fan Coil Unit, and Ventilated Slab). Similar to *AirLoopHVAC* or *PlantLoop*, inputs of these zone components refer to their availability managers through a *AvailabilityManagerAssignmentList*.

System availability managers only operate when zone components are available. If the Window AC (or any other unit) is scheduled off then the system availability manager will not operate until the Window AC is scheduled on. The functioning of the system availability manager for zone components is same as for AirLoopHVAC or PlantLoop. Except night ventilation SAM, all other SAMs can be specified for these zone components.

The actual action of turning on or off a loop is taken by the loop prime movers: fans for AirLoopHVACs and pumps for plant loops. For instance when a fan is deciding whether it is on or off, it checks its on/off schedule and whether the loop availability status flag is *CycleOn* or *ForceOff*. If the schedule is on and the status flag is *ForceOff*, the fan will be off. If the fan schedule says off and the status flag is *CycleOn*, the fan will be on. Thus the availability managers overrule the fan on/off schedule.

18.5.2 Scheduled

The input object AvailabilityManager:Scheduled provides the simplest availability manager. The sole input for this manager is a schedule name. If the current schedule value is > 0.0 , the availability status flag is set to *CycleOn*; otherwise it is set to *ForceOff*.

18.5.3 Scheduled On

An alternative to the AvailabilityManager:Scheduled object is the *AvailabilityManager:ScheduledOn* that is used specifically to turn equipment on while other availability managers may be used to turn the equipment off. The sole input for this manager is a schedule name. If the current schedule value is > 0.0 , the availability status flag is set to *CycleOn*; otherwise it is set to *NoAction*.

18.5.4 Scheduled Off

An alternative to the AvailabilityManager:Scheduled object is the *AvailabilityManager:ScheduledOff* that is used specifically to turn equipment off while other availability managers may be used to turn the equipment on. The sole input for this manager is a schedule name. If the current schedule value is $= 0.0$, the availability status flag is set to *ForceOff*; otherwise it is set to *NoAction*.

18.5.5 Night Cycle

The input object AvailabilityManager:NightCycle is to specify when a system that has been scheduled off during unoccupied hours should cycle on to prevent building temperatures from becoming too hot or too cold. This manager can not be used to force a system off. The inputs are:

- A manager applicability schedule;
- The name of the fan schedule this manager will override;
- The control type: *StayOff*, *CycleOnAny*, *CycleOnControlZone*, *CycleOnAnyZoneFansOnly*, *CycleOnAnyCoolingOrHeatingZone*, *CycleOnAnyCoolingZone*, *CycleOnAnyHeatingZone*, or *CycleOnAnyHeatingZoneFansOnly*;
- Thermostat on/off tolerance T_{tol} ($^{\circ}\text{C}$);

- Cycling run time control type: *FixedRunTime*, *Thermostat*, or *ThermostatWithMinimumRunTime*;
- Cycling run time in seconds; used to calculate a stop time (in time steps since the start of the current run period) once the status has become *Cycle On*.
- A control zone or zone list name.
- Cooling control zone or zone list name.
- Heating control zone or zone list name.
- Heating zone fans only control zone or zone list name.

If the fan schedule current value is > 0 or the applicability schedule value is ≤ 0 , *AvailStatus* = *NoAction*.

If the program is in warmup, the start time stop time are reset to the current time.

Otherwise:

1. If current time (in time steps since the start of the run period) is greater than the start time and less than the stop time, *AvailStatus* = *CycleOn* (or *CycleOnZoneFansOnly* if the control type is *Cycle On Any – Zone Fans only*) for *CyclingRunTimeControlType* = *CyclingRunTimeControlType* = *FixedRunTime*, or *CyclingRunTimeControlType* = *ThermostatWithMinimumRunTime* but for *CyclingRunTimeControlType* = *Thermostat* the availability status is determined based on the zone air and the thermostat setpoint temperature difference and the tolerance limits.
2. If the current time equals the stop time and the *CyclingRunTimeControlType* = *CyclingRunTimeControlType* = *FixedRunTime*, or *CyclingRunTimeControlType* = *ThermostatWithMinimumRunTime*, *AvailStatus* = *NoAction* and the fan schedule will determine if the system is on. For *CyclingRunTimeControlType* = *Thermostat* the availability status is determined based on the zone air and the thermostat setpoint temperature difference and the tolerance limits, and the fan schedule will determine if the system is on.
3. If the current time is greater than the stop time, the manager can potentially cycle the system on for *CyclingRunTimeControlType* = *FixedRunTime*, *CyclingRunTimeControlType* = *Thermostat*, or *CyclingRunTimeControlType* = *ThermostatWithMinimumRunTime*.
 - (a) For control types *CycleOnAny* and *CycleOnAnyZoneFansOnly* the manger looks at each zone served by the air loop and detects whether the zone temperature at the thermostat is greater than the cooling setpoint plus $\frac{1}{2} T_{tol}$ or less than the heating setpoint minus $\frac{1}{2} T_{tol}$. If it is, *AvailStatus* is set to *CycleOn* (or *CycleOnZoneFansOnly*). If not, *AvailStatus* is set to *NoAction*.
 - (b) For control type *CycleOnControlZone*, the manager does the same check just for the control zone or zone list.
 - (c) For control type *CycleOnAnyCoolingOrHeatingZone*, the manager checks the cooling setpoint for the cooling control zone or zone list and sets *AvailStatus* to *CycleOn*, then

it checks the heating setpoint for the heating control zone or zone list and sets *AvailStatus* to *CycleOn*. If the *AvailStatus* is still *NoAction*, then the manager checks the heating setpoint for the heating zone fans only zone or zone list and sets *AvailStatus* to *CycleOnZoneFansOnly*). If none of these checks are true then *AvailStatus* is set to *NoAction*.

- (d) For control type *CycleOnAnyCoolingZone*, the manager checks the cooling setpoint for the cooling control zone or zone list and sets *AvailStatus* to *CycleOn*. If none of these checks are true then *AvailStatus* is set to *NoAction*.
- (e) For control type *CycleOnAnyHeatingZone*, the manager checks the heating setpoint for the heating control zone or zone list and sets *AvailStatus* to *CycleOn*. If the *AvailStatus* is still *NoAction*, then the manager checks the heating setpoint for the heating zone fans only zone or zone list and sets *AvailStatus* to *CycleOnZoneFansOnly*). If none of these checks are true then *AvailStatus* is set to *NoAction*.
- (f) For control type *CycleOnAnyHeatingZoneFansOnly*, the manager checks the heating setpoint for the heating zone fans only zone or zone list and sets *AvailStatus* to *CycleOnZoneFansOnly*). If none of these checks are true then *AvailStatus* is set to *NoAction*.

4. Lastly if the new status is *CycleOn* the start time is reset to the current time and the stop time is reset. When this availability manager is specified for a zone component then the only allowed control types are *StayOff* and *CycleOnControlZone*.

18.5.6 Night Ventilation

The input object *AvailabilityManager:NightVentilation* is a manager that looks at indoor and outdoor conditions to see if night ventilation might be beneficial. In addition to being able to cycle the air system on, this manager can specify what the ventilation air flow rate should be. The inputs are:

- A manager applicability schedule;
- The name of the fan schedule this manager will override;
- A ventilation temperature schedule;
- A ventilation delta T;
- A ventilation low limit temperature;
- The night ventilation flow fraction;
- The name of the control zone.

If the fan schedule current value is > 0 or the applicability schedule value is ≤ 0 or if the program is in warmup, *AvailStatus* = *NoAction*.

Otherwise, the manager performs 3 limit checks.

1. If for all the zones connected to the air loop the room temperature at the thermostat of any zone is greater than the ventilation temperature schedule value, this check is true.

2. If for all the zones connected to the air loop the room temperature at the thermostat of any zone is less than the ventilation low limit temperature, this check is true.
3. If the difference between the control zone room temperature at the thermostat and the outside temperature is greater than the specified night venting delta T, this check is true.

If 1) and 3) are true and 2) is false, the status is set to *CycleOn*; otherwise the status is *NoAction*. If the status is *CycleOn* this manager sets some additional values in the *AirLoopControlInfo* data structure (a flag is set to indicate night ventilation is occurring and a flag is set to indicate that the air system flow rate has been specified by a manager) and in the *AirLoopFlow* data structure (the system flow fraction is specified). The night ventilation flag indicates to the fan that it should use alternate performance characteristics if they have been specified in a *FanPerformance:NightVentilation* object.

18.5.7 Differential Thermostat

The input object *AvailabilityManager:DifferentialThermostat* is a manager that overrides fan or pump schedules depending on the temperature difference between two nodes. A typical use would be for one node to be an outdoor air node and the other a zone node. The inputs are:

- name of the hot node;
- name of the cold node;
- temperature difference for turning the system on (ΔT_{on});
- temperature difference for turning the system off (ΔT_{off}).

As shown by the following pseudo code, there is no applicability schedule for this manager. Also, this manager always returns a status of *CycleOn* or *ForceOff*, never *NoAction*.

```

 $\Delta T = T_{hot\ node} - T_{cold\ node}$ 
If  $\Delta T \geq \Delta T_{on}$  then
     $AvailStatus = CycleOn$ 
Else if  $\Delta T \leq \Delta T_{off}$  then
     $AvailStatus = ForceOff$ 
Else
     $AvailStatus$  remains in its previous state.
End If

```

18.5.8 High Temperature Turn Off

The input object *AvailabilityManager:HighTemperatureTurnOff* is used to turn off a central air system or a plant loop if a sensed node temperature exceeds a temperature limit. The inputs are:

- name of the sensed node;
- limit temperature (T_u).

In pseudo code:

If $T_{sensed\ node} \geq T_u$ then

$AvailStatus = ForceOff$

Else

$AvailStatus = NoAction$

End If

18.5.9 High Temperature Turn On

The input object AvailabilityManager:HighTemperatureTurnOn is used to turn on a central air system or a plant loop if a sensed node temperature exceeds a temperature limit. The inputs are:

- name of the sensed node;
- limit temperature (T_u).

In pseudo code:

If $T_{sensed\ node} \geq T_u$ then

$AvailStatus = CycleOn$

Else

$AvailStatus = NoAction$

End If

18.5.10 Low Temperature Turn Off

The input object AvailabilityManager:LowTemperatureTurnOff is used to turn off a central air system or a plant loop if a sensed node temperature is lower than a temperature limit. The inputs are:

- name of the sensed node;
- limit temperature (T_l);
- applicability schedule name.

If the applicability schedule exists and has a current value of ≤ 0 , the manager returns an availability status of *NoAction*.

Otherwise, as shown by the following pseudo code:

If $T_{sensed\ node} \leq T_l$ then

$AvailStatus = ForceOff$

Else

$AvailStatus = NoAction$

End If

18.5.11 Low Temperature Turn On

The input object `AvailabilityManager:LowTemperatureTurnOn` is used to turn on a central air system or a plant loop if a sensed node temperature is less than a temperature limit. The inputs are:

- name of the sensed node;
- limit temperature (T_l).

In pseudo code:

```
If  $T_{sensed\ node} \leq T_l$  then
    AvailStatus = CycleOn
Else
    AvailStatus = NoAction
End If
```

18.5.12 Hybrid Ventilation Control

The input object `AvailabilityManager:HybridVentilation` serves two purposes: 1) it prevents simultaneous natural ventilation and HVAC system operation, and 2) it allows users to examine various strategies to maximize natural ventilation in order to reduce heating/cooling loads. This availability manager works with either the `AirflowNetwork` model or the simple airflow objects to provide controlled natural ventilation. The controlled natural ventilation objects referred to here are either `AirflowNetwork:Multizone:ComponentDetailedOpening` and `AirflowNetwork:Multizone:ComponentSimpleOpening` objects, or `ZoneVentilation` and `ZoneMixing` objects. The simple airflow objects are not allowed to work with the `AirflowNetwork` objects simultaneously. If there is no air loop, this availability manager can still be applied to controlled zone specified in the object. In order to apply hybrid ventilation manager to the controlled zone not served by any air loop, the HVAC air loop name input field must be left blank. Currently, zone component objects such as unit heater, unit ventilator, packaged terminal air conditioner, packaged terminal heat pump, zone water source heat pump, window air conditioner, variable refrigerant flow, energy recovery ventilator, outdoor air unit, fan coil unit, and ventilated slab can individually use hybrid ventilation managers to make a decision regarding whether their fan should be on or off. Also, hybrid ventilation manager can be applied to zones served by the ideal load zone component to turn them off when natural ventilation is active. Currently, hybrid ventilation manager is restricted to one per zone. It can either be applied through the air loop or directly to the zone. If hybrid ventilation manager is applied to an air loop and one of the zones served by the air loop also has hybrid ventilation manager, then zone hybrid ventilation manager is disabled. This availability manager performs somewhat differently from the other availability managers:

- This availability manager is called before the program estimates (predicts) the cooling or heating load that needs to be met by the cooling/heating systems for the simulation time step. On the other hand, the other availability managers are called after the system cooling/heating load prediction. The main reason for calling `AvailabilityManager:HybridVentilation` early is that this manager determines whether natural ventilation is allowed or not, and the loads from natural ventilation are used to predict system loads.

- This availability manager has its own control schedule and does not work in tandem with *AvailabilityManager:Scheduled*.
- *AvailabilityManager:HybridVentilation* works completely independent of the other system availability managers, so this manager is not a valid system availability manager type in the *AvailabilityManagerAssignmentList* object.

18.5.12.1 Control Logic

The control logic for each ventilation control mode is described below.

18.5.12.2 Temperature Control

This control mode checks whether the outdoor air dry-bulb temperature is between the Minimum Outdoor Temperature and Maximum Outdoor Temperature specified. If the outdoor temperature is between the two values then natural ventilation is allowed, else natural ventilation is not allowed.

When natural ventilation is allowed, the control then checks the temperature difference between the zone temperature and the temperature setpoint(s) in the controlled zone based on the specified temperature control type (four available temperature control types) to make a final decision:

Single Heating Setpoint:

If the zone temperature is below the setpoint, then the initial decision is overridden and natural ventilation is not allowed. This is intended to avoid overcooling a space, which could result in additional heating load.

Single Cooling Setpoint:

If the zone temperature is above the setpoint, then the initial decision is overridden and natural ventilation is not allowed. This is intended to avoid overheating a space, which could result in additional cooling load.

Single Heating Cooling Setpoint:

Since this temperature control type requires only a single setpoint, natural ventilation is not allowed. A recurring warning message is issued.

Dual Setpoint with DeadBand:

If the zone temperature is beyond the deadband, the initial decision is overridden and natural ventilation is not allowed. This is intended to avoid either overcooling a space, which could result in additional heating load when the zone temperature is below the heating setpoint, or overheating a space, which could result in additional cooling load when the zone temperature is above the cooling setpoint.

18.5.12.3 Enthalpy Control

This control mode checks whether the outdoor air enthalpy is between the Minimum Outdoor Enthalpy and Maximum Outdoor Enthalpy specified. If the outdoor enthalpy is between the two values then natural ventilation is allowed, else natural ventilation is not allowed.

When natural ventilation is allowed, the control then checks the temperature difference between the zone temperature and the temperature setpoint(s) in the controlled zone based on the specific temperature control type to make a final decision. This procedure is the same as defined above for the temperature control mode.

Single Heating Setpoint:

If the zone temperature is below the setpoint, then the initial decision is overridden and natural ventilation is not allowed. This is intended to avoid overcooling a space, which could result in additional heating load.

Single Cooling Setpoint:

If the zone temperature is above the setpoint, then the initial decision is overridden and natural ventilation is not allowed. This is intended to avoid overheating a space, which could result in additional cooling load.

Single Heating Cooling Setpoint:

Since this temperature control type requires only a single setpoint, natural ventilation is not allowed. A recurring warning message is issued.

Dual Setpoint with DeadBand:

If the zone temperature is beyond the deadband, then the initial decision is overridden and natural ventilation is not allowed. This is intended to avoid either overcooling a space, which could result in additional heating load when the zone temperature is below the heating setpoint, or overheating a space, which could result in additional cooling load when the zone temperature is above the cooling setpoint.

18.5.12.4 Dew-Point Control

This control mode checks whether the outdoor air dewpoint temperature is between the Minimum Outdoor Dew-Point and Maximum Outdoor Dew-Point specified. If the outdoor dewpoint temperature is between the two values then natural ventilation is allowed, else natural ventilation is not allowed.

When natural ventilation is allowed and a humidistat is available in the controlled zone, the control then checks the humidity ratio difference between the zone air humidity ratio and humidistat setpoint in the controlled zone to make a final decision. It should be pointed out that the humidistat object provides the setpoint of relative humidity, the value of relative humidity has to be converted into the setpoint of humidity ratio using the actual zone air temperature for comparison. Since the humidistat only provides a single value for relative humidity, there are two possible scenarios:

If the actual zone air humidity ratio is below the humidity ratio setpoint and the controlled zone needs humidification as the first scenario, then the initial decision is overridden and natural ventilation is not allowed. This is intended to avoid dehumidifying a space, which could result in additional humidification load.

If the actual zone air humidity ratio is above the humidity ratio setpoint and the controlled zone needs dehumidification as the second scenario, then the initial decision is overridden and natural ventilation is not allowed. This is intended to avoid humidifying a space, which could result in additional dehumidification load.

18.5.12.5 Operative Temperature Control with 80 Percent Acceptability Limits

This control mode checks whether the zone air operative temperature is between the lower and upper adaptive comfort 80% acceptability limits or not. If the zone air operative temperature is between the lower and upper limits, then natural ventilation is allowed, else natural ventilation is not allowed.

18.5.12.6 Operative Temperature Control with 90 Percent Acceptability Limits

This control mode checks whether the zone air operative temperature is between the lower and upper adaptive comfort 90% acceptability limits or not. If the zone air operative temperature is between the lower and upper limits, then natural ventilation is allowed, else natural ventilation is not allowed.

18.5.12.7 CO2 Control

This control mode checks whether the zone air CO2 concentration level is above the CO2 setpoint or not. If the zone air CO2 concentration level is above the setpoint, the control checks availability of HVAC system. If available, The available status will be ForceOn. If not available, natural ventilation will be allowed.

18.5.12.8 Outdoor Ventilation Air Control

This control mode does not require any additional checks. The control only works with Airflow Network opening objects only, and is not allowed to work with ZoneVentilation and ZoneMixing objects.

18.5.12.9 Availability Status

After the hybrid ventilation control determines whether natural ventilation is allowed or not, the availability status flag is set as follows:

```
If Natural Ventilation then
    AvailStatus = CycleOn
Else
    AvailStatus = ForceOn
End If
```

18.5.13 Optimum Start Controls

18.5.13.1 Overview

Optimum start is often also referred to as optimum recovery time. Commercial buildings are often operated intermittently by lowering heating set-point and increasing cooling set-point during unoccupied period. The building should return to set-point just before occupancy period starts. Therefore it is important to start the operation of heating and cooling plant before building is occupied. If the operation is started too early before the occupants return, energy is wasted. If it is started too late the occupants will be uncomfortable. An optimum start time for operation will save energy without compromising comfort.

In practice a few proprietary algorithms are used to predict this start time value for preheating and precooling operation. ASHRAE Handbook refers to work done by (Seem, Armstrong, & Hancock, 1989) which compares seven different equations and suggests a set of equations for preheating and precooling time prediction.

Figure 18.41: Optimal Start Control

18.5.13.2 Algorithms

There are a few algorithms to predict the start time for the HVAC system. Among these algorithms following are the promising ones that can be implemented in a simulation environment.

18.5.13.3 Constant Start Time

This is the simplest format of the optimum start algorithm. The HVAC system will start the HVAC system at a fixed number of hours before occupancy as specified by the user.

18.5.13.4 Constant Temperature Gradient

In practice most of the HVAC control manufacturers use a temperature gradient as a thermal capacity factor, in which temperature rise per unit time i.e. °C/hour is measured for the unoccupied building and then the difference between space temperature and set-point temperature is divided by this factor to calculate the actual number of hours before occupancy are needed to start the HVAC system.

18.5.13.5 Adaptive Temperature Gradient

Adaptive control is used to modify the temperature gradient depending on the time required to meet the set-point on the prior days. The adaptive algorithm takes the arithmetic average of the actual temperature gradients calculated for the specified number of previous days.

18.5.13.6 Adaptive ASHRAE Algorithm

The equations suggested in the ASHRAE Handbook are used in combination with a recursive linear least square method to determine the optimum start/recovery time empirically. Depending on heating or cooling operation the start time is categorized as preheating or precooling time. According to (Seem, Armstrong, & Hancock, 1989) the preheating time is a strong function of outdoor temperature whereas precooling time is not strong function of outdoor temperature if space temperature is close or less than the setback temperature. Thus, two different equations are suggested for preheating and precooling time.

For precooling time:

$$t_i = a_0 + a_1 T_{z,i} + a_2 T_{z,i}^2 \quad (18.405)$$

For preheating time:

$$t_i = a_0 + (1 - w_i) (a_1 T_{z,i} + a_2 T_{z,i}^2) + w_i a_3 T_{o,i} \quad (18.406)$$

where, on i^{th} day:

t_i is the start/recovery time

$T_{z,i}$ is the zone temperature

$T_{o,i}$ is the outdoor temperature

w_i is a weighting factor which determines weighting given to outside and zone temperature:

$$w_i = 1000^{-\frac{(T_{z,i} - T_{unocc})}{(T_{occ} - T_{unocc})}} \quad (18.407)$$

where T_{unocc} and T_{occ} are setpoint temperatures during unoccupied (setback) and occupied periods, respectively.

Coefficients a_0 , a_1 , a_2 (and a_3) are separately calculated for heating and cooling operation and are updated from the optimum times from last three days thus; these coefficients carry history and adapt the trend from previous days.

The optimum time for past days is determined using:

$$t_{opt,(i-1)} = k_{(i-1)} \Delta t - \Delta t \left(1 - \frac{q_{(i-1)}}{q_{max}} \right) \quad (18.408)$$

where:

k are the time steps required for recovery

Δt is the time-step

$t_{opt,(i-1)}$ is the recovery time on $(i-1)^{th}$ day

$q_{(i-1)}$ is the energy extracted or added during last time step

q_{max} is the maximum capacity of the equipments.

Chapter 19

Simulation Models – Encyclopedic Reference

The following descriptions are grouped alphabetically (as much as possible) with some also having additional tags of “Heat Balance”, “HVAC”, and “Plant”. With the integrated solution, these designations signify where the effects of these models have their first impacts.

Main Sections:

- Thermal Comfort
- Trombe Walls
- Water Thermal Tanks
- Water Systems
- Zone Controls
- Zone Equipment and Zone Forced Air Units

19.1 Occupant Thermal Comfort

The integration of a sophisticated building thermal analysis tool with thermal comfort models allows one to perform an energy analysis on a zone and simultaneously determine if the environmental control strategy will be sufficient for the occupants to be thermally comfortable. This section is intended to provide background on thermal comfort, present an overview of state of the art thermal comfort models, and present the mathematical models that have been incorporated into EnergyPlus.

Thermal comfort modeling in EnergyPlus is controlled primarily by the People input object. This includes input for selecting the type of thermal comfort model that is desired by the user as well as parameters that serve as inputs to the thermal comfort models. These parameters include the activity level, the work efficiency, the air velocity and the clothing insulation level for people within the space. All four of these parameters can be scheduled. More information on the People input object can be found in the EnergyPlus Input/Output Reference. More information on how each of these parameters is used and the specific modeling equations for the thermal comfort models can be found below.

19.1.1 Background on Thermal Comfort Models

Throughout the last few decades, researchers have been exploring the thermal, physiological and psychological response of people in their environment in order to develop mathematical models to predict these responses. Researchers have empirically determined building occupants' thermal responses to the combined thermal effect of the personal, environmental and physiological variables that influence the condition of thermal comfort.

There are two personal variables that influence the condition of thermal comfort: the thermal resistance of the clothing (I_{cl}), and the metabolic rate (H/A_{Du}).

The thermal resistance of the clothing (I_{cl}) is measured in units of “clo.” The 1985 ASHRAE Handbook of Fundamentals (ASHRAE 1985) suggests multiplying the summation of the individual clothing items clo value by a factor of 0.82 to determine the overall clo value for clothing ensembles.

The metabolic rate (H/A_{Du}) is a measure of the internal heat production rate of an occupant (H) in W/hr per unit of “Dubois” body surface area (A_{Du}) in units of m^2 . The DuBois body surface area is given by:

$$A_{Du} = 0.202(weight)^{0.425}(height)^{0.725} \quad (19.1)$$

Using this equation, an area of $1.8 m^2$ represents the surface area of an average person of weight 70 kg and height 1.73 m (Fanger 1967). In EnergyPlus, this average person area of $1.8 m^2$ is used for the body surface area all thermal comfort models. The metabolic rate is measured in mets, where $1 \text{ met} = 58.2 \text{ W}/m^2$.

The environmental variables that influence the conditions of thermal comfort include:

- (1) Air Temperature (T_a),
- (2) Mean Radiant Temperature (T_r),
- (3) Relative air velocity (v),
- (4) Water vapor pressure in ambient air (P_a).

The Air Temperature (T_a), a direct environmental index, is the dry-bulb temperature of the environment. It is calculated using either the mean air temperature for the zone in question or the air temperature calculated by some of the more detailed zone air models available in EnergyPlus. The Mean Radiant Temperature (T_r) is a rationally derived environmental index defined as the uniform black-body temperature that would result in the same radiant energy exchange as in the actual environment. This value can be calculated in several ways as outlined in the Mean Radiant Temperature Calculation section later in this document. The Relative air velocity (v) a direct environmental index is a measure of the air motion obtainable via a hot wire or vane anemometers. The Water vapor pressure in ambient air (P_a) is a direct environmental index.

The physiological variables that influence the conditions of thermal comfort include:

- (1) Skin Temperature (T_{sk}),
- (2) Core or Internal Temperature (T_{cr}),
- (3) Sweat Rate,
- (4) Skin Wettedness (w),

- (5) Thermal Conductance (K) between the core and skin.

where the Skin Temperature (T_{sk}), the Core Temperature (T_{cr}) and the Sweat Rate are physiological indices. The Skin Wettedness (w) is a rationally derived physiological index defined as the ratio of the actual sweating rate to the maximum rate of sweating that would occur if the skin were completely wet.

One more consideration is important in dealing with thermal comfort - the effect of asymmetrical heating or cooling. This could occur when there is a draft or when there is a radiant flux incident on a person (which is what is of primary interest to us here). Fanger (1967) noted that the human regulatory system is quite tolerant of asymmetrical radiant flux. A reasonable upper limit on the difference in mean radiant temperature (T_r) from one direction to the opposing direction is 15°C . (ASHRAE 1984). This limit is lower if there is a high air velocity in the zone.

Table 19.1: General Nomenclature list for Thermal Comfort Models

Mathematical variable	Description	Units	Range	Source Variable	Code
A_{Du}	Dubois body surface area	m^2	-	-	
H	Internal heat production rate of an occupant per unit area = $M - W$	W/m^2	-	IntHeatProd	
I_{cl}	Thermal resistance of the clothing	clo	-	CloUnit	
M	Metabolic rate per unit area	W/m^2	-	ActLevel	
P_a	Water vapor pressure in ambient air	Torr	-	VapPress	
T_a	Air temperature	$^\circ\text{C}$	-	AirTemp	
T_{cr}	Core or internal temperature	$^\circ\text{C}$	-	CoreTemp	
T_r	Mean radiant temperature	$^\circ\text{C}$	-	RadTemp	
T_{sk}	Skin temperature	$^\circ\text{C}$	-	-	
v	Relative air velocity	m/s	-	AirVel	
W	The rate of heat loss due to the performance of work	W/m^2	-	WorkEff	
w	Skin wettedness	-	-	-	

19.1.2 Mathematical Models for Predicting Thermal Comfort

Many researchers have been exploring ways to predict the thermal sensation of people in their environment based on the personal, environmental and physiological variables that influence thermal comfort. From the research done, some mathematical models that simulate occupants' thermal response to their environment have been developed. Most thermal comfort prediction models use a

seven or nine point thermal sensation scale, as in the following tables.

Table 19.2: Seven point Thermal Sensation Scale

Sensation	Description
3	Hot
2	Warm
1	slightly warm
0	neutral
-1	slightly cool
-2	cool
-3	cold

Table 19.3: Nine point Thermal Sensation Scale

Sensation Value	Description
4	very hot
3	hot
2	warm
1	slightly warm
0	neutral
-1	slightly cool
-2	cool
-3	cold
-4	very cold

The most notable models have been developed by P.O. Fanger (the Fanger Comfort Model), the J. B. Pierce Foundation (the Pierce Two-Node Model), and researchers at Kansas State University (the KSU Two-Node Model). Berglund (1978) presents a detailed description of the theory behind these three models.

Note for all Thermal Comfort reporting: Though the published values for thermal comfort “vote” have a discrete scale (e.g. -3 to $+3$ or -4 to $+4$), the calculations in EnergyPlus are carried out on a continuous scale and, thus, reporting may be “off the scale” with specific conditions encountered in the space. This is not necessarily an error in EnergyPlus – rather a different approach that does not take the “limits” of the discrete scale values into account.

The main similarity of the three models is that all three apply an energy balance to a person and use the energy exchange mechanisms along with experimentally derived physiological parameters to predict the thermal sensation and the physiological response of a person due to their environment. The models differ somewhat in the physiological models that represent the human passive system (heat transfer through and from the body) and the human control system (the neural control of

shivering, sweating and skin blood flow). The models also differ in the criteria used to predict thermal sensation. However, all three models use information from the People statement and the thermal comfort model is selected via the People statement in a user's input file. Scheduled parameters such as the activity level, work efficiency, air velocity, and clothing insulation level all have a direct bearing on the thermal comfort models. For more information on the input of these parameters, see the People statement in the EnergyPlus Input/Output Reference. For more information on how each individual thermal comfort model uses these parameters, please consult the next several sections.

19.1.3 Fanger Comfort Model

Fanger's Comfort model was the first human comfort model that was developed. It was first published in 1967 (Fanger 1967), then updated in 1970 (Fanger 1970), and helped set the stage for the Pierce and KSU models. The mathematical model developed by P.O. Fanger is probably the most well known of the three models and is the easiest to use because it has been put in both chart and graph form.

19.1.3.1 Fanger Model Nomenclature List

Table 19.4: Nomenclature list for Fanger model

Mathematical variable	Description	Units	Range	Source Variable	Code
A_{Du}	Dubois body surface area	m^2	-	BodySurfaceArea	
C_{res}	The rate of dry respiratory heat loss	W/m^2	-	DryRespHeatLoss	
E_{dif}	The rate of heat loss from the diffusion of water vapor through the skin	W/m^2	-	EvapHeatLossDiff	
E_{res}	The rate of latent respiratory heat loss	W/m^2	-	LatRespHeatLoss	
$E_{rsw,req}$	The rate of heat loss from the evaporation of regulatory sweating at the state of comfort	W/m^2	-	EvapHeatLossRegComf	
E_{sk}	Total evaporative heat loss from skin	W/m^2		EvapHeatLoss	
f_{cl}	The ratio of clothed body	-		CloBodyRat	
f_{eff}	The fraction of surface effective for radiation (= 0.72)	-	-	RadSurfEff	
H	Internal heat production rate of an occupant per unit area (= $M - W$)	W/m^2	-	IntHeatProd	

Table 19.4: Nomenclature list for Fanger model

Mathematical variable	Description	Units	Range	Source Variable	Code
h_c	Convective heat transfer coefficient	$W/m^2-^{\circ}C$	-	Hc	
L	All the modes of energy loss from body	W/m^2	-	-	
M	Metabolic rate per unit area	W/m^2	-	ActLevel	
P_a	Water vapor pressure in ambient air	Torr	-	VapPress	
PMV	Predicted Mean Vote	-	(-4)-4	PMV	
PPD	Predicted Percentage of Dissatisfied	-	0-100	PPD	
Q_c	The rate of convective heat loss	W/m^2	-	ConvHeatLoss	
Q_{dry}	Sensible heat flow from skin	W/m^2		DryHeatLoss	
Q_r	The rate of radiative heat loss	W/m^2	-	RadHeatLoss	
Q_{res}	The rate of respiratory heat loss	W/m^2	-	RespHeatLoss	
T_a	Air temperature	$^{\circ}C$	-	AirTemp	
T_{cl}	Clothing surface temperature	$^{\circ}C$	-	CloSurfTemp	
T_{cla}	Clothing surface temperature (Absolute)	K	-	AbsCloSurfTemp	
T_{ra}	Mean radiant temperature	K	-	AbsRadTemp	
W	The rate of heat loss due to the performance of work	W/m^2	-	WorkEff	
ε	The emissivity of clothing-skin surface	-	-	SkinEmiss	
σ	The Stefan-Boltzman constant (= 5.67×10^{-8})	W/m^2K^4	-	StefanBoltz	

19.1.3.2 Description of the model and algorithm

Fanger developed the model based on the research he performed at Kansas State University and the Technical University of Denmark. Fanger used the seven-point form of a thermal sensation scale along with numerous experiments involving human subjects in various environments. He related the subjects' response to various environmental variables which influence the condition of thermal comfort. Fanger's model is based upon an energy analysis that takes into account all the modes of energy loss (L) from the body, including: the convection and radiant heat loss from the outer

surface of the clothing, the heat loss by water vapor diffusion through the skin, the heat loss by evaporation of sweat from the skin surface, the latent and dry respiration heat loss and the heat transfer from the skin to the outer surface of the clothing. The model assumes that the person is thermally at steady state with the interior environment.

$$M = L \quad (19.2)$$

$$L = Q_{res} + Q_{dry} + E_{sk} \quad (19.3)$$

$$Q_{res} = E_{res} + C_{res} = 0.000017M(5867 - P_a) + 0.0014M(34 - T_a) \quad (19.4)$$

In the EnergyPlus source code, Q_{res} , E_{res} and C_{res} are calculated using the following equations, respectively:

$$\begin{aligned} \text{RespHeatLoss} &= \text{LatRespHeatLoss} + \text{DryRespHeatLoss} \\ \text{LatRespHeatLoss} &= 0.000017 * \text{ActLevel} * (5867. - \text{VapPress}) \\ \text{DryRespHeatLoss} &= 0.0014 * \text{ActLevel} * (34. - \text{AirTemp}) \end{aligned}$$

$$Q_{dry} = Q_c + Q_r \quad (19.5)$$

$$Q_c = h_c \times f_{cl}(T_{cl} - T_a) \quad (19.6)$$

$$Q_r = 3.96 * f_{cl} * [(0.01 * T_{cl})^4 - (0.01 * T_a)^4] \quad (19.7)$$

In the EnergyPlus source code, Q_{dry} , Q_c and Q_r are calculated using the following equations, respectively:

$$\begin{aligned} \text{DryHeatLoss} &= \text{ConvHeatLoss} + \text{RadHeatLoss} \\ \text{ConvHeatLoss} &= \text{CloBodyRat} * h_c * (\text{CloSurfTemp} - \text{AirTemp}) \\ \text{RadHeatLoss} &= 3.96 * \text{CloBodyRat} * [(0.01 * \text{AbsCloSurfTemp})^4 - (0.01 * \text{AbsRadTemp})^4] \end{aligned}$$

$$E_{rsu} = 0.42(H - 58.2) \quad \text{for } (H > 58.2) \quad (19.8)$$

$$E_{rsu} = 0 \quad \text{for } (H \leq 58.2) \quad (19.9)$$

$$E_f = 0.00305 * (5733.0 - 6.99H - P_a) \quad (19.10)$$

$$E_{sk} = E_{rsu} + E_{diff} \quad (19.11)$$

In the EnergyPlus source code, E_{rsu} , E_f and E_{sk} are calculated using the following equations, respectively:

$$\begin{aligned} \text{EvapHeatLossRegComf} &= 0.42 * (\text{IntHeatProd} - \text{ActLevelConv}) \text{ or } 0.0 \text{ depending on } H \text{ value} \\ \text{EvapHeatLossDiff} &= 0.00305 * (5733.0 - 6.99 * \text{IntHeatProd} - \text{VapPress}) \\ \text{EvapHeatLoss} &= \text{EvapHeatLossRegComf} + \text{EvapHeatLossDiff} \end{aligned}$$

The Fanger model was developed using the thermal sensation votes from subjects at KSU and in Denmark, and the Predicted Mean Vote (PMV) thermal sensation scale is based on how the energy loss (L) deviates from the metabolic rate (M) in the following form:

$$PMV = (0.303e^{-0.036M} + 0.028)(H - L) \quad (19.12)$$

In the EnergyPlus source code, PMV is calculated using the following equations in conjunction with the equations shown above:

$$PMV = ThermSensTransCoef * (IntHeatProd - EvapHeatLoss - RespHeatLoss - DryHeatLoss)$$

$$ThermSensTransCoef = 0.303 * EXP(-0.036 * ActLevel) + 0.028$$

$$IntHeatProd = ActLevel - WorkEff$$

Predicted Percent of Dissatisfied (PPD) people at each PMV is calculated as follows:

$$PPD = 100.0 - 95.0 * EXP(-0.03353PMV^4 - 0.2179PMV^2) \quad (19.13)$$

19.1.4 Pierce Two-Node Model

The Pierce Two-Node model was developed at the John B. Pierce Foundation at Yale University. The model has been continually expanding since its first publication in 1970 (Gagge et.al. 1970). The most recent version on the model appears in the 1986 ASHRAE Transactions (Gagge et.al. 1986).

19.1.4.1 Pierce Two-Node Model Nomenclature List

Table 19.5: Nomenclature list for Pierce Two-Node model

Mathematical variable	Description	Units	Range	Source Variable	Code
C_{dil}	Constant for skin blood flow			SkinBloodFlowConst

19.1.4.2 Description of the model and algorithm

The Pierce model thermally lumps the human body as two isothermal, concentric compartments, one representing the internal section or core (where all the metabolic heat is assumed to be generated) and the other representing the skin. This allows the passive heat conduction from the core compartment to the skin to be taken into account. The boundary line between the two compartments changes with the skin blood flow rate per unit skin surface area (SKBF in L/h • m²) and is described by α – the fraction of total body mass attributed to the skin compartment (Doherty and Arens 1988).

$$\alpha = 0.0417737 + 0.7451832 / (SKBF + 0.585417) \quad (19.14)$$

In the EnergyPlus code, α or SkinMassRat is calculated using the equivalent equation:

$$\text{SkinMassRat} = 0.0417737 + 0.7451832 / (\text{SkinBloodFlow} + 0.585417)$$

Furthermore, the model takes into account the deviations of the core, skin, and mean body temperature weighted by alpha from their respective setpoints. Thermoregulatory effector mechanisms (regulatory sweating, skin blood flow, and shivering) are defined in terms of thermal signals from the core, skin and body in °C (Doherty and Arens 1988) by the following equations:

$$SIG_{cr} = T_{cr} - 36.8 \quad (19.15)$$

$$SIG_{sk} = T_{sk} - 33.7 \quad (19.16)$$

$$SIG_b = T_b - 36.49 \quad (19.17)$$

In the EnergyPlus code, when SkinTemp is greater than SkinTempSet (33.7°C), then SkinThermSigWarm = SkinTemp - SkinTempSet and SkinThermSigCold = 0.0. Otherwise, when SkinTemp is less than or equal to SkinTempSet, then SkinThermSigWarm = 0.0 and SkinThermSigCold = SkinTempSet - SkinTemp.

In the EnergyPlus code, when CoreTemp is greater than CoreTempSet (36.8°C), then CoreThermSigWarm = CoreTemp - CoreTempSet and CoreThermSigCold = 0.0. Otherwise, when CoreTemp is less than or equal to CoreTempSet, then CoreThermSigWarm = 0.0 and CoreThermSigCold = CoreTempSet - CoreTemp.

In the EnergyPlus code, when AvgBodyTemp is greater than AvgBodyTempSet (36.49°C), then BodyThermSigWarm = AvgBodyTemp - AvgBodyTempSet and BodyThermSigCold = 0.0. Otherwise, when AvgBodyTemp is less than or equal to AvgBodyTempSet, then BodyThermSigWarm = 0.0 and BodyThermSigCold = AvgBodyTempSet - AvgBodyTemp.

The skin blood flow rate in L/hr·m² is calculated using:

$$SKBF = (6.3 + C_{dil} \times SIG_{cr}) / (1 + S_{tr} \times (SIG_{sk})) \quad (19.18)$$

In the EnergyPlus code, this equation is calculated using the following equations:

$$\text{SkinBloodFlow} = (6.3 + \text{VasodilationFac}) / (1. + \text{VasoconstrictFac})$$

$$\text{VasodilationFac} = \text{SkinBloodFlowConst} * \text{CoreWarmDelTemp}$$

$$\text{VasoconstrictFac} = \text{Str} * \text{SkinColdDelTemp}$$

The rate of regulatory sweating in g/hr·m² is calculated using:

$$SW_{reg} = C_{sw} SIG_b e^{(SIG_{sk}/10.7)} \quad (19.19)$$

and the shivering response in W/m² is calculated using:

$$M_{shiv} = 19.4(SIG_{cr})(SIG_{sk}) \quad (19.20)$$

In the EnergyPlus code, the sweat and shivering response determined by the above two equations are calculated using the follow expressions:

$$\text{RegSweat} = \text{SweatContConst} * \text{BodyThermSigWarm} * \text{EXP}(\text{SkinThermSigWarm}/10.7)$$

$$\text{ShivResponse} = 19.4 * \text{SkinThermSigCold} * \text{CoreThermSigCold}$$

The latest version of the Pierce model (Fountain and Huizenga 1997) discusses the concepts of SET* and ET*. The Pierce model converts the actual environment into a “standard environment” at a Standard Effective Temperature, SET*. SET* is the dry-bulb temperature of a hypothetical environment at 50% relative humidity for subjects wearing clothing that would be standard for the given activity in the real environment. Furthermore, in this standard environment, the same physiological strain, i.e. the same skin temperature, skin wettedness and heat loss to the environment, would exist as in the real environment. The Pierce model also converts the actual environment into an environment at an Effective Temperature, ET*, that is the dry-bulb temperature of a hypothetical

environment at 50% relative humidity and uniform temperature ($T_a = \text{MRT}$) where the subjects would experience the same physiological strain as in the real environment.

In the latest version of the model, it is suggested that the classical Fanger PMV be modified by using ET* or SET* instead of the operative temperature. This gives a new index PMV* which is proposed for dry or humid environments. It is also suggested that PMV* is very responsive to the changes in vapor permeation efficiency of the occupants clothing.

$$M = M_{act} + M_{shiv} \quad (19.21)$$

which in the EnergyPlus code takes on the form $\text{ActLevel} = \text{ActLevel} + \text{ActShiv}$.

$$L = Q_{res} + Q_{dry} + E_{sk} + W \quad (19.22)$$

$$\begin{aligned} Q_{res} &= E_{res} + C_{res} = 0.0023M(44 - P_a(\text{torr})) + 0.0014M(34 - T_a) \\ Q_{res} &= 0.017251M(5.8662 - P_a(\text{kPa})) + 0.0014M(34 - T_a) \end{aligned} \quad (19.23)$$

In the EnergyPlus code, the calculation of Q_{res} or RespHeatLoss is accomplished using the following equations:

$$\begin{aligned} \text{RespHeatLoss} &= \text{LatRespHeatLoss} + \text{DryRespHeatLoss} \\ \text{LatRespHeatLoss} &= 0.017251 * \text{ActLevel} * (5.8662 - \text{VapPress}) \\ \text{DryRespHeatLoss} &= 0.0014 * \text{ActLevel} * (34 - \text{AirTemp}) \end{aligned}$$

$$Q_{dry} = Q_c + Q_r \quad (19.24)$$

$$Q_c = h_c \times f_{cl}(T_{cl} - T_a) \quad (19.25)$$

$$Q_r = h_r \times f_{cl}(T_{cl} - T_r) \quad (19.26)$$

Q_{dry} or DryHeatLoss is calculated in the EnergyPlus code using the following equation:

$$\text{DryHeatLoss} = \text{CloBodyRat} * (\text{Hc} * (\text{CloSurfTemp} - \text{AirTemp}) + \text{Hr} * (\text{CloSurfTemp} - \text{RadTemp}))$$

In Pierce model, the convective heat transfer coefficient, h_c , varies with the air velocity around body and metabolic rate. The model uses the maximum value of following equations:

$$h_c = 8.6 \times v^{0.53} \quad (19.27)$$

$$h_c = 5.66(M/58.2 - 0.85)^{0.39} \quad (19.28)$$

In the EnergyPlus code, the following equations are used to calculate h_c or Hc:

$\text{Hc} = 8.6 * \text{AirVel}^{0.53}$ where AirVel is reset to 0.137 if it drops below this value

$\text{HcAct} = 5.66 * (\text{ActMet} - 0.85)^{0.39}$ when ActMet is greater than 0.9

When ActMet is greater than 0.9, EnergyPlus uses the larger value of Hc and HcAct for h_c .

Also, in the model, the radiant heat transfer coefficient, h_r , is defined by following equation (Doherty and Arens 1988):

$$h_r = 4. \times f_{eff} \varepsilon \sigma ((T_{cl} + T_r)/2 + 273.15)^3 \quad (19.29)$$

In the EnergyPlus code, h_r or Hr is calculated using the following equation:

$H_r = 4 \cdot \text{RadSurfEff} \cdot \text{StefanBoltz} \cdot ((\text{CloSurfTemp} + \text{RadTemp})/2. + \text{TAbsConv})^{**3}$

In the Pierce model, T_{cl} in °C is estimated by each iteration using following equation:

$$T_{cl} = (T_{sk}/I_{cl} + f_{cl}(h_c T_a + h_r T_r)) / (1/I_{cl} + f_{cl}(h_c + h_r)) \quad (19.30)$$

Or as shown in the EnergyPlus code:

$\text{CloSurfTemp} = (\text{CloCond} \cdot \text{SkinTemp} + \text{CloBodyRat} \cdot (\text{Hc} \cdot \text{AirTemp} + \text{Hr} \cdot \text{RadTemp})) / (\text{CloCond} + \text{CloBodyRat} \cdot (\text{Hc} + \text{Hr}))$

The total evaporative heat loss from the skin, E_{sk} , includes evaporation of water produced by regulatory sweating, E_{rsw} , and evaporation of water vapor that diffuses through the skin surface, E_{diff} .

$$E_{sk} = E_{rsw} + E_{diff} \quad (19.31)$$

$$E_{rsw} = 0.68 \times SW_{reg} \quad (19.32)$$

$$E_{diff} = w_{diff} \times E_{max} \quad (19.33)$$

Within the EnergyPlus source code, these equations are shown as:

$\text{EvapHeatLoss} = \text{EvapHeatLossRegSweat} + \text{EvapHeatLossRegDiff}$

$\text{RegHeatLoss} = 0.68 \cdot \text{RegSweat}$

$\text{DiffHeatLoss} = \text{SkinWetDiff} \cdot \text{MaxEvapHeatLoss}$

where 0.68 is the passive water vapor diffusion rate in $\text{g/h} \cdot \text{m}^2 \cdot \text{Torr}$ and

$$w_{diff} = 0.06(1 - w_{rsw}) \quad (19.34)$$

$$E_{max} = h_e'(P_{sk} - P_a) \quad (19.35)$$

$$w_{rsw} = E_{rsw}/E_{max} \quad (19.36)$$

These equations within the EnergyPlus source code appear as:

$\text{SkinWetDiff} = .06 \cdot (1 - \text{SkinWetSweat})$

$\text{MaxEvapHeatLoss} = (1./\text{TotEvapHeatResist}) \cdot (\text{SatSkinVapPress} - \text{VapPress})$

$\text{SkinWetSweat} = \text{EvapHeatLossRegSweat}/\text{MaxEvapHeatLoss}$

The Pierce model has one additional heat flow term describing the heat transfer between the internal core compartment and the outer skin shell (Doherty and Arens 1988).

$$Q_{crsk} = (5.28 + 1.163SKBF)(T_{cr} - T_{sk}) \quad (19.37)$$

or as shown in the EnergyPlus source code:

$\text{HeatFlow} = (\text{CoreTemp} - \text{SkinTemp}) \cdot (5.28 + 1.163 \cdot \text{SkinBloodFlow})$

where 5.28 is the average body tissue conductance in $\text{W/m}^2 \cdot \text{K}$ and 1.163 is the thermal capacity of blood in $\text{W} \cdot \text{h/L} \cdot \text{K}$.

Thus, individual heat balance equations for core and skin compartments are expressed using this term, Q_{c-s} . New temperatures of core, skin and body are calculated for each iteration from rates of heat storage in the core and skin.

$$S_{sk} = Q_{c-s} - Q_c - Q_r - E_{sk} \quad (19.38)$$

$$S_{cr} = M - W - Q_{res} - Q_{c-s} \quad (19.39)$$

These equations are represented by the following source code lines in EnergyPlus:

SkinHeatStorage = HeatFlow - DryHeatLoss - EvapHeatLoss

CoreHeatStorage = IntHeatProd - RespHeatLoss - HeatFlow

As a result, PMV evaluated for ET* and SET* can be calculated using:

$$PMVET = (0.303e^{-0.036M} + 0.028)(H - L_{ET*}) \quad (19.40)$$

$$PMVSET = (0.303e^{-0.036M} + 0.028)(H - L_{SET*}) \quad (19.41)$$

These equations are represented by the following lines of source code in EnergyPlus:

ThermSensTransCoef = 0.303*EXP(-0.036*ActLevel) + 0.028

PMVET = ThermSensTransCoef*(IntHeatProd - EvapHeatLossDiff - EvapHeatLossRegComf
- RespHeatLoss - DryHeatLossET)

PMVSET = ThermSensTransCoef*(IntHeatProd - EvapHeatLossDiff
- EvapRegHeatLossRegComf - RespHeatLoss - DryHeatLossSET)

Besides PMV*, the Pierce Two Node Model uses the indices TSENS and DISC as predictors of thermal comfort. Where TSENS is the classical index used by the Pierce foundation and is a function of the mean body temperature. DISC is defined as the relative thermoregulatory strain that is needed to bring about a state of comfort and thermal equilibrium. DISC is a function of the heat stress and heat strain in hot environments and equal to TSENS in cold environments. In summary, the Pierce Model, for our purposes, uses four thermal comfort indices; PMVET—a function of ET*, PMVSET—a function of SET*, TSENS and DISC.

$$T_{b-c} = (0.185/58.2)(M - W) + 36.313 \quad (19.42)$$

$$T_{b-h} = (0.359/58.2)(M - W) + 36.664 \quad (19.43)$$

When $T_b \leq T_{b-c}$, TSENS is calculated using:

$$TSENS_c = 0.68175(T_b - T_{b-c}) \quad (19.44)$$

Otherwise, when $T_b > T_{b-c}$, TSENS is calculated using:

$$TSENS_h = 4.7(T_b - T_{b-c})/(T_{b-h} - T_{b-c}) \quad (19.45)$$

Finally, DISC is calculated using the following equation:

$$DISC = 5.(E_{rsw} - E_{rsw-comf})/(E_{max} - E_{rsw-comf} - E_{diff}) \quad (19.46)$$

These final equations for the Pierce Two Node Model are calculated using the following lines of source code:

AvgBodyTempLow = (0.185/ActLevelConv)*IntHeatProd + 36.313

AvgBodyTempHigh = (0.359/ActLevelConv)*IntHeatProd + 36.664

$$\begin{aligned}
\text{TSENS} &= .68175 * (\text{AvgBodyTemp} - \text{AvgBodyTempLow}) \\
\text{TSENS} &= 4.7 * (\text{AvgBodyTemp} - \text{AvgBodyTempLow}) / (\text{AvgBodyTempHigh} - \text{AvgBodyTempLow}) \\
\text{DISC} &= 5. * (\text{EvapHeatLossRegSweat} - \text{EvapHeatLossRegComf}) \\
&\quad / (\text{MaxEvapHeatLoss} - \text{EvapHeatLossRegComf} - \text{DiffHeatLoss})
\end{aligned}$$

19.1.5 KSU Two-Node Model

The KSU Two-Node Model, developed at Kansas State University, was published in 1977 (Azer and Hsu 1977). The KSU model is quite similar to that of the Pierce Foundation. The main difference between the two models is that the KSU model predicts thermal sensation (TSV) differently for warm and cold environment.

19.1.5.1 KSU Two Node Model Nomenclature List

Table 19.6: Nomenclature list for KSU Two-Node model

Mathematical variable	Description	Units	Range	Source Variable	Code
C_{cr}	Specific heat of body core	W-hr/kg°C			
C_{sk}	Specific heat of skin	W-hr/kg°C			
C_{res}	The rate of dry respiratory heat loss	W/m ²	-	DryRespHeatLoss	
E_{dif}	The rate of heat loss from the diffusion of water vapor through the skin	W/m ²	-	EvapHeatLossDiff	
E_{max}	Maximum evaporative heat loss	W/m ²		EvapHeatLossMax	
E_{sk}	Total evaporative heat loss from skin	W/m ²		EvapHeatLoss	
E_{sw}	Equivalent evaporation heat loss from the sweat secreted	W/m ²		EvapHeatLossSweat	
$E_{sw.d}$	Sweat function for warm and dry skin	W/m ²		EvapHeatLossDrySweat	
E_{res}	The rate of latent respiratory heat loss	W/m ²	-	LatRespHeatLoss	
F_{cl}	The Burton thermal efficiency factor for clothing		-	CloThermEff	
F_{pcl}	Permeation efficiency factor for clothing		-	CloPermeatEff	

Table 19.6: Nomenclature list for KSU Two-Node model

Mathematical variable	Description	Units	Range	Source Variable	Code
H	Internal heat production rate of an occupant per unit area = $M - W$	W/m ²	-	IntHeatProd	
H	Combined heat transfer coefficient	W/m ² -°C		H	
h_c	Convective heat transfer coefficient	W/m ² -°C	-	Hc	
h_r	Radiant heat transfer coefficient	W/m ² -°C	-	Hr	
KS	Overall skin thermal conductance	W/m ² -°C		ThermCndct	
KS_o	Skin conductance at thermal neutrality	W/m ² -°C		ThermCndctNeut	
KS_{-4}	Skin conductance at thermal sensation very cold	W/m ² -°C		ThermCndctMin	
M	Metabolic rate per unit area	W/m ²	-	ActLevel	
M_{shiv}	Metabolic heat production due to shivering	W/m ²		ShivResponse	
P_a	Water vapor pressure in ambient air	Torr	-	VapPress	
P_{sk}	Saturated water vapor pressure at required skin temperature	Torr	-	SatSkinVapPress	
PT_{accl}	The pattern of acclimation			AcclPattern	
Q_c	The rate of convective heat loss	W/m ²	-	ConvHeatLoss	
Q_{dry}	Sensible heat flow from skin	W/m ²		DryHeatLoss	
Q_r	The rate of radiative heat loss	W/m ²	-	RadHeatLoss	
Q_{res}	The rate of respiratory heat loss	W/m ²	-	RespHeatLoss	
RH	Relative humidity			RelHum	
T_a	Air temperature	°C	-	AirTemp	
T_{cr}	Core or internal temperature	°C	-	CoreTemp	
T_o	Operative temperature	°C	-	OpTemp	
T_r	Mean radiant temperature	°C	-	RadTemp	

Table 19.6: Nomenclature list for KSU Two-Node model

Mathematical variable	Description	Units	Range	Source Variable	Code
T_{sk}	Skin temperature	$^{\circ}\text{C}$		SkinTemp	
TSV	Thermal sensation vote		(-4)-4	TSV	
V	Relative air velocity	m/s	-	AirVel	
W	The rate of heat loss due to the performance of work	W/m^2	-	WorkEff	
w	Skin wettedness	-	-	SkinWetTot	
W_{cr}	Mass of body core per unit body surface	kg/m^2		-	
W_{rsw}	Skin wettedness due to regulatory sweating			SkinWetSweat

W_{sk}	Mass of skin per unit body surface	kg/m^2		-	

19.1.5.2 Description of the model and algorithm

The KSU Two-Node Model is based on the changes that occur in the thermal conductance between the core and the skin temperature in cold environments. In warm environments, the thermal conductance of the model is based on changes in the skin wettedness.

In this model, metabolic heat production is generated in the core which exchanges energy with the environment by respiration, and the skin exchanges energy with the interior environment by convection and radiation. In addition, body heat is dissipated through the evaporation of sweat and/or water vapor diffusion through the skin. These principles are outlined in the following system of equations.

$$W_{cr}C_{cr}dT_{cr}/dt = M - W - Q_{res} - KS(T_{cr} - T_{sk}) \quad (19.47)$$

$$W_{sk}C_{sk}dT_{sk}/dt = KS(T_{cr} - T_{sk}) - Q_{dry} - E_{sk} \quad (19.48)$$

where Q_{res} and Q_{dry} are calculated using:

$$Q_{res} = E_{res} + C_{res} = 0.0023M(44 - P_a(\text{torr})) + 0.0014M(34 - T_a) \quad (19.49)$$

$$Q_{dry} = Q_c + Q_r = hf_{cl}F_{cl}(T_{sk} - T_o) \quad (19.50)$$

The calculation of Q_{res} (RespHeatLoss) and Q_{dry} (DryHeatLoss) in the source code are accomplished through the following equations:

$$\text{RespHeatLoss} = \text{LatRespHeatLoss} + \text{DryRespHeatLoss}$$

$$\text{LatRespHeatLoss} = 0.0023 * \text{ActLevelTot} * (44. - \text{VapPress})$$

DryRespHeatLoss = 0.0014*ActLevelTot*(34. - AirTemp)

DryHeatLoss = H*CloBodyRat*CloThermEff*(SkinTemp - OpTemp)

In the equation for Q_{dry} , h and T_o are calculated using:

$$h = h_c + h_r \quad (19.51)$$

$$h_c = 8.3\sqrt{v} \quad (19.52)$$

$$h_r = \epsilon_{avg}(3.87 + 0.031T_r) \quad (19.53)$$

$$T_o = (h_c T_a + h_r T_r) / (h_c + h_r) \quad (19.54)$$

These equations are represented by the following source code equations:

H = Hc + Hr

Hc = 8.3*SQRT(AirVel) where AirVel is reset to 0.137 if it drops below this value

Hr = EmissAvg*(3.87 + 0.031*RadTemp)

OpTemp = (Hc*AirTemp + Hr*RadTemp)/H

In the KSU Two-Node Model, evaporative heat losses are defined by these equations:

$$For (E_{sw} \leq E_{max}), E_{sk} = E_{sw} + (1 - w_{rsw})E_{diff} \quad (19.55)$$

$$For (E_{sw} > E_{max}), E_{sk} = E_{max} \quad (19.56)$$

$$E_{diff} = 0.408(P_{sk} - P_a) \quad (19.57)$$

$$E_{max} = 2.2h_c F_{pcl}(P_{sk} - P_a) \quad (19.58)$$

These equations are shown in the EnergyPlus source code as:

EvapHeatLoss = SkinWetSweat*EvapHeatLossMax+(1. - SkinWetSweat)*EvapHeatLossDiff

SkinWetSweat = EvapHeatLossDrySweat/EvapHeatLossMax

EvapHeatLossDiff = 0.408*(SkinVapPress - VapPress)

EvapHeatLossMax = 2.2*Hc*(SkinVapPress - VapPress)*CloPermeatEff

Here, control signals, based on setpoint temperatures in the skin and core, are introduced into the system of equations, and these equations are integrated numerically for small time increments or small increments in core and skin temperature. The control signals modulate the thermoregulatory mechanism and regulate the peripheral blood flow, the sweat rate, and the increase of metabolic heat by active muscle shivering. The development of the controlling functions of skin conductance (KS), sweat rate (E_{sw}), and shivering (M_{shiv}) is based on their correlation with the deviations in skin and core temperatures from their setpoints.

$$KS = 5.3 + \frac{[6.75 + 42.45 (T_{cr} - 36.98) + 8.15 (T_{cr} - 35.15)^{0.8} (T_{sk} - 33.8)]}{1 + 0.4 (32.1 - T_{sk})} \quad (19.59)$$

$$E_{sw} = \phi \frac{[260 (T_{cr} - 36.9) + 26 (T_{sk} - 33.8)] \exp [(T_{sk} - 33.8) / 8.5]}{1.0 + 0.05 (33.37 - T_{sk})^{2.4}} \quad (19.60)$$

$$M_{shiv} = 20(36.9 - T_{cr})(32.5 - T_{sk}) + 5(32.5 - T_{sk}) \quad (19.61)$$

where $\phi = 1.0$ for $w \leq 0.4$ and when $w > 0.4$:

$$\phi = 0.5 + 0.5 \exp[-5.6(w - 0.4)] \quad (19.62)$$

Within EnergyPlus, these variables are calculated using the following source code equations:

SkinCndctDilation = 42.45*CoreSignalWarmMax+8.15*CoreSignalSkinSens**0.8*SkinSignalWarmMax

SkinCndctConstriction = 1.0 + 0.4*SkinSignalColdMax

ThermCndct = 5.3+(6.75+SkinCndctDilation)/SkinCndctConstriction

WeighFac = 260.+70.*AcclPattern where the pattern of acclimation is assumed to be zero in the equation for E_{sw} above

SweatCtrlFac = 1. + 0.05*SkinSignalSweatColdMax**2.4

EvapHeatLossDrySweat = ((WeighFac*CoreSignalSweatMax+0.1*WeighFac*SkinSignalSweatMax)*EXP(SkinSignalSweatMax/8.5))/SweatCtrlFac

SweatSuppFac = 1. for $w \leq 0.4$

SweatSuppFac = 0.5 + 0.5*EXP(-5.6*SkinWetSignal) for $w > 0.4$

ShivResponse = 20.*CoreSignalShivMax*SkinSignalShivMax + 5.*SkinSignalShivMax

In the KSU model, two new parameters are introduced and used in correlating thermal sensations with their associated physiological responses. Instead of correlating warm thermal sensations with skin wettedness, it is correlated with a wettedness factor defined by:

$$\varepsilon_{wsw} = (w_{rsw} - w_{rsw-o}) / (1.0 - w_{rsw-o}) \quad (19.63)$$

where:

$$w_{wsw} = E_{sw} / E_{max} \quad (19.64)$$

$$w_{rsw-o} = 0.2 + 0.4\{1.0 - \exp[-0.6(H/58.2 - 1.0)]\} \quad (19.65)$$

The wettedness factor is calculated using the following EnergyPlus equations:

SkinWetFac = (SkinWetSweat - SkinWetNeut)/(1. - SkinWetNeut)

SkinWetSweat = DrySweatRate/EvapHeatLossMax

SkinWetNeut = 0.02 + 0.4*(1.-EXP(-0.6*(IntHeatProdMetMax - 1.)))

In addition, instead of correlating cold thermal sensation with the skin temperature in the KSU model, it is correlated with a factor identified as vasoconstriction factor defined by:

$$\varepsilon_{vc} = (KS_o - KS) / (KS_o - KS_{(-4)}) \quad (19.66)$$

or in the source code:

VasoconstrictFac=(ThermCndctNeut-ThermCndct)/(ThermCndctNeut-ThermCndctMin)

Thus, for a cold environment, TSV is a function of a vasoconstriction factor (ε_{vc}):

$$TSV = -1.46 \times \varepsilon_{vc} + 3.75 \times \varepsilon_{vc}^2 - 6.17 \times \varepsilon_{vc}^3 \quad (19.67)$$

and for the warm environments, TSV is defined as:

$$TSV = [5.0 - 6.56(RH - 0.5)] \times \varepsilon_{wsw} \quad (19.68)$$

In EnergyPlus, these two equations for TSV in cold and warm environments, respectively, show up as:

$$\text{TSV} = -1.46153 \cdot \text{VasoconstrictFac} + 3.74721 \cdot \text{VasoconstrictFac}^2 - 6.168856 \cdot \text{VasoconstrictFac}^3$$

$$\text{TSV} = (5. - 6.56 \cdot (\text{RelHum} - 0.50)) \cdot \text{SkinWetFac}$$

The KSU model's TSV was developed from experimental conditions in all temperature ranges and for clo levels between 0.05 clo and 0.7 clo and for activities levels ranging from 1 to 6 mets (Berglund 1978).

Adaptive Comfort Model

Adaptive comfort model, intended for use in naturally ventilated buildings, determines the acceptability of indoor conditions given the monthly mean outdoor air temperature and the indoor operative temperature. This is used as an index for occupant adaptation to outdoor conditions, and determines the acceptability of indoor conditions. The model also accounts for people's clothing adaptation in naturally conditioned spaces by relating the acceptable range of indoor temperatures to the outdoor climate, so it is not necessary to estimate the clothing values for the space. No humidity or air-speed limits are required when this option is used. This section summarizes the adaptive comfort models based on the ASHRAE Standard 55-2010 and CEN 15251. Details are available in the two standards.

Adaptive Comfort Model Based on ASHRAE Standard 55-2010

In ASHRAE Standard 55, the monthly mean outdoor air temperature, used in the adaptive comfort model, is defined as the simple running average of the previous thirty daily average outdoor air temperatures.

The model defines two comfort regions: 80% Acceptability, and 90% Acceptability. If the monthly mean outdoor air temperature is not within the specified domain of 10.0 to 33.5C, the model is not applicable.

The central line of the model (shown in red), or comfort temperature, is defined as

$$T_{ot} = 0.31 \cdot T_o + 17.8 \quad (19.69)$$

where:

T_{ot} is the operative temperature (°C), calculated as the average of the indoor air dry-bulb temperature and the mean radiant temperature of zone inside surfaces

T_o is the monthly mean outdoor air dry-bulb temperature (°C).

If the .stat file is provided for the simulation, T_o is drawn directly from the daily average temperatures in the .stat file, which provides a value for each month. If no .stat file is provided, the monthly mean outdoor temperature is a simple running average of the previous thirty daily average temperatures, calculated directly from the weather file (.epw):

$$T_o = \frac{(T_{od-1} + T_{od-2} + \dots + T_{od-30})}{30} \quad (19.70)$$

$$T_o = (1 - \alpha) \cdot T_{od-1} + \alpha \cdot T_{od-1} \quad (19.71)$$

$$\alpha = \frac{29}{30} \quad (19.72)$$

T_{od-i} is defined as the daily average temperature of the i^{th} previous day.

Figure 19.1: Acceptable operative temperature ranges for naturally conditioned spaces (ASHRAE Standard 55-2010)

Note that the weather file must be a standard .epw containing a full year of data.

The comfort regions for 80% and 90% acceptability are symmetric about the central line.

For 90% Acceptability Limits:

$$T_{ot} = 0.31 * T_o + 17.8 \pm 2.5 \quad (19.73)$$

80% Acceptability Limits:

$$T_{ot} = 0.31 * T_o + 17.8 \pm 3.5 \quad (19.74)$$

If, using either method, T_o is less than 10°C or greater than 33.5°C , the model is not applicable.

For a detailed description of this model, please see *ASHRAE Standard 55-2010, Thermal Environmental Conditions for Human Occupancy*.

19.1.6 Adaptive Comfort Model Based on European Standard EN15251-2007

The EN15251-2007 is similar to ASHRAE 55-2010, but with slightly different curves of the indoor operative temperature and acceptability limits (Fig. 2). The model, intended for use in naturally ventilated buildings, determines the acceptability of indoor conditions given the 7-day weighted mean outdoor air temperature and the indoor operative temperature. The 7-day weighted mean outdoor air temperature (T_{rm}) is defined as the weighted running average of the previous 7 daily average outdoor air temperatures.

This weighted running average is calculated from a full annual weather file that must be specified for the simulation. This is used as an index for occupant adaptation to outdoor conditions, and

determines the acceptability of indoor conditions. The model also accounts for people's clothing adaptation in naturally conditioned spaces by relating the acceptable range of indoor temperatures to the outdoor climate, so it is not necessary to estimate the clothing values for the space. No humidity or air-speed limits are required when this option is used. The model defines three comfort regions: Category I (90%) Acceptability, Category II (80%) Acceptability, and Category III (65%) Acceptability. If T_{rm} is not within the specified domain of 10.0 to 30.0C, the model is not applicable.

Cat	Explanation
I	High level of expectation and is recommended for spaces occupied by very sensitive and fragile persons with special requirements like handicapped, sick, very young children and elderly persons
II	Normal level of expectation and should be used for new buildings and renovations
III	An acceptable, moderate level of expectation and may be used for existing buildings
IV	Values outside the criteria for the above categories. This category should only be accepted for a limited part of the year

Figure 19.2: Categories for European Standard EN15251-2007

For the central line (shown as red in Figure 19.3):

$$T_{ot} = 0.33 * T_o + 18.8 \quad (19.75)$$

For Category I, 90% Acceptability Limits:

$$T_{ot} = 0.33 * T_o + 18.8 \pm 2.0 \quad (19.76)$$

For Category II, 80% Acceptability Limits:

$$T_{ot} = 0.33 * T_o + 18.8 \pm 3.0 \quad (19.77)$$

For Category III, 65% Acceptability Limits:

$$T_{ot} = 0.33 * T_o + 18.8 \pm 4.0 \quad (19.78)$$

Figure 19.3: Acceptable operative temperature ranges for naturally conditioned spaces (CEN EN15251-2007)

For $10^{\circ}\text{C} < T_{rm} < 15^{\circ}\text{C}$, the comfort temperature of the lower boundaries of the comfort regions is $T_{comf} = 23.75^{\circ}\text{C}$. That is, the lower boundaries are constant according to the same ranges above:

For Category I, 90% Acceptability Limits:

$$T_{ot} = 23.75 - 2.0 \quad (19.79)$$

For Category II, 80% Acceptability Limits:

$$T_{ot} = 23.75 - 3.0 \quad (19.80)$$

For Category III, 65% Acceptability Limits:

$$T_{ot} = 23.75 - 4.0 \quad (19.81)$$

where:

T_{ot} is the operative temperature calculated as the average of the indoor air dry-bulb temperature and the mean radiant temperature of zone inside surfaces ($^{\circ}\text{C}$)

T_o is the mean outdoor air dry-bulb temperature ($^{\circ}\text{C}$), calculated as the weighted mean of the previous 7-day daily mean outdoor air dry-bulb temperature (T_{od}) using:

$$T_o = (1 - \alpha) * \{T_{od-1} + \alpha * T_{od-2} + \alpha^2 * T_{od-3} + \alpha^3 * T_{od-4} + \alpha^4 * T_{od-5} + \alpha^5 * T_{od-6} + \alpha^6 * T_{od-7}\} \quad (19.82)$$

$$T_o = (1 - \alpha) * T_{od-1} + \alpha * T_{o-1} \quad (19.83)$$

$$\alpha = 0.8 \quad (19.84)$$

19.1.7 Dynamic Clothing Model

In most building energy simulations, thermal comfort condition is calculated based on the assumption that the clothing insulation is equal to a constant value of 0.5 clo during the cooling season and 1.0 clo during heating season. Usually those two values are used and the change from 0.5 to 1 or vice-versa is made suddenly from one day to another. In addition, there is no standardized guideline on how to set clothing insulation schedules in the international standards. This simplified assumption may lead to systems that are incorrectly sized and operated and to the incorrect assessment of comfort conditions. In reality, occupants frequently adjust their clothing depending on the thermal conditions around them, as opposed to the assumption of constant clothing values. Therefore, the clothing insulation variation should be captured during the building simulation to realistically model HVAC systems. In order to overcome the limitations of the constant clothing insulation assumption, three new predictive clothing insulation models were developed by Schiavon and Lee (2012) based on 6,333 selected observations taken from ASHRAE RP-884 and RP-921 databases. The first and third models vary the clothing insulation as a function of outdoor air temperature measured at 6 o'clock and the second model takes into account both 6 o'clock outdoor air temperature and indoor operative temperature when adjusting the clothing insulation. The dynamic clothing models should be implemented in dynamic building energy simulation.

The model proposed to ASHRAE 55 is described below.

For $t_{a(out,6)} < -5^{\circ}\text{C}$:

$$I_{cl} = 1.00 \quad (19.85)$$

For $-5^{\circ}\text{C} \leq t_{a(out,6)} < 5^{\circ}\text{C}$:

$$I_{cl} = 0.818 - 0.0364 * t_{a(out,6)} \quad (19.86)$$

For $5^{\circ}\text{C} \leq t_{a(out,6)} < 26^{\circ}\text{C}$:

$$I_{cl} = 10^{(-0.1635 - 0.0066 * t_{a(out,6)})} \quad (19.87)$$

Or for $t_{a(out,6)} \geq 26^{\circ}\text{C}$:

$$I_{cl} = 0.46 \quad (19.88)$$

where I_{cl} is the clothing insulation value and $t_{a(out,6)}$ is the outdoor air temperature measured at 6 o'clock in the morning. Figure 19.5 illustrates the proposed clothing insulation model.

In Figure 19.4, clothing insulation schedule for a fixed model (blue) typically used in energy simulation software and for the clothing model based on outdoor air temperature measured at 6 o'clock. Climate data for Chicago O'hare International Airport has been used.

The dynamic predictive clothing insulation model is implemented into EnergyPlus for realistic energy simulation. Addenda A to ASHRAE 55 with the clothing model has been approved by the ASHRAE committee and the chance to be included in ASHRAE 55-2013 is high.

19.1.8 Mean Radiant Temperature Calculation

There are three options to calculate mean radiant temperature in the thermal comfort models. One is the zone averaged MRT, another is the surface weighted MRT, and the other is angle factor MRT. The zone averaged MRT is calculated on the assumption that a person is in the center of a space, whereas the surface weighted MRT is calculated in consideration of the surface that a person is closest to, and the angle factor MRT is calculated based on angle factors between a person and the different surfaces in a space. Here, the surface weighted MRT is the average temperature of the selected surface and zone averaged MRT for the remaining surfaces in the zone and is intended to represent conditions in the limit as a person gets closer and closer to a particular surface. In that limit, half of the person's radiant field will be dominated by that surface and the other half will be exposed to the rest of the zone. Note that the surface weighted MRT is only an approximation. The angle factor MRT is the mean temperature of the surrounding surface temperatures weighted according to the magnitude of the respective angle factors and allows the user to more accurately predict thermal comfort at a particular location within a space.

Table 19.7: Nomenclature and variable list for MRT calculation

Mathematical variable	Description	Units	Range
T_r	Mean radiant temperature	°C	-
T_{r-avg}	Zone averaged radiant temperature	°C	-
T_{surf}	Surface temperature	°C	-
F_{surf}	Angle factor between person and surface	-	0-1
A_{surf}	Area of the surface	m ²	-
ϵ_{surf}	Emissivity of the surface	-	-

19.1.8.1 Description of the model and algorithm

The radiant temperature for the "zone averaged" option is simply calculated from the zone mean radiant temperature (MRT) without weighting any surface temperature of the zone more than the standard MRT calculation.

$$T_r = T_{r-avg} \quad (19.89)$$

where the standard MRT is calculated using the following equation summed over all zone surfaces:

$$T_{r-avg} = \frac{\sum \epsilon_i A_i T_i}{\sum \epsilon_i A_i} \quad (19.90)$$

In the surface weighted option, the radiant temperature is the average temperature of the modified zone averaged MRT and the temperature of the surface that a person is closest to.

$$T_r = (T_{r-avg*} + T_{surf})/2 \quad (19.91)$$

where the modified zone averaged MRT is calculated the same way as the standard MRT except that the surface closest to the person is left out of the summation:

$$T_{r-avg*} = \frac{\sum \epsilon_{i*} A_{i*} T_{i*}}{\sum \epsilon_{i*} A_{i*}} \quad (19.92)$$

where when i is equal to the surface being used for weighting it is not included in either summation.

When the angle factor option is requested, the radiant temperature is the mean value of surrounding surface temperatures weighted by the surface emissivity, the size of the respective angle factors between a person and each surface, and the temperature to the fourth power for the surface.

$$T_r = \frac{\sum \epsilon_i F_i (T_i)^4}{\sum \epsilon_i F_i} \quad (19.93)$$

If all surfaces have the same emissivity that is close to unity, the emissivities in the above equation can be ignored. However, since this is not always the case, the emissivity terms must be included in the above equation. In addition, the temperatures to the fourth power in the above equation could be simplified to linear temperatures when the temperatures of the surfaces are fairly close. However, as these temperatures get further apart, this linear approximation becomes increasingly poor. As a result, since there is no guarantee that inside face surface temperatures will be close, the fourth order temperature terms are used to calculate the radiant temperature.

19.1.9 ASHRAE 55 Elevated Air Speed Cooling Effect Model

ASHRAE Standard 55-2017 Section 5.3 requires that the Elevated Air Speed Comfort Zone Method be used when average air speed v_a is greater than 0.10 m/s. The method provides cooling credit for elevated air velocity in the space. The method can be used to evaluate passive cooling technologies such as natural ventilation, ceiling fan, and portable fan.

19.1.9.1 Description of the model and algorithm

The Pierce Two-Node Standard Effective Temperature (SET) model is used to account for the cooling effect of air speeds greater than the 0.10 m/s. Specifically, for a given set of environmental and personal variables, including an elevated average air speed, an average air temperature t_a , and a mean radiant temperature t_r , the SET is first calculated. Then the average air speed v_a

is replaced by still air (0.1 m/s), and the average air temperature and radiant temperature are adjusted according to the cooling effect (CE). The CE of the elevated air speed is the value that, when subtracted equally from both the average air temperature and the mean radiant temperature, yields the same SET under still air as in the first SET calculation under elevated air speed.

The following is a formal description of this process. To define the CE, we assert that it satisfies the following:

$$SET(t_a, t_r, v_{elev}, *) = SET(t_a - CE, t_r - CE, v_{still}, *) \quad (19.94)$$

where t_a is the average air temperature, t_r is the mean radiant temperature, v_{elev} is the elevated average air speed, such that $v_{elev} > 0.1 \text{ m/s}$, v_{still} is the elevated average air speed ($v_{still} = 0.1 \text{ m/s}$). The other parameters (indoor air humidity, clothing, metabolic rate) that stay the same are denoted by “*”.

It should be noted that v_{elev} is the relative air velocity caused by body movement and not the air speed measured by the air velocity sensor. It can be calculate using the function below.

$$v_{elev} = \max(v_{measured}, v_{measured} + 0.3 * (met - 1)) \quad (19.95)$$

where met is the metabolic rate in [met].

The Cooling Effect adjusted PMV/PPD for an environment with elevated average air speed is calculated using the adjusted average air temperature, the adjusted radiant temperature, and still air (0.1 m/s). The following are equations to calculate the adjusted PMV and PPD.

$$PMV_{adj} = PMV(t_a - CE, t_r - CE, v_{still}, *) \quad (19.96)$$

$$PPD_{adj} = 100 - 95 * \exp(-0.03353 * PMV_{adj}^4 - 0.2179 * PMV_{adj}^2) \quad (19.97)$$

19.1.10 ASHRAE 55 Ankle Draft Risk Model

Draft is unwanted local cooling of the body caused by air movement. It is most prevalent when the whole-body thermal sensation is cool (below neutral). Draft sensation depends on air speed, air temperature, activity, and clothing. Sensitivity to draft is greatest where the skin is not covered by clothing, especially the head region comprising the head, neck, and shoulders and the leg region comprising the ankles, feet, and legs. Draft at the lower leg region may occur in the buildings conditioned by thermally stratified systems, such as displacement ventilation and underfloor air distribution, or with cold-dropping airflow along external walls and/or windows.

19.1.10.1 Description of the model and algorithm

The predicted percentage dissatisfied on draft at ankle level PPD_{AD} is used as the metric to evaluate the ankle draft risk as a function of PMV and air speed at the ankle level (0.1 m). The following is the equation to calculate PPD_{AD} .

$$PMV_{vr} = PMV(t_a, t_r, v_r, *) \quad (19.98)$$

$$PPD_{ad} = \frac{\exp(-2.58 + 3.05 * v_{ankle} - 1.06 * PMV_{vr})}{1 + \exp(-2.58 + 3.05 * v_{ankle} - 1.06 * PMV_{vr})} * 100 \quad (19.99)$$

Where v_r is the relative air velocity caused by body movement, and v_{ankle} is the air speed at 0.1 m above the floor.

This equation is only applicable for $v_r < 0.2 \text{ m/s}$. And the subject's metabolic rate and clothing level should be kept below 1.3 met and 0.7 clo, respectively. PPD at ankle draft will be set to -1.0 if these conditions are not met.

It should be noted that the metrics only measures the predicted percentage dissatisfied on the sensation of draft. PPD_{AD} levels at various air speeds and thermal sensations are depicted in Figure 19.6

Figure 19.6: Ankle Draft PPD Levels

19.2 Trombe Walls

Trombe walls are passive solar devices designed for thermal storage and delivery. It consists of a thick wall (150mm to 300mm) [8” to 16”] faced with a selective surface solar absorber, air gap, and high transmissivity glass pane. Trombe walls are usually South facing (in the Northern Hemisphere) for maximum sun exposure. An overhang above the wall is used to decrease exposure in the summer when the sun is high in the sky and heating is not required, yet still allows for full exposure in the winter when the sun is low in the sky and heating is desirable.

In EnergyPlus, there is no Trombe wall object per se; rather, it is composed of other existing EnergyPlus objects in the input file (except for a special key choice for Zone Inside Convection Algorithm in the Zone input object). This approach provides flexibility in specifying the various

wall parameters and allows the freedom to explore unusual configurations. On the other hand, this approach puts more of a burden on the user to be sure that all parts of the Trombe wall are correctly specified; otherwise unexpected results may be obtained.

To simulate the Trombe wall, a very narrow zone is coupled to the desired surface via an interzone partition. The depth of the zone corresponds to the size of the air space usually 18mm to 150mm ($\frac{3}{4}$ " to 6"). In most cases the Trombe zone will be a sealed zone with no ventilation. The exterior wall of the Trombe zone contains a single or double-pane window. Optimally, the window covers nearly all of the wall area and has a very high transmissivity to allow the maximum amount of solar flux into the Trombe zone. Frames and dividers can be defined as usual for the window. The interior wall is usually constructed of very thick masonry materials with a solar absorber surface as the innermost layer of the wall. The absorber is a selective surface material with very high absorptivity and very low emissivity, e.g. copper with a special black surface treatment. It is important to make sure the Solar Distribution field in the **Building** object is set to FullInteriorAndExterior so that the majority of the solar flux is directed on the absorber surface and not just on the very small area of the Trombe zone floor. The Zone Inside Convection Algorithm for the Trombe's Zone object should also be set to TrombeWall to correctly model the air space. As is the case for all interzone partitions, the wall construction of the adjoining zone must be the mirror image of the wall construction in the Trombe zone. Finally, an overhang is optionally attached to the Trombe zone to control the amount of seasonal sun exposure. Since the user selects all of the Trombe wall parameters in the input file, there is considerable freedom to experiment with different materials, sizes, and configurations.

Figure 19.7: Building with Trombe Wall

19.2.1 Passive Trombe Wall

Passive Trombe walls perform without the assistance of any additional mechanical equipment. Most Trombe walls are passive Trombe walls. They can be either sealed or naturally ventilated.

For a sealed or unvented Trombe wall, the *Zone Inside Convection Algorithm* field in the Zone object should be set to “TrombeWall”. This algorithm correctly calculates the convection coefficients for a narrow sealed vertical cavity based on the ISO 15099 standard. Refer to the “Trombe Wall Algorithm” subsection (under Interior Convection, above) for a complete description of the algorithm. The EnergyPlus modeling approach for the sealed passive Trombe wall has been validated with experimental data (Ellis 2003).

For a naturally ventilated Trombe wall, there is no built-in algorithm for calculating the correct convection coefficients on the inside of the cavity walls. One option is to use the “Detailed” convection algorithm. This algorithm takes into account some natural convection effects but is intended for a normal sized room. Therefore, some error may be incurred when used with a narrow cavity. Another option is to use the SurfaceProperty:ConvectionCoefficients object to schedule coefficients that have been determined beforehand by the user.

19.2.1.1 Input File

An input file (PassiveTrombeWall.idf) is provided to demonstrate a sample sealed Trombe wall implementation. In this file two separated fictional buildings are simulated for summer and winter design days in Zion, Utah. The buildings are identical in size and construction except that one has a Trombe wall and the other does not. The buildings have uncontrolled zones with no internal loads and heavy insulation. All floors use interzone partitions to disconnect them from the ground. The window on the Trombe zone is a 3 mm, low iron, single pane glazing with very high transmissivity (0.913 visible, 0.899 solar). The absorber surface is a Tabor solar absorber with an emittance of 0.05 and absorptance of 0.85.

19.2.1.2 Results

The resulting temperature profiles for winter and summer design days are plotted below.

19.2.1.3 References

Ellis, Peter G. 2003. *Development and Validation of the Unvented Trombe Wall Model in EnergyPlus*, Master’s Thesis, University of Illinois at Urbana-Champaign.

19.2.2 Active Trombe Wall

The active Trombe wall is the same as the passive Trombe wall with the addition of a simple fan system to circulate air between the Trombe zone and the main zone. The fan is scheduled to operate only during winter daylight hours to improve the heat transfer from the Trombe zone.

As with the passive Trombe wall, there is no EnergyPlus object for the active Trombe wall; it is simulated using a collection of other EnergyPlus objects. Like the passive Trombe wall, the active Trombe wall uses a narrow zone coupled to the main zone with interzone partitions. However, the unique part of the active Trombe wall is that the Trombe zone is used to define a zone supply plenum object which allows the Trombe zone to be integrated into the air system. A constant volume fan is the main component of the air system. To make the zone connections, the Direct Air component is used.

Figure 19.8: Passive Trombe Wall Winter

Figure 19.9: Passive Trombe Wall Summer

For the active Trombe wall, there is no built-in algorithm for calculating the correct convection coefficients due to forced convection on the inside of the cavity walls. One approach is to use the `SurfaceProperty:ConvectionCoefficients` object to schedule coefficients that have been determined beforehand by the user.

19.2.2.1 Input File

An input file (`ActiveTrombeWall.idf`) is provided to demonstrate a sample active Trombe wall implementation. The building and Trombe wall in this file are identical to the ones described above for `PassiveTrombeWall.idf`. However, this input file adds a system in the form of a low flow rate ($0.1 \text{ m}^3/\text{s}$) constant volume fan and the necessary duct connections. The fan is scheduled to operate October through March from 10 AM to 8 PM.

19.2.2.2 Results

The resulting temperature profile for the winter design day is plotted below. The plot for the summer design day is not shown because it is identical to Figure 19.9 above since the fan is not scheduled to operate in the summer.

19.3 Water Thermal Tanks (includes Water Heaters)

Water thermal tanks are devices for storing thermal energy in water. The most common types are water heaters, devices for storing and heating water. Typical water heater applications are for domestic hot water heating, low-temperature radiant space heating, and energy storage for solar hot water systems or waste heat recovery. In EnergyPlus, water heater objects can be coupled to a plant loop simulation or used stand-alone. There are also chilled water storage tanks that can be used to hold cold water.

19.3.1 Mixed Water Thermal Tank

The input object `WaterHeater:Mixed` provides a model that simulates a well-mixed water tank, i.e. non-stratified, and is appropriate for simulating many types of water heaters and storage tanks, including gas and electric residential water heaters, a variety of large commercial water heaters, and also instantaneous, tankless water heaters. This model is used for both the mixed water heater and the mixed chilled water storage tanks.

19.3.1.1 Energy Balance

The well-mixed assumption implies that all water in the tank is at the same temperature. To calculate the water temperature, the model analytically solves the differential equation governing the energy balance of the water tank:

$$\rho V c_p \frac{dT}{dt} = q_{net} \quad (19.100)$$

where:

ρ is the density of water

Figure 19.10: Active Trombe Wall Winter

V is the volume of the tank

c_p is the specific heat of water

T is the temperature of the tank water

t is the time

q_{net} is the net heat transfer rate to the tank water.

The density and volume can be replaced with the total mass m of water in the tank to get:

$$mc_p \frac{dT}{dt} = q_{net} \quad (19.101)$$

The net heat transfer rate q_{net} is the sum of gains and losses due to multiple heat transfer pathways.

$$q_{net} = q_{heater} + q_{oncyclepara} + q_{offcyclepara} + q_{oncycleloss} + q_{offcycleloss} + q_{use} + q_{source} \quad (19.102)$$

where:

q_{heater} is the heat added by the heating element or burner

$q_{oncyclepara}$ is the heat added due to on-cycle parasitic loads (zero when off)

$q_{offcyclepara}$ is the heat added due to off-cycle parasitic loads (zero when on)

$q_{oncycleloss}$ is the heat transfer to/from the ambient environment (zero when off)

$q_{offcycleloss}$ is the heat transfer to/from the ambient environment (zero when on)

q_{use} is the heat transfer to/from the use side plant connections

q_{source} is the heat transfer to/from the source side plant connections

$q_{oncycleloss}$ and $q_{offcycleloss}$ are defined as:

$$q_{oncycleloss} = UA_{oncycle}(T_{amb} - T) \quad (19.103)$$

$$q_{offcycleloss} = UA_{offcycle}(T_{amb} - T) \quad (19.104)$$

where:

$UA_{oncycle}$ is the on-cycle loss coefficient to ambient environment (zero when off)

$UA_{offcycle}$ is the off-cycle loss coefficient to ambient environment (zero when on)

T_{amb} is the temperature of ambient environment

q_{use} and q_{source} are defined as:

$$q_{use} = \varepsilon_{use} \dot{m}_{use} c_p (T_{use} - T) \quad (19.105)$$

$$q_{source} = \varepsilon_{source} \dot{m}_{source} c_p (T_{source} - T) \quad (19.106)$$

where:

ε_{use} is the heat exchanger effectiveness for the use side plant connections

\dot{m}_{use} is the mass flow rate for the use side plant connections

T_{use} is the inlet fluid temperature of the use side plant connections

ε_{source} is the heat exchanger effectiveness for the source side plant connections

\dot{m}_{source} is the mass flow rate for the source side plant connections

T_{source} is the inlet fluid temperature of the use side plant connections.

Incorporating all of these equations into the original differential equation:

$$mC_p \frac{dT}{dt} = q_{heater} + q_{oncyc} + q_{offcyc} + UA_{oncyc}(T_{amb} - T) + UA_{offcyc}(T_{amb} - T) + \varepsilon_{use}\dot{m}_{use}C_p(T_{use} - T) + \varepsilon_{source}\dot{m}_{source}C_p(T_{source} - T) \quad (19.107)$$

Associating terms not dependent on temperature T and terms dependent on temperature T yields:

$$\frac{dT}{dt} = \left[\frac{1}{mC_p} \left(q_{heater} + q_{oncyc} + q_{offcyc} + UA_{oncyc}T_{amb} + UA_{offcyc}T_{amb} + \varepsilon_{use}\dot{m}_{use}C_pT_{use} + \varepsilon_{source}\dot{m}_{source}C_pT_{source} \right) \right] + \left[\frac{-1}{mC_p} (UA_{oncyc} + UA_{offcyc} + \varepsilon_{use}\dot{m}_{use}C_p + \varepsilon_{source}\dot{m}_{source}C_p) \right] T \quad (19.108)$$

The differential equation now has the form:

$$\frac{dT}{dt} = a + bT \quad (19.109)$$

where:

$$a = \frac{1}{mC_p} \left(q_{heater} + q_{oncyc} + q_{offcyc} + UA_{oncyc}T_{amb} + UA_{offcyc}T_{amb} + \varepsilon_{use}\dot{m}_{use}C_pT_{use} + \varepsilon_{source}\dot{m}_{source}C_pT_{source} \right) \quad (19.110)$$

$$b = \frac{-1}{mC_p} (UA_{oncyc} + UA_{offcyc} + \varepsilon_{use}\dot{m}_{use}C_p + \varepsilon_{source}\dot{m}_{source}C_p) \quad (19.111)$$

The solution to the differential equation can be written in terms of a and b as:

$$T(t) = \left(\frac{a}{b} + T_i \right) e^{bt} - \frac{a}{b} \quad (19.112)$$

where

$T(t)$ = temperature of the tank water at time t

T_i = initial temperature of the tank water at time $t = 0$

However, if $b = 0$, the solution instead is:

$$T(t) = at + T_i \quad (19.113)$$

Since the control algorithm must sometimes calculate the time needed to reach a specified temperature, the equations above can also be rearranged to solve for t .

$$t = \frac{1}{b} \ln \left(\frac{a/b + T_f}{a/b + T_i} \right) \quad (19.114)$$

or, if $b = 0$:

$$t = \frac{T_f - T_i}{a} \quad (19.115)$$

where T_f is the final temperature of the tank water at time t .

In the special case where $b = 0$ and $a = 0$, and $T_f \neq T_i$, the time t is infinity.

19.3.1.2 Water Heater Control Algorithm

For water heaters, control options allow the heater to cycle or modulate to meet the load. When cycling, the heater element or burner is either on or off. The heater remains fully on while heating the tank up to the setpoint temperature. When the setpoint is reached, the heater turns off. The heater remains off until the tank temperature falls below the “cut-in” temperature, i.e., the setpoint temperature minus the deadband temperature difference. The heater continuously cycles on and off to maintain the tank temperature within the deadband. Most storage-tank water heaters cycle.

When modulating, the heater power varies between the maximum and minimum heater capacities. The heater stays on as long as the required total demand is above the minimum capacity. Below the minimum capacity, the heater will begin to cycle on and off based on the deadband temperature difference. Most tankless/instantaneous water heaters modulate.

Within a time step, the differential equation is solved separately for when the heater element or burner is “on” (on-cycle) and when it is “off” (off-cycle). This approach allows ambient losses and parasitic loads to be divided into on-cycle and off-cycle effects and accounted for in detail.

An illustration of how the control algorithm cycles on and off is shown below. Ambient losses cool the tank temperature until the bottom of the deadband is reached (50°C) at which point the heater cycles on and reheats the tank back to the setpoint (60°C). A water draw causes hot water to be replaced with cold water from the water mains. The incoming cold water rapidly cools the tank. In this example the heater cannot keep up with the water draw and the tank temperature continues to drop until the water draw ends.

Although the instantaneous tank water temperature may vary considerably within a timestep (due to cycling, etc.), only the average temperature over the timestep is reported. The model calculates the average by piece-wise integration of the area under the instantaneous temperature curve for each unique set of conditions. The instantaneous temperature is preserved internally by the program and is propagated from the end of one timestep to the beginning of the next.

19.3.1.3 Chilled Water Tank Control Algorithm

The input objects ThermalStorage:ChilledWater:Mixed and ThermalStorage:ChilledWater:Stratified provide chilled water tank models that do not include active cooling elements, there is only indirect cooling by remote devices such as a chiller. The tank’s setpoint controls are used to determine if flow is to be requested through the source side of the tank. The setpoint and deadband control scheme is similar to the water heater but the logic is flipped around for cooling instead of heating. The setpoint temperature is the “cut-out” temperature and the setpoint plus deadband is the “cut-in” temperature. If the tank temperature (or tank sensing node for stratified tanks) is above the “cut-in” temperature, then flow is requested. If temperatures are below the “cut-out” temperature, then flow is not requested. The chilled water tanks also have separate availability schedules for the use side and source side for additional control options.

19.3.1.4 Standard Ratings

For water heaters, the industry standard ratings of Recovery Efficiency and Energy Factor are calculated according to the 10CFR430 test procedure. To emulate the test procedure, a 24-hour simulation of the water heater is performed internally using the specified test conditions:

- Setpoint Temperature = 57.2°C (135°F)

Figure 19.11: Water Heater Cycle Control Algorithm

- Ambient Temperature = 19.7°C (67.5°F)
- Ambient Relative Humidity = 50% (used for heat pump water heaters)
- Inlet Temperature (Water Mains) = 14.4°C (58°F)

For heat pump water heaters, the water heater tank's heating element and water heater tank parasitic loads are disabled and the user-defined water heating capacity, energy use, and parasitic loads for the heat pump are used to calculate Recovery Efficiency and Energy Factor.

The simulated test procedure performs six equal draws of approximately 0.041 m³ (10.7 gal) in each of the first six hours of the simulation. Each draw occurs over the first timestep of the hour.

The Recovery Efficiency is calculated when the water heater recovers to the setpoint after the first draw.

$$RE = \frac{m_1 c_p (57.2 - 14.4)}{E_1} \quad (19.116)$$

where:

m_1 is the water mass of the first draw

c_p is the specific heat of water

E_1 is the fuel energy consumed until the setpoint is recovered (including parasitics).

Note: When the standards rating for a heat pump water heater is calculated, the fuel energy consumed refers to the total energy consumed by the heat pump compressor, evaporator fan, condenser pump, and parasitic loads. It is assumed that the parasitic loads for a heat pump water heater do not contribute to heating the water (ref. Heat Pump Water Heater).

The Energy Factor is calculated at the end of the 24-hour simulation period.

$$EF = \frac{m_{total} c_p (57.2 - 14.4)}{E_{total}} \quad (19.117)$$

where:

m_{total} is the total water mass of all six draws

c_p is the specific heat of water

E_{total} is the total fuel energy consumed over 24 hours (including parasitics).

Under certain input parameters, the rating method will not succeed and a warning message will be generated. Problems occur when inputs do not allow the tank to recover to the setpoint temperature within the test period. This can occur if the maximum heater capacity is undersized, or if the deadband temperature difference is large enough that the first draw of the test does not trigger the heater to come on. In either case, the Recovery Efficiency test will not compute properly because recovery to the setpoint was not achieved.

19.3.2 Heat Pump Water Heater

19.3.2.1 Overview

The input objects `WaterHeater:HeatPump:*` provide models for a heat pump water heater (HPWH) that is a compound object consisting of a water heater tank (e.g., `WaterHeater:Mixed` or `WaterHeater:Stratified`), a direct expansion (DX) “coil” (i.e., an air-to-water DX compression system which includes a water heating coil, air coil, compressor, and water pump), and a fan to provide air flow across the air coil associated with the DX compression system. These objects work together to model a system which heats water using zone air, outdoor air, or a combination of zone and outdoor air as the primary heat source.

There are two types of heat pump water heater models available:

1. `WaterHeater:HeatPump:PumpedCondenser`: This model is used to represent a heat pump water heater where water is removed from the tank, pumped through a condenser, and returned to the tank at a higher temperature.
2. `WaterHeater:HeatPump:WrappedCondenser`: This model is used for heat pump water heaters that are more typical in the residential building context where the heating coil is wrapped around or submerged in the tank.

Each type of `WaterHeater:HeatPump:*` object is compatible with certain `Coil:WaterHeating:AirToWaterHe` objects as shown in Table 19.8.

Table 19.8: Compatibility of Water Heater Objects

<code>WaterHeater:HeatPump:*</code>	<code>WaterHeater:*</code>
<code>PumpedCondenser</code>	<code>Pumped</code>
<code>PumpedCondenser</code>	<code>VariableSpeed</code>
<code>WrappedCondenser</code>	<code>Wrapped</code>

Additionally the `WaterHeater:HeatPump:WrappedCondenser` object is only compatible with stratified tanks. Therefore, `WaterHeater:HeatPump:*` has the tank compatibility as shown in Table 19.9.

<code>Wrapped</code>		X

Numerous configurations of tank location, inlet air source, and DX coil compressor location can be modeled. The DX coil compressor may be located in a zone, outdoors, or the ambient

temperature surrounding the compressor may be scheduled. The location of the compressor controls the operation of its crankcase heater. The water heater tank location is specified in the water heater tank object and is independent of the compressor location. In addition, the inlet air configuration may be specified in one of several ways. The heat pump water heater air coil and fan assembly may draw its inlet air from the zone and outdoor air using an optional mixer and splitter assembly as shown in the first figure below. When used, the mixer and splitter air streams are controlled by a single inlet air mixer schedule. When the HPWH draws its inlet air solely from a zone, the mixer/splitter assembly is not required as shown in the second figure below. In this case, the inlet air to the evaporator and fan assembly is made up entirely of zone air and the heat pump outlet air is directed back to the zone. The final figure illustrates a HPWH that draws its inlet air solely from outdoors and exhausts its outlet air outdoors as well. Each of these configurations may also be connected to a plant hot water loop (via the water heater tank use nodes).

Figure 19.12: Schematic of a heat pump water heater using optional mixer/splitter nodes

Note: The water heater tank location shown in the figures above is completely independent of the heat pump water heater's inlet air configuration and its compressor location. The water heater tank may be located outdoors, in a zone, or the ambient temperature surrounding the tank can be scheduled as described in the mixed water heater section below.

19.3.2.2 Model Description

The heat pump water heater input requires a compressor setpoint temperature schedule and dead band temperature difference, which are independent from the setpoint temperature schedule and dead band temperature difference for the heater (element or burner) associated with the water heater tank. The cut-in temperature for the heat pump compressor is defined as the heat pump compressor's setpoint temperature minus its dead band temperature difference.

Figure 19.13: Schematic of a Heat Pump Water Heater with Inlet Air from a Zone

Figure 19.14: Schematic of a Heat Pump Water Heater with Inlet Air from Outdoors

$$T_{HP, cut-in} = T_{HP, set point} - T_{HP, dead band} \quad (19.118)$$

where:

$T_{HP, cut-in}$ is the cut-in temperature for the heat pump compressor (°C)

$T_{HP, set point}$ is the heat pump compressor setpoint temperature (°C)

$T_{HP, dead band}$ is the heat pump compressor dead band temperature difference (°C).

In this model, the heat pump water heater's DX compression system is considered the primary heat source and the water tank's heater (element or burner) provides supplemental heat as necessary. Therefore, the cut-in temperature for the heat pump compressor (setpoint minus dead band temperature difference) is usually higher than the setpoint temperature for the heater (element or burner) in the associated water heater tank object. At times when the water heater tank setpoint temperature is greater than the cut-in temperature of the heat pump compressor, the heat pump compressor is disabled and the tank's heater is used to heat the water.

The simulation starts by first calculating the air conditions entering the air coil (evaporator)/fan assembly based on the inlet air configuration of the heat pump water heater and the presence of the optional mixer/splitter nodes. When the HPWH draws its inlet air from the zone and outdoors using the optional mixer/splitter nodes (i.e., Inlet Air Configuration = Zone and Outdoor Air), the inlet air conditions are calculated as follows:

$$Frac = GetScheduleValue(MixerInletAirSchedule) \quad (19.119)$$

$$T_{inlet} = T_{outdoor} (Frac) + T_{zone} (1 - Frac) \quad (19.120)$$

$$\omega_{inlet} = \omega_{outdoor} (Frac) + \omega_{zone} (1 - Frac) \quad (19.121)$$

where:

$Frac$ is the current value of the inlet air mixer schedule (fraction of outdoor air, 0-1)

T_{inlet} is the inlet air dry-bulb temperature to the HPWH evaporator/fan assembly (°C)

$T_{outdoor}$ is the outdoor air dry-bulb temperature (°C)

T_{zone} is the zone (exhaust) air dry-bulb temperature (°C)

ω_{inlet} is the inlet air humidity ratio to the HPWH evaporator/fan assembly (kg/kg)

$\omega_{outdoor}$ is the outdoor air humidity ratio (kg/kg)

ω_{zone} is the zone (exhaust) air humidity ratio (kg/kg).

When the heat pump water heater draws its inlet air solely from the zone (i.e., Inlet Air Configuration = Zone Air Only), the inlet air conditions to the evaporator/fan assembly are simply set equal to the zone (exhaust) air conditions. If the heat pump water heater draws its inlet air solely from outdoors (i.e., Inlet Air Configuration = Outdoor Air Only), the inlet air conditions to the evaporator/fan assembly are simply set equal to the outdoor air conditions. When the inlet air to the heat pump water heater evaporator and fan assembly is scheduled (i.e., Inlet Air Configuration = Schedule), the inlet air conditions are determined directly from the user-supplied schedules as follows.

$$T_{inlet} = GetScheduleValue(InletAirTemperatureSchedule) \quad (19.122)$$

$$RH_{inlet} = GetScheduleValue(InletAirHumiditySchedule) \quad (19.123)$$

$$\omega_{inlet} = PsyWFnTdbRhPb(T_{inlet}, RH_{inlet}, OutBaroPress) \quad (19.124)$$

where:

RH_{inlet} is the inlet air relative humidity to heat pump water heater evaporator/fan assembly (0-1)

$PsyWFnTdbRhPb$ is a psychrometric function returning air humidity ratio given dry-bulb temperature, relative humidity, and barometric pressure

$OutBaroPress$ is the outdoor barometric pressure (Pa).

For each simulation time step, the heat pump water heating capacity, energy use, and air-side/water-side mass flow rates are set to zero and the water heater tank is simulated with the heat pump compressor disabled when any of the following conditions apply:

- the HPWH is scheduled off by its availability schedule,
- the water heater tank setpoint temperature is greater than or equal to the heat pump compressor cut-in temperature,
- the inlet air dry-bulb temperature to the evaporator/fan assembly is less than the Minimum Inlet Air Temperature for Heat Pump Compressor Operation (as specified by the user in the HPWH input object), or
- the HPWH setpoint temperature is greater than or equal to the Maximum Temperature Limit (specified in the Water Heater:Mixed object).

Otherwise, simulation of the heat pump water heater is based on its current mode of operation. This mode of operation is either floating (heat pump compressor is off and tank water temperature has not fallen below the heat pump compressor cut-in temperature) or heating (tank water temperature dropped below the compressor cut-in temperature on a previous time step but was unable to reach the compressor setpoint temperature). Each mode is handled differently and they will be discussed separately.

If the heat pump water heater is using the stratified tank model, then there is more than one value for the tank temperature. The model includes input for where the heat pump controls detect the temperature. The input data in the associated WaterHeater:Stratified includes up to two heights in the tank where the temperature is measured and a weight associated with each. The associated stratified tank nodes are selected based on these heights. When the heat pump model needs to evaluate the tank temperature of a stratified tank, it evaluates the temperature at the tank nodes associated with these locations.

19.3.2.3 Float Mode

When the heat pump water heater tank temperature is floating between the heat pump compressor's cut-in and cut-out temperatures at the end of the previous simulation time step, both the heat pump compressor and the water heater tank's heating element are disabled and a resulting tank temperature is calculated. If the resulting tank temperature is below the heat pump compressor's cut-in temperature, the heat pump compressor part-load ratio is estimated using the ratio of the temperature differences shown below. The part-load ratio can not be less than zero or greater than one.

$$PLR = MIN \left(1.0, MAX \left(0.0, \left(\frac{T_{HP, cut-in} - T_{tank, float}}{T_{tank, initial} - T_{tank, float}} \right) \right) \right) \quad (19.125)$$

where:

PLR is the part-load ratio of the heat pump water heater compressor

$T_{tank, float}$ is the tank temperature in float mode when heating capacity is set to zero (°C)

$T_{tank, initial}$ is the tank temperature at the beginning of the simulation time step (°C).

Since the pump and fan are assumed to cycle on and off with the heat pump compressor, the average condenser water (for pumped condensers only) and evaporator air mass flow rates for the simulation time step are calculated based on the PLR calculated above:

$$\dot{m}_{water, avg} = \dot{V}_{water} (\rho_{water}) (PLR) \quad (19.126)$$

$$\dot{m}_{air, avg} = \dot{V}_{air} (\rho_{air}) (PLR) \quad (19.127)$$

where:

$\dot{m}_{water, avg}$ is the average condenser water mass flow rate for the time step (kg/s)

\dot{V}_{water} is the condenser water volumetric flow rate, user input (m³/s)

ρ_{water} is the density of condenser inlet water (kg/m³)

$\dot{m}_{air, avg}$ is the average evaporator/fan air mass flow rate for the time step (kg/s)

\dot{V}_{air} is the evaporator/fan air volumetric flow rate, user input (m³/s)

ρ_{air} is the density of evaporator/fan inlet air (kg/m³).

The water tank temperature is then calculated based on heat pump operation at the part-load ratio estimated above and with the water tank's heating element enabled. If the resulting water tank temperature is above the heat pump compressor's setpoint (cut-out) temperature, then the part-load ratio is reduced and the water heater tank is simulated again. The process is performed iteratively until the part-load ratio of the heat pump compressor achieves the desired setpoint temperature (to the extent possible).

19.3.2.4 Heating Mode

When the HPWH is in heating mode at the end of the previous simulation time step (i.e., the heat pump compressor operated during the previous simulation time step but was unable to achieve the setpoint temperature), both the heat pump compressor and the water heater tank's heating element are enabled. The part-load ratio of the heat pump compressor is set to 1, and the condenser water (for pumped condensers) and evaporator air mass flow rates are set to their maximum flow rates.

$$\dot{m}_{water, avg} = \dot{V}_{water} (\rho_{water}) \quad (19.128)$$

$$\dot{m}_{air, avg} = \dot{V}_{air} (\rho_{air}) \quad (19.129)$$

If the resulting tank temperature is above the heat pump compressor's setpoint (cut-out) temperature, the part-load ratio of the heat pump compressor is reduced and the water heater tank is simulated again. The process is performed iteratively until the part-load ratio of the heat pump compressor achieves the desired setpoint temperature (to the extent possible).

The air-side outlet conditions of the HPWH are calculated through simulation of the fan and DX coil with either a blow through or draw through fan placement (user selectable). If mixer/splitter

nodes are used, the HPWH model splits the heat pump outlet air mass flow rate with exhaust air flow equaling the outdoor air flow, and the balance of the outlet air being sent to the zone supply air node (i.e., ensures that the heat pump water heater does not contribute to zone pressurization or depressurization). Calculations of heat pump water heating capacity, energy use, air-side performance, and water-side temperature difference are performed in the associated DX Coil object. See the engineering reference section for the Coil:WaterHeating:AirToWaterHeatPump object for details.

19.3.2.5 Model Outputs

After completing the float mode or heating mode calculations and the final part-load ratio has been determined, the output (report) variables are calculated as follows:

$$\text{Heat Pump Water Heater Compressor Part-Load Ratio} = PLR \quad (19.130)$$

$$\text{Heat Pump Water Heater On-Cycle Parasitic Electric Power (W)} = P_{\text{parasitic,on}}(PLR) \quad (19.131)$$

$$\begin{aligned} \text{Heat Pump Water Heater On-Cycle Parasitic Electric Consumption (J)} = \\ P_{\text{parasitic,on}}(PLR)(3600)t_{\text{sys}} \end{aligned} \quad (19.132)$$

$$\begin{aligned} \text{Heat Pump Water Heater Off-Cycle Parasitic Electric Power (W)} = \\ P_{\text{parasitic,off}}(1 - PLR) \end{aligned} \quad (19.133)$$

$$\begin{aligned} \text{Heat Pump Water Heater Off-Cycle Parasitic Electric Consumption (J)} = \\ P_{\text{parasitic,off}}(1 - PLR)(3600)(t_{\text{sys}}) \end{aligned} \quad (19.134)$$

where:

$P_{\text{parasitic,on}}$ is the on-cycle parasitic electric load, user input (W)

$P_{\text{parasitic,off}}$ is the off-cycle parasitic electric load, user input (W)

t_{sys} is the HVAC system simulation time step (hours).

Note: All heat pump water heater output variables, including off-cycle ancillary electric power and consumption, equal 0 when the heat pump water heater availability schedule equals 0 (i.e., the heat pump water heater is scheduled OFF).

19.3.3 Stratified Water Thermal Tank

The input objects WaterHeater:Stratified and ThermalStorage:ChilledWater:Stratified provide models for a stratified water thermal tank that divides the water tank into multiple nodes of equal volume. This model is used for both the stratified water heater and the stratified chilled water storage tank. The nodes are coupled by vertical conduction effects, internode fluid flow, and temperature inversion mixing. The object simultaneously solves the differential equations governing the energy balances on the nodes using an analytical solution to a simplified representation of the heat balance equation. The system time step is divided into multiple substeps at which control decisions are evaluated that allow the simulation to capture events that occur on a short time scale.

19.3.3.1 Energy Balance

Similar to the well-mixed model, the stratified model solves the same fundamental differential equation governing the energy balance on a mass of water:

$$mc_p \frac{dT}{dt} = q_{net} \quad (19.135)$$

where:

m is the mass of water

c_p is the specific heat of water

T is the temperature of water

t is the time

q_{net} is the net heat transfer rate.

The difference for the stratified model is that it must solve the energy balance on n number of nodes simultaneously. Node 1 is at the top of the water tank and node n is at the bottom of the water tank.

$$m_n c_p \frac{dT_n}{dt} = q_{net,n} \quad (19.136)$$

where:

m_n is the mass of water for node n

c_p is the specific heat of water

T_n is the temperature of water for node n

t is the time

$q_{net,n}$ is the net heat transfer rate for node n .

It will be advantageous for the numerical solution to rearrange the nodal differential equation into the form

$$\frac{dT}{dt} = aT + b \quad (19.137)$$

The net heat transfer rate q_{net} is the sum of gains and losses due to multiple heat transfer pathways. Each term is defined as described below and separated into the part that is multiplied by the current node temperature (a term) and everything else (b term).

$$\begin{aligned} q_{net,n} = & q_{heater,n} + q_{oncyclepara,n} + q_{offcyclepara,n} + q_{oncycleloss,n} + q_{offcycleloss,n} \\ & + q_{cond,n} + q_{use,n} + q_{source,n} + q_{flow,n} \end{aligned} \quad (19.138)$$

where:

$q_{heater,n}$ is the heat added by Heater 1 or Heater 2

$q_{oncyclepara,n}$ is the heat added due to on-cycle parasitic loads (zero when off)

$q_{offcyclepara,n}$ is the heat added due to off-cycle parasitic loads (zero when on)

$q_{oncycleloss,n}$ is the heat transfer to/from the ambient environment (zero when off)

$q_{offcycleloss,n}$ is the heat transfer to/from the ambient environment (zero when on)

$q_{cond,n}$ is the heat transfer due to conduction between the node above and below

$q_{use,n}$ is the heat transfer to/from the use side plant connections

$q_{source,n}$ is the heat transfer to/from the source side plant connections

$q_{flow,n}$ is the heat transfer due to fluid flow from the node above and below

19.3.3.1.1 Heater and Parasitic Loads

q_{heater} , $q_{oncyclepara,n}$, and $q_{offcyclepara,n}$ are all added to the b coefficient because they do not depend on the current node temperature.

19.3.3.1.2 On- and Off-cycle Losses to Ambient

$q_{oncycleloss,n}$ and $q_{offcycleloss,n}$ are defined as:

$$q_{oncycleloss,n} = (UA_{tank} + UA_{add,n})(T_{amb} - T_n) \quad (19.139)$$

$$q_{offcycleloss,n} = (UA_{tank} + UA_{flue})(T_{amb} - T_n) \quad (19.140)$$

where:

UA_{tank} is the loss coefficient to ambient environment for the tank

$UA_{add,n}$ is the additional node loss coefficient

UA_{flue} is the additional off-cycle flue loss coefficient to ambient environment (zero when on)

T_{amb} is the temperature of ambient environment.

Separating it into a and b terms for on-cycle losses:

$$\begin{aligned} a_n &= -(UA_{tank} + UA_{add,n}) \\ b_n &= (UA_{tank} + UA_{add,n})T_{amb} \end{aligned} \quad (19.141)$$

And for off-cycle losses:

$$\begin{aligned} a_n &= -(UA_{tank} + UA_{flue}) \\ b_n &= (UA_{tank} + UA_{flue})T_{amb} \end{aligned} \quad (19.142)$$

19.3.3.1.3 Conduction to Adjacent Nodes

$q_{cond,n}$ is defined as:

$$q_{cond,n} = \frac{kA_{n+1}}{L_{n+1}}(T_{n+1} - T_n) + \frac{kA_{n-1}}{L_{n-1}}(T_{n-1} - T_n) \quad (19.143)$$

where:

k is the fluid thermal conductivity of water (0.6 W/m-K)

A_{n+1} is the shared surface area between node n and node $n+1$

L_{n+1} is the distance between the center of mass of node n and $n+1$

T_{n+1} is the temperature of node $n+1$

A_{n-1} is the shared surface area between node n and node $n-1$

L_{n-1} is the distance between the center of mass of node n and $n-1$

T_{n-1} is the temperature of node $n-1$.

Separating into a and b terms yields:

$$\begin{aligned} a_n &= -\left(\frac{kA_{n+1}}{L_{n+1}} + \frac{kA_{n-1}}{L_{n-1}}\right) \\ b_n &= \frac{kA_{n+1}}{L_{n+1}}T_{n+1} + \frac{kA_{n-1}}{L_{n-1}}T_{n-1} \end{aligned} \quad (19.144)$$

19.3.3.1.4 Use- and Source-side Plant Connections

$q_{use,n}$, and $q_{source,n}$ are defined as:

$$q_{use} = \varepsilon_{use} \dot{m}_{use} c_p (T_{use} - T) \quad (19.145)$$

$$q_{source} = \varepsilon_{source} \dot{m}_{source} c_p (T_{source} - T) \quad (19.146)$$

where:

ε_{use} is the heat exchanger effectiveness for the use side plant connections

\dot{m}_{use} is the mass flow rate for the use side plant connections

T_{use} is the inlet fluid temperature of the use side plant connections

ε_{source} is the heat exchanger effectiveness for the source side plant connections

\dot{m}_{source} is the mass flow rate for the source side plant connections

T_{source} is the inlet fluid temperature of the source side plant connections.

Separating into a and b terms for the source side connection yields:

$$\begin{aligned} a_n &= -\varepsilon_{source} \dot{m}_{source} c_p \\ b_n &= \varepsilon_{source} \dot{m}_{source} c_p T_{source} \end{aligned} \quad (19.147)$$

And for the use side connection:

$$\begin{aligned} a_n &= -\varepsilon_{use} \dot{m}_{use} c_p \\ b_n &= \varepsilon_{use} \dot{m}_{use} c_p T_{use} \end{aligned} \quad (19.148)$$

19.3.3.1.5 Internodal Flow

$q_{flow,n}$ is defined as:

$$q_{flow,n} = \dot{m}_{n+1} c_p (T_{n+1} - T_n) + \dot{m}_{n-1} c_p (T_{n-1} - T_n) \quad (19.149)$$

where:

\dot{m}_{n+1} is the mass flow rate from node $n+1$

\dot{m}_{n-1} is the mass flow rate from node $n-1$.

Separating into a and b terms:

$$\begin{aligned} a_n &= -c_p (\dot{m}_{n+1} + \dot{m}_{n-1}) \\ b_n &= c_p (\dot{m}_{n+1} T_{n+1} + \dot{m}_{n-1} T_{n-1}) \end{aligned} \quad (19.150)$$

19.3.3.1.6 Inversion Mixing

Inversion mixing occurs when the node below is warmer than the node above. The difference in temperatures drives a difference in density that causes the nodes to mix. Usually inversion mixing occurs very rapidly.

At the end of each sub timestep, the algorithm checks for temperature inversions and instantaneously mixes inverted nodes by calculating a weighted average of the node temperatures of the inverted nodes. This is done iteratively up the tank until there are no more temperature inversions.

19.3.3.1.7 Use and Source Effectiveness Correction

The use and source fluid steam outlet temperatures calculation procedure depends on the values of the effectiveness. If the effectiveness is 1.0, then complete mixing of these fluid steam and the tank water is assumed. In this case the outlet temperatures for the use and source streams will be simply the tank water temperatures at point of the outlet nodes. When the effectiveness is less than 1.0, an indirect heat exchange is assumed between the use or source stream and the water in the stratified thermal storage tank. When the effectiveness is less than 1.0, the use and source outlet temperatures are calculated using Q_{use} and Q_{source} , and energy balance equations as follows:

$$T_{use\ out,n} = T_{use,n} + \frac{q_{use,n}}{\dot{m}_{use}C_p} \quad (19.151)$$

$$T_{source\ out,n} = T_{source,n} - \frac{q_{source,n}}{\dot{m}_{source}C_p} \quad (19.152)$$

where:

$T_{use\ out}$ is the outlet fluid temperature of the use side plant connections

$T_{source\ out}$ is the outlet fluid temperature of the source side plant connections.

19.3.3.2 Numerical Solution

To solve the differential equations the nodal heat balance equations are modified into the form:

$$\frac{dT_n}{dt} = aT_n + b \quad (19.153)$$

Where a is a constant and b can be a function of either time or the temperature of adjacent nodes. If b is assumed to be constant, the solution of the differential equation is readily solved. Since b is not generally constant a reasonable approximation can be made by assuming b is equal to its average value over the sub timestep.

Solving the differential equation yields the following solution for the temperature of a node at the end of a sub timestep.

$$T_{final} = \left(T_{initial} + \frac{b}{a}\right)e^{a\Delta t} - \frac{b}{a} \quad (19.154)$$

Where b is a function of the average temperature as calculated by

$$\begin{aligned} b &= b(T_{avg}) \\ T_{avg} &= \frac{(T_{initial} - \frac{b}{a})(e^{a\Delta t} - 1)}{a\Delta t} - \frac{b}{a} \end{aligned} \quad (19.155)$$

The solution is obtained by separating the q_{net} terms described above into their respective a and b parts, solving for T_{final} and T_{avg} , recalculating b using the new average temperatures and iterating until the temperatures converge, at which point temperature inversions are resolved and controls decisions are made before moving on to the next sub timestep.

19.3.3.2.1 Adaptive Sub Timestep

The sub timestep is allowed to vary between 10 seconds and 10 minutes. The length of the sub timestep is determined by the current heat transfer rates in the tank, which are used to predict the

amount of time until a control decision (19.3.3.2.2) will need to be made. The sub timestep is then selected to approach the time of the control decision.

First, the temperature difference required for a heater to turn on or off for each control node is calculated by determining the difference between its setpoint temperature and the current temperature if the heater is on or its cut in temperature and current temperature if the heater is off. The minimum of the temperature differences is selected as the maximum allowable nodal temperature change dT_{max} . The time until that temperature change occurs is estimated for each node by rearranging 19.153 to solve for dt .

$$dt = \frac{dT_{max}}{aT + b} \quad (19.156)$$

Finally, the minimum of the nodal dt values is used as the sub timestep unless it is outside the allowable bounds or it will extend beyond the end of the timestep. In those cases, the sub timestep is adjusted to fit within the bounds.

19.3.3.2.2 Control Logic Evaluation

Before each system time step is calculated the following evaluations are made:

1. Use and source inlet flow rates are applied to the inlet nodes
2. Internode flow is determined and net flow rates are determined

Before each sub timestep is calculated, the following evaluations are made:

1. Thermostatic controls for heater 1 and heater 2 are evaluated to determine if the heater elements should turn on or off
2. Node 1 temperature is compared against the maximum limit to determine if venting is necessary
3. Adjoining node temperatures are compared to determine if there are any temperature inversions for which the inversion mixing rate should be used.
4. Source inlet temperatures for the desuperheater are recalculated and applied to the inlet nodes using the heat rate calculated in the system time step loop

The solution continues looping through all substeps until the system time step is completed.

19.3.4 Water Heating Sizing

Some inputs for water heaters can be autosized using the input object WaterHeater:Sizing. This section describes the sizing calculations for water heaters. There are six general methods for sizing tank volume and heating capacity.

19.3.4.1 Autosizing Tank Volume

The volume a water heater can be sized in the following ways depending on the design method chosen by the user.

- **Peak Draw.** The volume is determined from the loop design flow rate. The water heater is positioned on the supply side of a plant loop. After the plant sizing routines have run, the model obtains the design flow rate for all components on the demand side. The tank volume is then: $V = \dot{V}_{loop.des} * t_{draw}$
- **Residential HUD-FHA Minimum.** The volume is determined from a set of rules defined in Table 19.10. This is from Chapter 48 of 1999 ASHRAE Handbook HVAC Applications, American Society of Heating Refrigeration and Air-conditioning Engineers, Atlanta GA. (also used in the Building America Benchmark).

Table 19.10: Residential HUD-FHA Minimum

Residential HUD-FHA Minimum DHW Storage and Burner Capacity (ASHRAE 1999)												
# Bedrooms	1	2	2	2	3	3	3	4	4	4	5	6
# Bathrooms	All	≤ 1.5	2-2.5	≥ 3	≤ 1.5	2-2.5	≥ 3	≤ 1.5	2-2.5	≥ 3	All	All
Gas												
Storage (gal)	20	30	30	40	30	40	40	40	40	50	50	50
Burner (kBtu/hr)	27	36	36	36	36	36	38	36	38	38	47	50
Electric												
Storage (gal)	20	30	40	50	40	50	50	50	50	66	66	80
Burner (kW)	2.5	3.5	4.5	5.5	4.5	5.5	5.5	5.5	5.5	5.5	5.5	5.5

- **Per Person.** The tank volume is determined by summing the design level of people in the model and multiplying by a user-entered volume per person factor.
- **Per Floor Area.** The tank volume is determined by summing the floor area in all the zones in the model and multiplying by a user-entered volume per floor area factor.
- **Per Unit.** The tank volume is determined by multiplying a user-entered volume per unit and a user-entered number of units.
- **Per Solar Collector Area.** The tank volume is determined by summing the collector area in all the hot water solar collectors in the model and multiplying by a user-entered volume per collector area factor.

19.3.4.2 Autosizing Heater Capacity

The heater capacity can be sized in the following ways depending on the design method chosen by the user.

- **Peak Draw.** The heater capacity is determined from the tank volume, assumed start and finish temperatures and a user defined time for recovery. The heater capacity is then:

$$q_{heat} = V \rho C_p (T_{finish} - T_{start}) \quad (19.157)$$

where:

$$T_{finish} = 57.2^\circ C \quad (19.158)$$

$$T_{start} = 14.4^\circ C \quad (19.159)$$

- Residential HUD-FHA Minimum. The heater capacity is determined from a set of rules defined by the table above. This is from 1999 ASHRAE Handbook HVAC Applications, American Society of Heating Refrigeration and Air-conditioning Engineers, Atlanta GA. (also used the Building America Benchmark).
- Per Person. The heater capacity is determined by summing the design level of people in the model and using a user-entered factor for recovery capacity per person. The heater capacity is then:

$$q_{heat} = \frac{N_{people} f_{RecoveryPerPerson} (T_{finish} - T_{start}) \rho C_p}{3600} \quad (19.160)$$

- Per Floor Area. The heater capacity is determined by summing the floor area in all the zones in the model and using a user-entered factor for recovery capacity per floor area. The heater capacity is then:

$$q_{heat} = \frac{A_{floors} f_{RecoveryPerFloorArea} (T_{finish} - T_{start}) \rho C_p}{3600} \quad (19.161)$$

- Per Unit. The heater capacity is determined from a user-entered Recovery Capacity per unit and a user-entered number of units. The heater capacity is then:

$$q_{heat} = \frac{N_{units} f_{RecoveryPerUnit} (T_{finish} - T_{start}) \rho C_p}{3600} \quad (19.162)$$

- Per Solar Collector Area. The water heater is assumed to be used for solar hot water storage and the heater capacity is set to zero.

19.3.4.3 Autosizing Tank Height

If the water heater is Stratified, then the geometry is important and the height of the tank can be scaled with changes in volume. For tank shapes of Vertical Cylinder, the user defined height aspect ratio, AR , is used to calculate a tank height, H , using

$$H = \left(\frac{4 V AR^2}{\pi} \right)^{1/3} \quad (19.163)$$

19.3.4.4 Autosizing Plant Connection Flow Rates

When the water thermal tank is connected to a plant loop, it is convenient to autosize the design volume flow rates through the plant connections. When the water thermal tank is connected to the supply side of plant loop and flow rates are autosized, the flow rate is the sum of the flow requests of all the various components on the demand side of that plant loop. When the water thermal tank is connected on the demand side of a plant loop (e.g. as for indirect water heating with a boiler) and flow rates are autosized, the design flow rates are calculated with the following equation:

$$\dot{V} = - \left(\frac{V}{t_{Recover} * 3600 * \varepsilon} \right) * Ln \left(\frac{T_{PlantDesign} - T_{Setpoint}}{T_{PlantDesign} - T_{start}} \right) \quad (19.164)$$

where:

V is the volume of the tank

$t_{Recover}$ is the user parameter for the time it takes for the tank to recover from assumed starting temperature to an assumed setpoint temperature. For water heaters, the starting temperature is 14.4°C and the final assumed setpoint temperature is 57.2°C. For chilled water tanks, the starting temperature is 14.4°C and the final temperature is 9.0°C.

ε is ε_{use} or ε_{source}

$T_{PlantDesign}$ is the exit temperature specified in the Plant Sizing object

$T_{setpoint}$ is the final tank temperature of 57.2°C for heaters and 9.0°C for chilled water tanks

T_{start} is the initial tank temperature of 14.4°C.

If the demand side connections are autosized and a water heater's tank volume is autosized, then the problem cannot be readily solved in EnergyPlus because the demand side connection flows need to be reported earlier in the simulation and the tank volume is not yet available. This situation is resolved by using an interim, nominal tank volume for sizing the connections and the actual volume is calculated later in the simulation.

19.4 Water Systems

Water systems include a variety of components that simulate water consumption, production, and storage, including:

1. Water Use Equipment and Connections
2. Rainwater Collection
3. Groundwater Well
4. Water Storage Tanks

19.4.1 Water Mains Temperatures

The input object Site:WaterMainsTemperature provides a model for the temperature of water mains that deliver water to a building via underground pipes. The water mains temperatures are an important input for plant equipment that require make-up water from the water mains, such as for domestic hot water systems.

Water mains temperatures are a function of outdoor climate conditions and vary with time of year. A correlation has been formulated to predict water mains temperatures based on two weather inputs:

- average annual outdoor air temperature (dry-bulb)
- maximum difference in monthly average outdoor air temperatures

These values can be easily calculated from annual weather data using a spreadsheet.

The correlation was developed by Craig Christensen and Jay Burch and is described in Hendron et al. (2004). The correlation is:

$$T_{mains} = (T_{out,avg} + 6) + ratio * (\Delta T_{out,maxdiff}/2) * SIN(0.986 * (day - 15 - lag) - 90) \quad (19.165)$$

where:

TT_{mains} is the water mains temperature (°F)

$TT_{out,avg}$ is the average annual outdoor air temperature (°F)

$\Delta T_{out,maxdiff}$ is the maximum difference in monthly average outdoor air temperatures (°F)

day is Julian day of the year (1-365)

ratio is equal to $0.4 + 0.01 * (T_{amb,avg} - 44)$

lag is equal to $35 - 1.0 * (T_{amb,avg} - 44)$ (°F).

For the Chicago-O'Hare TMY2 weather file, $T_{out,avg} = 9.69^\circ\text{C}$ and $\Delta T_{out,maxdiff} = 28.1^\circ\text{C}$. The resulting water mains temperature profile is graphed in Figure 19.15.

Figure 19.15: Water Mains Temperatures for Chicago-O'Hare TMY2 Data

19.4.1.1 References

Hendron, R., Anderson, R., Christensen, C., Eastment, M., and Reeves, P. 2004. “Development of an Energy Savings Benchmark for All Residential End-Uses”, Proceedings of SimBuild 2004, IBPSA-USA National Conference, Boulder, CO, August 4 - 6, 2004.

19.4.2 Water Use Equipment and Connections

Essential parts of most water systems are the end uses where the water is utilized for a purpose. These end uses are characterized by familiar pieces of equipment such as sinks, showers, dishwashers, clothes washers, and toilets. End uses can also include outdoor uses such as landscape irrigation and agricultural irrigation.

Water end-use modeling in EnergyPlus is accomplished via two input objects:

- WaterUse:Equipment
- WaterUse:Connections

The WaterUse:Equipment object simulates all different types of water end uses. The WaterUse:Connections object manages multiple pieces of water equipment with a common supply and return, internally providing the services of a splitter and a mixer. The WaterUse:Connections object also allows water consuming equipment to be simulated in a closed plant loop by supplying makeup water from the water mains.

19.4.3 Unconnected Water Use Equipment

Common water equipment, such as sinks and showers, requires mixing of hot and cold water to provide a desired temperature at the tap. Water use equipment that is simulated in “unconnected” mode, i.e., without being referenced by a WaterUse:Connections object, presents a relatively simple modeling problem illustrated in Figure 19.16.

The variables are defined as:

\dot{m}_{hot} is the hot water supply mass flow rate

T_{hot} is the hot water supply temperature

\dot{m}_{cold} is the cold water supply mass flow rate

T_{cold} is the cold water supply temperature

\dot{m}_{target} is the target mass flow rate at the tap

T_{target} is the target temperature at the tap.

The basic physics of the problem are described by two equations representing conservation of mass and conservation of energy respectively:

$$\dot{m}_{target} = \dot{m}_{hot} + \dot{m}_{cold} \quad (19.166)$$

$$\dot{m}_{target}T_{target} = \dot{m}_{hot}T_{hot} + \dot{m}_{cold}T_{cold} \quad (19.167)$$

The hot and cold water supply temperatures, T_{hot} and T_{cold} , are specified by the user with schedules (or indirectly from the water mains temperatures). The target flow rate and target temperature, \dot{m}_{target} and T_{target} , at the tap are also specified with schedules. The target conditions

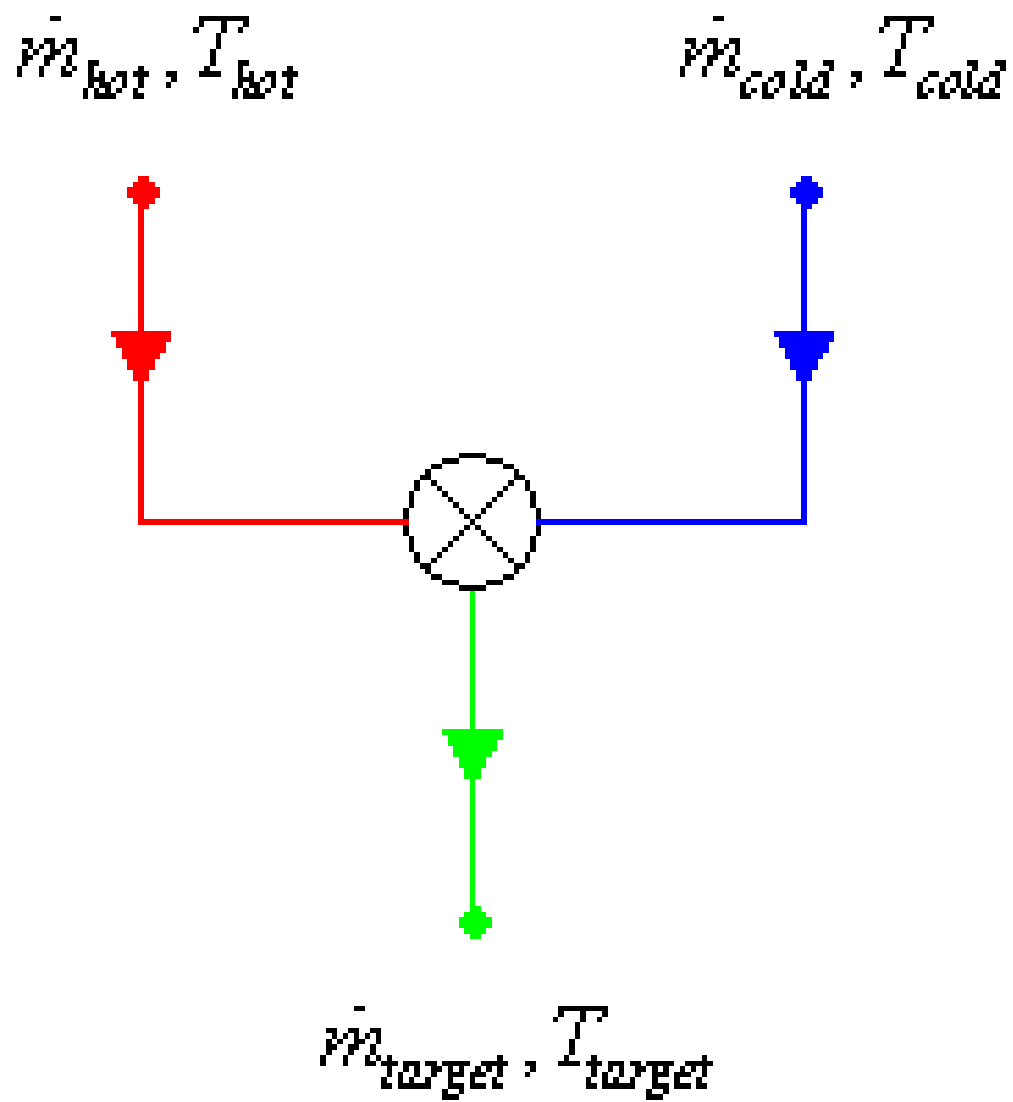

Figure 19.16: Hot and Cold Water Mixing

can be thought of as a way to simulate occupant behavior; a person at a sink will adjust the hot and cold flow rates to get the overall water flow and temperature that is desired.

The two equations above are easily solved to calculate the necessary hot and cold flow rates needed to attain the target conditions.

$$\dot{m}_{hot} = \dot{m}_{target} \left(\frac{T_{target} - T_{cold}}{T_{hot} - T_{cold}} \right) \quad (19.168)$$

$$\dot{m}_{cold} = \dot{m}_{target} - \dot{m}_{hot} \quad (19.169)$$

Even though hot and cold flow rates are unlimited in “unconnected” mode, it is still possible to fail to meet the target conditions if $T_{target} > T_{hot}$. In this case, the actual mixed water temperature at the tap, T_{mixed} , is set equal to T_{hot} . The target flow rate is always met.

Water equipment that omits schedules for the target temperature and/or hot water supply temperature implies that no hot water is needed. The result is all cold water at the target flow rate.

For “unconnected” water equipment, the heating rate and energy that is required to supply the hot water is calculated by the following equations.

$$Q = \dot{m}_{hot} c_p (T_{hot} - T_{cold}) \quad (19.170)$$

$$\Delta E = Q \Delta t \quad (19.171)$$

where:

Q is the heating rate

c_p is the specific heat of water

ΔE is the heating energy

Δt is the time step interval.

All heating is assigned to “Purchased Heating”.

19.4.4 Zone Heat Gain from Water Use Equipment

Some water use equipment can be a significant source of sensible and latent heat gain when located in a zone. Showers, for example, add a noticeable latent gain as some of the hot water evaporates into the zone air (and at the same time adding some sensible gain). Other types of equipment may contribute greater sensible gain but less latent gain.

Calculating the amount of sensible and latent heat gain can be extremely complicated and depends on many variables. One set of variables is related to the initial conditions of the entering water and the undisturbed zone air, namely:

- Entering water temperature
- Entering water flow rate
- Ambient zone air temperature
- Ambient zone humidity
- Ambient zone barometric pressure

A second set of variables is tied to the specifics of the water equipment which describe the heat and mass transfer processes that occur as the water passes through the zone. These variables might include the velocity of the water in the zone air, the surface area of water exposed to the zone air, the dwell time of water in the zone, and possibly others. The complexity of these variables cannot be easily cast into a generalized EnergyPlus input object. Consider that in a shower, the velocity of water droplets is increasing as they fall, and the surface area of the spray is increasing. How does one even determine the surface area of the spray at any point?

The approach taken here is to utilize the first set of initial condition variables and forego the overly-complex second set. The initial conditions can be used to calculate a maximum possible change in sensible and latent energy between the entering water conditions and the leaving water conditions at an infinite time later. Sensible and latent energy are calculated separately and represent the maximum heat gain, respectively, that could be added to the zone air. The user simply specifies a fraction of the maximum heat gain for sensible and latent that is actually added to the zone air. The fraction is specified with a schedule to account for different modes of operation. The split between sensible and latent will vary depending on the type of equipment that is to be modeled. Typically, both fractions should be small numbers.

The maximum sensible heat gain rate is calculated by assuming that all of the water flow is allowed to cool to the zone dry-bulb temperature. The actual sensible zone heat gain rate is found by multiplying the maximum by the user fraction.

$$Q_{sens} = f_{sens} \dot{m}_{target} c_p (T_{target} - T_{zone}) \quad (19.172)$$

$$\Delta E_{sens} = Q_{sens} \Delta t \quad (19.173)$$

where:

Q_{sens} is the sensible heat gain rate

f_{sens} is the user fraction of maximum sensible heat

\dot{m}_{target} is the target mass flow rate at the tap

c_p is the specific heat of water

T_{target} is the target temperature at the tap

T_{zone} is the zone dry-bulb air temperature

ΔE_{sens} is the sensible heat gain

Δt is the time step interval.

The maximum latent heat gain rate is calculated by assuming that the maximum amount of water is evaporated into the zone air during the time step. The actual latent zone heat gain rate is found by multiplying the maximum by the user fraction.

$$m_{evap,zonemax} = (W_{sat} - W_{zone}) \rho_{zone} V_{zone} \quad (19.174)$$

$$m_{evap,flowmax} = \dot{m}_{target} \Delta t \quad (19.175)$$

$$m_{evap,max} = MIN(m_{evap,zonemax}, m_{evap,flowmax}) \quad (19.176)$$

$$m_{evap} = f_{lat} m_{evap,max} \quad (19.177)$$

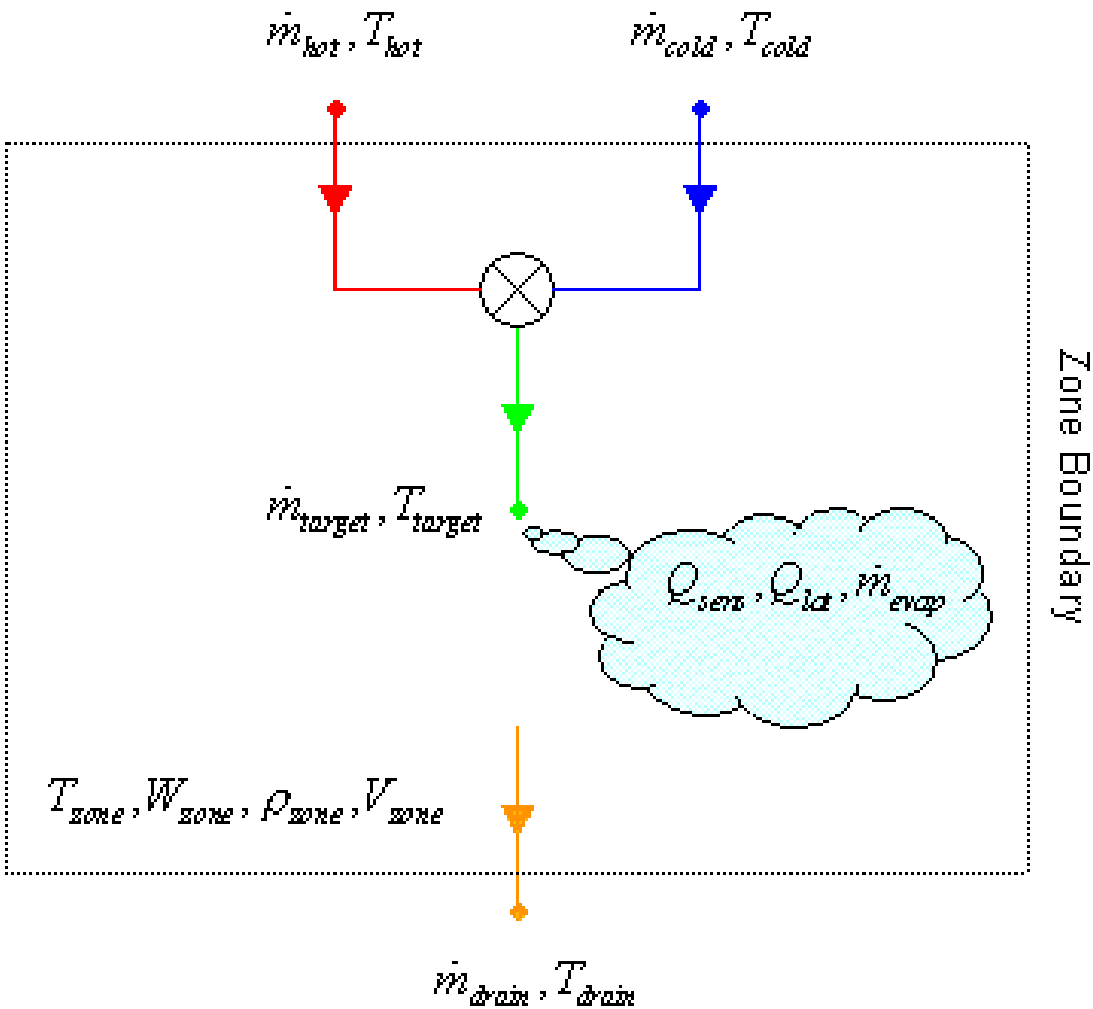

Figure 19.17: Zone Heat Gain from Water Use Equipment

$$\dot{m}_{evap} = m_{evap}/\Delta t \quad (19.178)$$

$$Q_{lat} = h_{fg}\dot{m}_{evap} \quad (19.179)$$

$$\Delta E_{lat} = Q_{lat}\Delta t \quad (19.180)$$

where:

$m_{evap,zonemax}$ is the mass of water that can be absorbed by the zone air in one timestep
 W_{sat} is the fully-saturated zone humidity ratio (function of air temperature and pressure)
 W_{zone} is the zone humidity ratio
 ρ_{zone} is the zone dry-air density (function of air temperature and pressure)
 V_{zone} is the zone air volume
 $m_{evap,flowmax}$ is the mass of water available in the flow in one timestep
 \dot{m}_{target} is the target mass flow rate at the tap
 Δt is the time step interval
 $m_{evap,max}$ is the maximum mass of water that can be evaporated
 m_{evap} is the actual mass of water evaporated into the zone air
 f_{lat} is the user fraction of maximum latent heat
 \dot{m}_{evap} is the mass rate of water evaporation into the zone air
 Q_{lat} is the latent heat gain rate
 h_{fg} is the heat of vaporization for water
 ΔE_{lat} is the latent heat gain.

Sensible and latent heat gains to the zone are lagged by one zone time step.

Note that this method allows the heat gain to vary dynamically according to changing water and zone conditions instead of the fixed or scheduled value that is traditionally used. However, sensible and latent fractions may be difficult to estimate. Experimental measurement is probably the best way to determine the fractions.

A related result of any zone heat and moisture gain is that the water undergoes an equal heat and moisture loss. For a shower the water will generally leave the zone at a cooler temperature and slightly reduced flow rate when compared to the entering water conditions.

$$\dot{m}_{drain} = \dot{m}_{target} - \dot{m}_{evap} \quad (19.181)$$

$$T_{drain} = \frac{\dot{m}_{target}c_p T_{target} - Q_{sens} - Q_{lat}}{\dot{m}_{drain}c_p} \quad (19.182)$$

where:

\dot{m}_{drain} is the drainwater mass flow rate at the drain
 \dot{m}_{target} is the target mass flow rate at the tap
 \dot{m}_{evap} is the mass rate of water evaporation into the zone air
 T_{drain} is the water temperature at the drain
 c_p is the specific heat of water
 T_{target} is the target temperature at the tap
 Q_{sens} is the sensible heat gain rate
 Q_{lat} is the latent heat gain rate.

The change in leaving water conditions has implications for drainwater heat recovery and storage tank conditions.

19.4.5 Connected Water Use Equipment

Water use equipment referenced by a WaterUse:Connections object is considered to be in “connected” mode. The WaterUse:Connections object manages multiple pieces of water equipment with a common supply and return, internally providing the services of a splitter and a mixer. The connections object also offers three internal configurations for drainwater heat recovery. External connections are available for coupling to plant loop nodes or water storage tanks for graywater reuse or reclamation.

Keep in mind that water use equipment in “connected” mode does not imply that it is connected to a plant loop. WaterUse:Equipment objects are never directly connected to a plant loop; they are connected indirectly through the WaterUse:Connections object. WaterUse:Connections can operate either within a plant loop or in stand-alone mode, i.e., without plant loop connections.

The WaterUse:Connections object overrides the hot and cold water supply temperatures of its subordinate WaterUse:Equipment objects based on the specified schedules, plant loop conditions, or water storage tank conditions. But the WaterUse:Equipment objects still maintain their individual target flow rates and target temperatures.

Solving the water subsystem described by the WaterUse:Connections object is appreciably more difficult than solving a single, unconnected piece of water use equipment. The subsystem is illustrated in Figure 19.18.

The nomenclature here uses uppercase letters to indicate variables related to the connections object and lowercase letters to indicate variables related to the equipment objects. The variables are defined as:

\dot{M}_{hot} is the hot water supply mass flow rate

T_{hot} is the hot water supply temperature

\dot{M}_{cold} is the cold water supply mass flow rate

T_{cold} is the cold water supply temperature

\dot{M}_{drain} is the drainwater mass flow rate at the drain

T_{drain} is the water temperature at the drain

T_{waste} is the wastewater temperature after the drain

\dot{M}_{return} is the return water mass flow rate back to the plant loop

T_{return} is the return temperature of makeup water back to the plant loop.

19.4.6 Water Use Equipment Calculations

The solution method proceeds in steps:

- Initialize Connections Temperatures
- Calculate Connections Flow Rates
- Calculate Connections Drain Temperature
- Update Connections Nodes

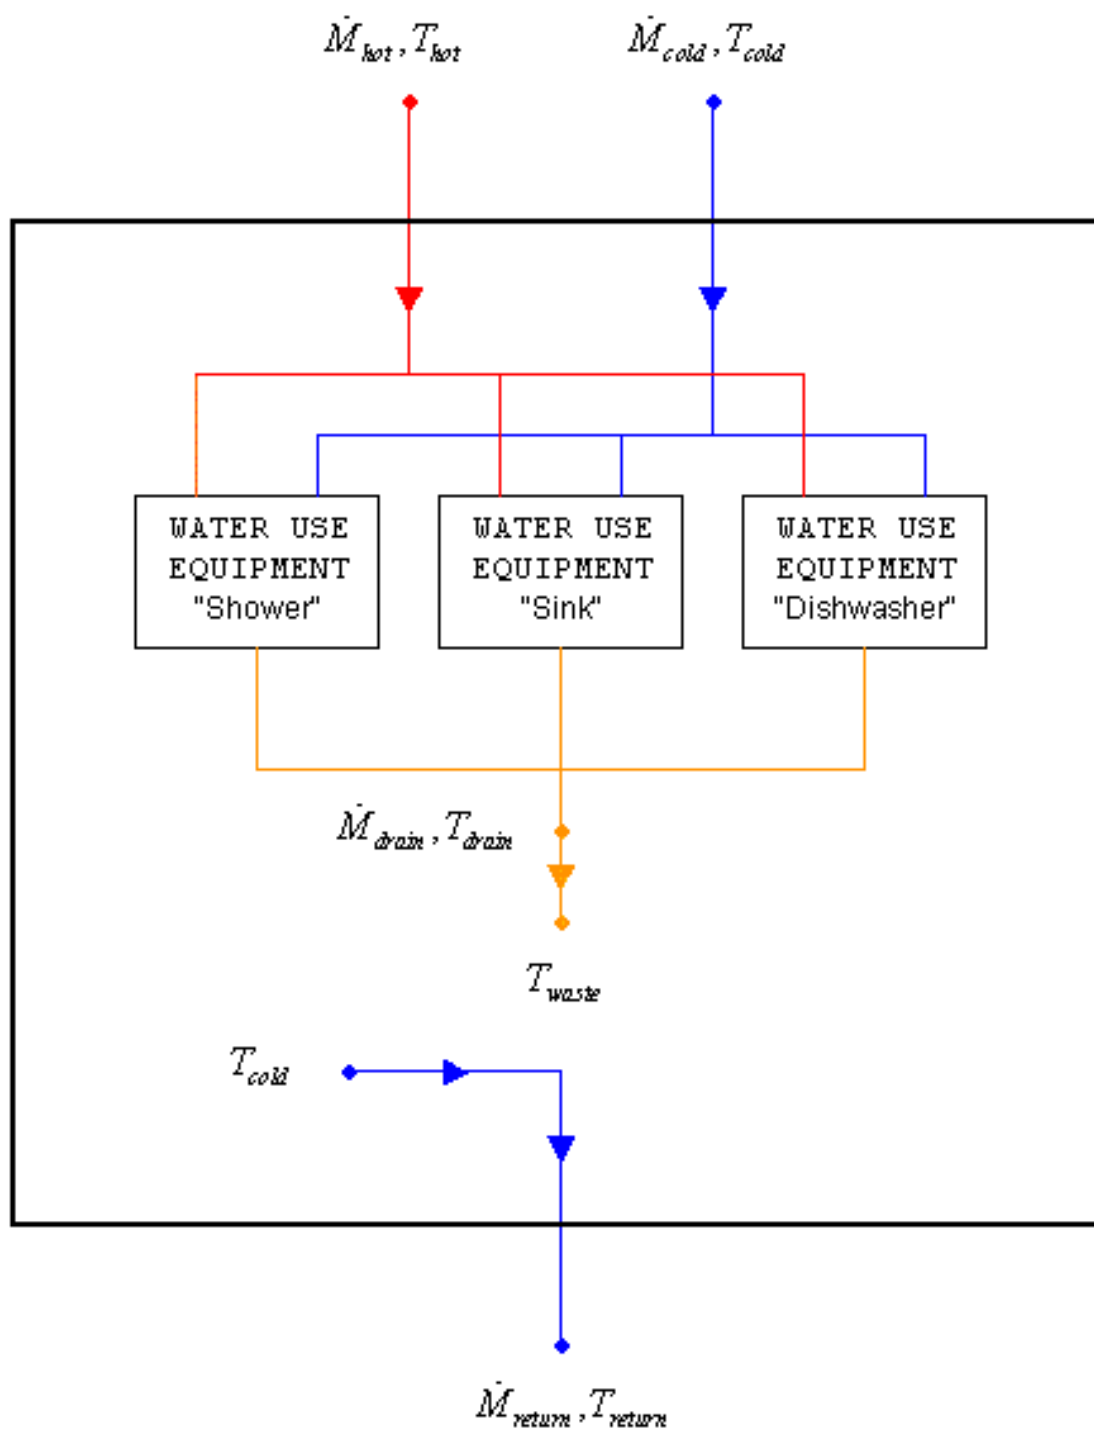

Figure 19.18: Water Use Connections Subsystem

19.4.6.1 Initialize Connections Temperatures

Initializes the hot and cold supply water temperatures, T_{hot} and T_{cold} , for the common supply to all the equipment. If plant-coupled, T_{hot} is taken from the plant loop inlet node. If stand-alone, T_{hot} is taken from the schedule.

T_{cold} is taken from the supply water storage tank, if specified. Otherwise T_{cold} is taken from the schedule. If a schedule is not specified, T_{cold} is taken from the water mains.

19.4.6.2 Calculate Connections Flow Rates

First calls on each piece of equipment to simulate itself with the given supply water temperatures T_{hot} and T_{cold} . The desired hot and cold flow rates for $\dot{m}_{hot,i}$ and $\dot{m}_{cold,i}$ are calculated (as described earlier) and passed back to the connections object. The total flow rates for \dot{M}_{hot} and \dot{M}_{cold} are then calculated:

$$\dot{M}_{hot} = \sum_i \dot{m}_{hot,i} \quad (19.183)$$

$$\dot{M}_{cold} = \sum_i \dot{m}_{cold,i} \quad (19.184)$$

If plant-coupled, \dot{M}_{hot} is compared to the maximum flow rate available in the plant loop (after the first HVAC iteration). If $\dot{M}_{hot} > \dot{M}_{hot,max}$, the actual flow rate is reset to equal the maximum: $\dot{M}_{hot} = \dot{M}_{hot,max}$. New hot and cold flow rates, $\dot{m}'_{hot,i}$ and $\dot{m}'_{cold,i}$, at the equipment level are then recalculated, decreasing the hot flow rate and increasing the cold flow rate in order to still meet the target flow rate.

$$\alpha = \frac{\dot{M}_{hot,max}}{\dot{M}_{hot}} \quad (19.185)$$

$$\dot{m}'_{hot,i} = \alpha \dot{m}_{hot,i} \quad (19.186)$$

$$\dot{m}'_{cold,i} = \dot{m}_{target,i} - \dot{m}'_{hot,i} \quad (19.187)$$

A new mixed water temperature is also recalculated at the equipment level.

Although water storage tanks can also have a maximum flow rate on the cold side, the cold flow rate is not limited in this implementation.

19.4.6.3 Calculate Connections Drain Temperature

At this point zone heat gains are calculated for all equipment in zones. The final drainwater temperatures and flow rates are determined for each piece of equipment by subtracting the lost heat and moisture (see above). The total drainwater temperature and flow rate for the subsystem are calculated:

$$\dot{M}_{drain} = \sum_i \dot{m}_{drain,i} \quad (19.188)$$

$$T_{\text{drain}} = \frac{\sum_i \dot{m}_{\text{drain},i} t_{\text{drain},i}}{\dot{M}_{\text{drain}}} \quad (19.189)$$

In the case of no drainwater heat recovery, the subsystem wastewater temperature, T_{waste} , is equal to the drainwater temperature, T_{drain} . (For drainwater heat recovery, see below.) The wastewater temperature and flow rate are propagated to the reclamation water storage tank, if specified.

19.4.6.4 Update Connections Nodes

Finally, if plant-coupled, the return water temperature, T_{return} , is passed on to the plant outlet node. T_{return} is taken from the cold water supply schedule or the water mains. The return flow rate is equal to the hot water supply flow rate in order to preserve a closed plant loop: $\dot{M}_{\text{return}} = \dot{M}_{\text{hot}}$.

For “connected” water equipment, the heating rate and energy that is required to supply the hot water for individual water equipment is calculated by the following equations.

$$Q = \dot{m}_{\text{hot}} c_p (T_{\text{hot}} - T_{\text{return}}) \quad (19.190)$$

$$\Delta E = Q \Delta t \quad (19.191)$$

where:

Q is the heating rate

c_p is the specific heat of water

ΔE is the heating energy

Δt is the time interval.

The heating rate and energy for the WaterUse:Connections is the sum of the values for its constituent water equipment objects. If the WaterUse:Connections object is stand-alone, all heating is assigned to “Purchased Heating” by the individual water equipment objects. If the WaterUse:Connections object is coupled to a plant loop, all heating is supplied by the plant loop equipment.

19.4.7 Drainwater Heat Recovery

Drainwater heat recovery adds one more complication to the water connections subsystem. A heat exchanger is added between the drain and the waste outlet to recover some heat from the water before it leaves the system. The heat is usually recovered by preheating the incoming makeup water from the mains.

The heat exchanger can be modeled as “ideal”, “counterflow”, or “crossflow”. One common type of drainwater heat exchanger is the gravity-film exchanger (GFX). The GFX can be approximated with a counterflow heat exchanger.

The destination of the preheated makeup water can be plumbed in three possible configurations: “plant”, “equipment”, “plant and equipment”. In the “plant” configuration, all preheated water flow is returned to the plant loop to match the makeup water for the hot water supply flow. In the “equipment” configuration, all preheated water flow is directed internally within the WaterUse:Connections object to provide the makeup water for the cold water supply flow for the

local water use equipment. In the “plant and equipment” configuration, the preheated water is split between both of the previous configurations. This is the only configuration where the flow rate is equal on both sides of the heat exchanger.

The new variables added here are defined as:

$\dot{M}_{recovery}$ is the makeup water mass flow rate in the heat exchanger

$T_{recovery}$ is the water temperature leaving the heat exchanger

T_{makeup} is the cold makeup water temperature supplied to various flows.

Another step is inserted into the solution method:

- Initialize Connections Temperatures
- Calculate Connections Flow Rates
- Calculate Connections Drain Temperature
- Update Connections Nodes
- ***Calculate Connections Heat Recovery***
- Update Connections Nodes

For the “equipment” and “plant and equipment” configurations, the solution requires iteration to solve because the preheated water leaving the heat exchanger is connected to the cold water supply water, creating a feedback loop.

19.4.7.1 Calculate Connections Heat Recovery

Based on the selected configuration, the flow rate through the heat exchanger is first determined. For the “plant” configuration, $\dot{M}_{recovery} = \dot{M}_{hot}$. For the “equipment” configuration, $\dot{M}_{recovery} = \dot{M}_{cold}$. For the “plant and equipment” configuration, $\dot{M}_{recovery} = \dot{M}_{hot} + \dot{M}_{cold}$.

The heat capacity rates on both sides of the heat exchanger are calculated and the minimum and maximum heat capacity rates, C_{min} and C_{max} , are determined.

$$C_{drain} = \dot{M}_{drain} c_p \quad (19.192)$$

$$C_{recovery} = \dot{M}_{recovery} c_p \quad (19.193)$$

$$C_{min} = MIN(C_{drain}, C_{recovery}) \quad (19.194)$$

$$C_{max} = MAX(C_{drain}, C_{recovery}) \quad (19.195)$$

$$R_c = \frac{C_{min}}{C_{max}} \quad (19.196)$$

where R_c is the heat capacity ratio.

The effectiveness ε is then calculated for the given type of heat exchanger. For the “ideal” heat exchanger, $\varepsilon = 1$.

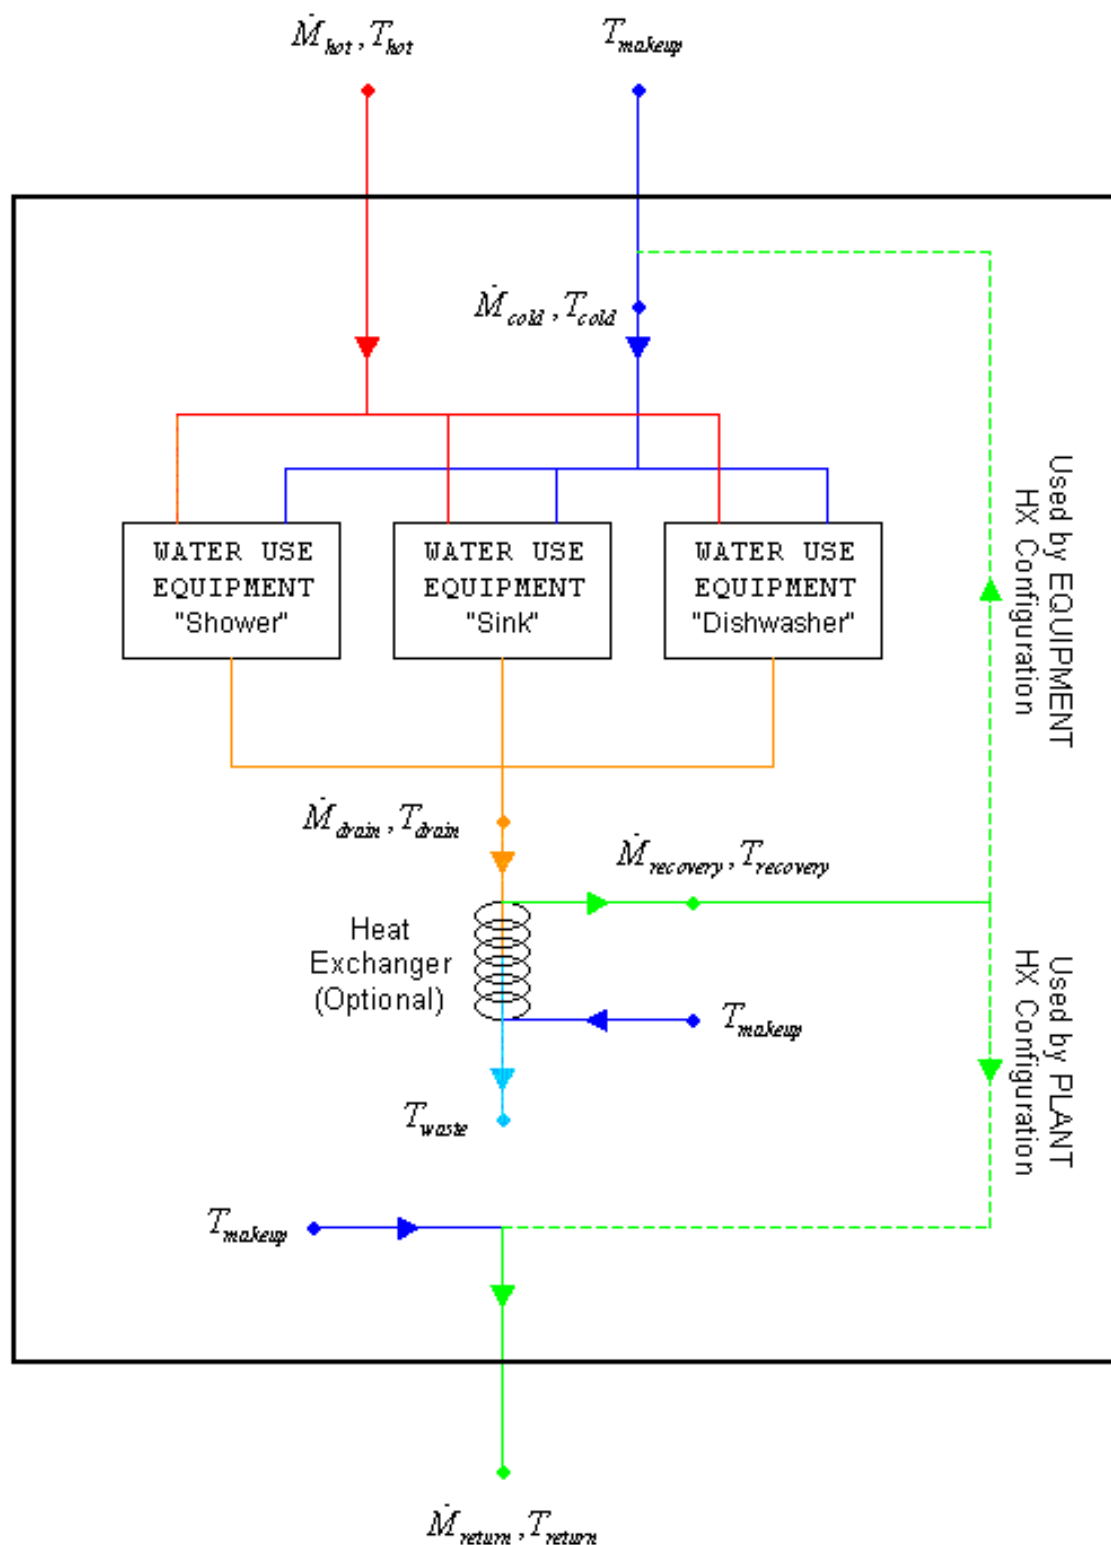

Figure 19.19: Water Use Connections Subsystem with Drainwater Heat Recovery

For the “counterflow” and “crossflow” heat exchangers, the effectiveness is calculated using the effectiveness-NTU method, where:

$$NTU = \frac{UA}{C_{min}} \quad (19.197)$$

For the “counterflow” heat exchanger:

$$\varepsilon = \frac{NTU}{1 + NTU}, \text{ if } R_c = 1 \quad (19.198)$$

$$\varepsilon = \frac{1 - \exp(-NTU(1 - R_c))}{1 - R_c \exp(-NTU(1 - R_c))}, \text{ if } R_c < 1 \quad (19.199)$$

For the “crossflow” heat exchanger:

$$\varepsilon = 1 - \exp\left(\frac{NTU^{0.22}}{R_c} (\exp(-R_c NTU^{0.78}) - 1)\right) \quad (19.200)$$

The heat recovery rate is then calculated.

$$Q_{recovery} = \varepsilon C_{min} (T_{drain} - T_{makeup}) \quad (19.201)$$

The outlet water temperatures can then be calculated for both sides of the heat exchanger.

$$T_{recovery} = T_{makeup} + \frac{Q_{recovery}}{\dot{M}_{recovery} c_p} \quad (19.202)$$

$$T_{waste} = T_{drain} - \frac{Q_{recovery}}{\dot{M}_{drain} c_p} \quad (19.203)$$

At each iteration the difference between $T_{recovery}$ and T_{cold} is compared and checked for convergence.

$$\Delta T_{error} = |T_{recovery} - T_{cold}| \quad (19.204)$$

Once the temperatures have converged, the solution is complete. T_{waste} is then passed on to a storage tank, if specified.

19.5 Zone Controls

19.5.1 Thermostatic Zone Control

The input object ZoneControl:Thermostat provides a way for the zone to be controlled to a specified temperature. ZoneControl:Thermostat references a control type schedule and one or more control type objects which in turn reference one or more setpoint schedules.

The control type schedule and the list of control type/name pairs are directly related. The schedule defines the type of control that is to be used during for each hour. Valid control types are

- 0 - Uncontrolled (No specification or default)
- 1 - Single Heating Setpoint
- 2 - Single Cooling SetPoint

3 - Single Heating/Cooling Setpoint

4 - Dual Setpoint (Heating and Cooling) with deadband

If the schedule referenced in the ZoneControl statement has a value of 4 for a particular hour, this indicates that during that hour “dual setpoint with deadband control” is to be used. The specific “dual setpoint with deadband” control object to be used is specified in the list of control type/name pairs. Then the specific control type objects reference the thermostat setpoint temperature schedule to be used. Because only one control can be specified for each control type in a ZoneControl statement, there are only four pairs possible in a particular ZoneControl type/name list. This is because individual controls can be defined hourly, thus giving the user a full range of flexibility. Since putting in the name of the control type directly in the schedule would be very cumbersome, the control types are assigned a number which is used in the hourly schedule profile.

For more information see ZoneControl:Thermostat in the Input Output Reference and succeeding sections in this document.

19.5.2 Zone Thermostats

The schema for the current set of four zone thermostats is given below. In each case, the keyword is accompanied by an identifying name and either one or two schedule names (depending on whether the control is a single or dual setpoint control). The schedule defines a temperature setpoint for the control type. The schedule would be defined through the standard schedule syntax described earlier in this document. For an uncontrolled zone no thermostat is specified or necessary. See the Input Output Reference for more details.

The control type schedule and the list of control type/name pairs are directly related. The schedule defines the type of control that is to be used during for each hour. Valid control types are shown in Table 19.11.

Table 19.11: Zone Thermostat Control Types

Control Type Value	Control Type Name
0	Uncontrolled (No specification or default)
1	Single Heating Setpoint (input object ThermostatSetpoint:SingleHeating)
2	Single Cooling SetPoint (input object ThermostatSetpoint:SingleCooling)
3	Single Heating/Cooling Setpoint (input object ThermostatSetpoint:SingleHeatingOrCooling)
4	Dual Setpoint (Heating and Cooling) with deadband (input object ThermostatSetpoint:DualSetpoint)

For the Uncontrolled case as shown in the pseudo code below, no heating or cooling requirement is calculated for the system to meet.

CASE (0)

! Uncontrolled Zone

LoadToHeatingSetPoint = 0.0

```

LoadToCoolingSetPoint = 0.0
ZoneSysEnergyDemand(ZoneNum)%TotalOutputRequired = 0.0

```

For the Single Heating Setpoint as shown in the pseudo code below, there would be a heating only thermostat. The setpoint can be scheduled and varied throughout the simulation but only heating is allowed with this control type.

```

CASE (SingleHeatingSetPoint)
! Determine zone load based on
! Qload + Qsys = 0 and Qsys = mCp(Tsys-Tzone)
! System Load Sign Convention:
!   - -> Cooling required to reach setpoint
!   + -> Heating required to reach setpoint
LoadToHeatingSetPoint = (TempDepZnLd(ZoneNum) *
                        TempZoneThermostatSetPoint(ZoneNum) -
                        TempIndZnLd(ZoneNum))
IF ((ZoneSysEnergyDemand(ZoneNum)%TotalOutputRequired - 1.0) < 0.0) THEN
  DeadBandOrSetback(ZoneNum) = .TRUE.
ENDIF

```

For the Single Cooling Setpoint there would be a cooling only thermostat. The setpoint can be scheduled and varied throughout the simulation but only cooling is allowed with this control type.

```

CASE (SingleCoolingSetPoint)
LoadToCoolingSetPoint = (TempDepZnLd(ZoneNum) *
                        TempZoneThermostatSetPoint(ZoneNum) -
                        TempIndZnLd(ZoneNum))
ZoneSysEnergyDemand(ZoneNum)%TotalOutputRequired = LoadToCoolingSetPoint
IF ((ZoneSysEnergyDemand(ZoneNum)%TotalOutputRequired + 1.0) > 0.0) THEN
  DeadBandOrSetback(ZoneNum) = .TRUE.
ENDIF

```

For the Single Heat Cool Setpoint there would be a cooling only thermostat there would be a heating and cooling thermostat. The setpoint can be scheduled and varied throughout the simulation for both heating and cooling. With this control type only 1 setpoint profile is needed or used.

```

CASE (SingleHeatCoolSetPoint)
LoadToHeatingSetPoint = (TempDepZnLd(ZoneNum) *
                        TempZoneThermostatSetPoint(ZoneNum) -
                        TempIndZnLd(ZoneNum))
LoadToCoolingSetPoint = (TempDepZnLd(ZoneNum) *
                        TempZoneThermostatSetPoint(ZoneNum) -
                        TempIndZnLd(ZoneNum))
! Possible combinations:
! 1/ LoadToHeatingSetPoint > 0 & LoadToCoolingSetPoint > 0 -> Heating required
! 2/ LoadToHeatingSetPoint > 0 & LoadToCoolingSetPoint < 0 -> Not Feasible
! 3/ LoadToHeatingSetPoint < 0 & LoadToCoolingSetPoint < 0 -> Cooling Required
! 4/ LoadToHeatingSetPoint < 0 & LoadToCoolingSetPoint > 0 -> Dead Band Operation
IF (LoadToHeatingSetPoint > 0.0 .AND. LoadToCoolingSetPoint > 0.0) THEN
  ZoneSysEnergyDemand(ZoneNum)%TotalOutputRequired = LoadToHeatingSetPoint
  ZoneSetPoint = ZoneThermostatSetPointLo(ZoneNum)

```

```

ELSEIF (LoadToHeatingSetPoint < 0.0 .AND. LoadToCoolingSetPoint < 0.0) THEN
  ZoneSysEnergyDemand(ZoneNum)%TotalOutputRequired = LoadToCoolingSetPoint
  ZoneSetPoint = ZoneThermostatSetPointHi(ZoneNum)
ELSEIF (LoadToHeatingSetPoint < 0.0 .AND. LoadToCoolingSetPoint > 0.0) THEN
  ZoneSysEnergyDemand(ZoneNum)%TotalOutputRequired = 0.0
  IF(Zone(ZoneNum)%SystemZoneNodeNumber > 0) THEN
    ZoneSetPoint = Node(Zone(ZoneNum)%SystemZoneNodeNumber)%Temp
  ENDIF
  DeadBandOrSetback(ZoneNum) = .TRUE.
ENDIF

```

For Dual Setpoint with DeadBand there would be a heating and cooling thermostat. For this case both a heating and cooling setpoint can be scheduled for any given time period. The setpoint can be scheduled and varied throughout the simulation for both heating and cooling.

CASE (DualSetPointWithDeadBand)

```

LoadToHeatingSetPoint = (TempDepZnLd(ZoneNum) *
  ZoneThermostatSetPointLo(ZoneNum) -
  TempIndZnLd(ZoneNum))
LoadToCoolingSetPoint = (TempDepZnLd(ZoneNum) *
  ZoneThermostatSetPointHi(ZoneNum) -
  TempIndZnLd(ZoneNum))

```

! Possible combinations:

- ! 1/ LoadToHeatingSetPoint > 0 & LoadToCoolingSetPoint > 0 -> Heating required
- ! 2/ LoadToHeatingSetPoint > 0 & LoadToCoolingSetPoint < 0 -> Not Feasible
- ! 3/ LoadToHeatingSetPoint < 0 & LoadToCoolingSetPoint < 0 -> Cooling Required
- ! 4/ LoadToHeatingSetPoint < 0 & LoadToCoolingSetPoint > 0 -> Dead Band Operation

```

IF (LoadToHeatingSetPoint > 0.0 .AND. LoadToCoolingSetPoint > 0.0) THEN
  ZoneSysEnergyDemand(ZoneNum)%TotalOutputRequired = LoadToHeatingSetPoint
  ZoneSetPoint = ZoneThermostatSetPointLo(ZoneNum)
ELSEIF (LoadToHeatingSetPoint < 0.0 .AND. LoadToCoolingSetPoint < 0.0) THEN
  ZoneSysEnergyDemand(ZoneNum)%TotalOutputRequired = LoadToCoolingSetPoint
  ZoneSetPoint = ZoneThermostatSetPointHi(ZoneNum)
ELSEIF (LoadToHeatingSetPoint < 0.0 .AND. LoadToCoolingSetPoint > 0.0) THEN
  ZoneSysEnergyDemand(ZoneNum)%TotalOutputRequired = 0.0
  IF(Zone(ZoneNum)%SystemZoneNodeNumber > 0) THEN
    ZoneSetPoint = Node(Zone(ZoneNum)%SystemZoneNodeNumber)%Temp
  ENDIF
  DeadBandOrSetback(ZoneNum) = .TRUE.
ENDIF

```

19.5.3 Operative Temperature Control

The input object ZoneControl:Thermostat:OperativeTemperature provides a model where the behavior of the zone thermostats described above can be modified to accommodate operative temperature control. The ZoneControl:Thermostat:OperativeTemperature input object is used to modify the behavior of any of the thermostatic control types described above. When this object is used,

the zone can be controlled by a weighted mixture of radiant and air temperatures (rather than just zone air temperatures).

In EnergyPlus, operative temperature, T_{OP} , is defined as:

$$T_{OP} = \gamma T_{MRT} + (1 - \gamma) T_{drybulb} \quad (19.205)$$

where:

γ is the radiative fraction

T_{MRT} is the mean radiant temperature for the thermal zone

$T_{drybulb}$ is the mean zone air temperature.

The radiative fraction γ is selected by the user and can be scheduled to vary during the simulation. A typical value is 0.5. The maximum value needs to be less than 0.9 and the minimum is 0.0. A value of 0.0 is the same as controlling on only zone air temperature. If air velocities are higher than 0.2 m/s, then lower values for radiative fraction might apply. Niu and Burnett (1998) cite International Standard ISO 77300 in recommending the values for this fraction listed in Table 19.12.

Table 19.12: Operative Temperature - Radiative Fraction vs Air Velocity

Air Velocity (m/s)	< 0.2	0.2 to 0.6	0.6 to 1.0
γ	0.5	0.4	0.3

The control is accomplished using the load to setpoint formulation that is fundamental to HVAC system control in EnergyPlus. Although real systems will not know the loads and operate on temperature-based control, EnergyPlus needs to be able to function at zone timesteps up to one hour and this is too long of a timeframe for true temperature-based zone control. Load-based control is an important method of determining the average HVAC system response to zone conditions over the time step. For operative temperature control, the same methods and routines are used for calculating loads to setpoints but the setpoints are shifted to emulate operative temperature control rather than air temperature control.

The user-defined setpoint for T_{OP} is an input in degrees Celsius. T_{MRT} is continually modeled by the full zone heat balance method and includes all the interactions between thermal loads and HVAC systems. A new setpoint for the zone's $T_{drybulb}$ is obtained for each zone timestep by rearranging the definition of T_{OP} to put $T_{drybulb}$ on the left hand side.

$$T_{drybulb, setpoint} = \frac{T_{OP, setpoint} - \gamma T_{MRT}}{(1 - \gamma)} \quad (19.206)$$

This adjustment to the target zone air drybulb temperature is made every timestep for every zone immediately after the setpoints are obtained from the schedule.

19.5.4 Temperature And Humidity Control

The input object `ZoneControl:Thermostat:TemperatureAndHumidity` is used to modify the behavior of `ZoneControl:Thermostat` objects (control types `ThermostatSetpoint:SingleCooling` and `ThermostatSetpoint:DualSetpoint` only) based on zone air humidity conditions. Specifically, this `TemperatureAndHumidity` zone control resets the `ZoneControl:Thermostat`'s cooling setpoint temperature downward when the zone air relative humidity exceeds the Dehumidifying Relative Humidity Setpoint defined in this object. The reduced cooling setpoint temperature typically results in longer cooling coil runtimes and additional dehumidification. While additional dehumidification (lower absolute humidity level in the zone air) may be achieved, the resulting dry-bulb temperature and absolute humidity of the zone air will determine if the zone air **relative humidity** is reduced.

The rate at which the cooling setpoint temperature is reduced is dictated by the user-specified Overcool Control Ratio. The maximum reduction in cooling setpoint temperature is defined by the user-entered Overcool Range, although the Overcool Range may be reduced from the user-defined value when this `TemperatureAndHumidity` control is used in tandem with a dual setpoint thermostat (see discussion below). Note that occupants are sensitive to overcooling and can experience discomfort if the overcool range is too large.

This control is accomplished using the load to setpoint formulation that is fundamental to HVAC system control in EnergyPlus. Although real systems will not know the loads and operate on temperature-based control, EnergyPlus needs to be able to function at zone timesteps up to one hour and this is too long of a timeframe for true temperature-based zone control. Load-based control is an important method of determining the average HVAC system response to zone conditions over the time step. For `TemperatureAndHumidity` control, the same methods and routines are used for calculating loads to setpoints but the cooling setpoint is shifted to emulate `TemperatureAndHumidity` control, as described above.

The overcool range limits the extent of the zone air temperature reduction below the cooling setpoint. When a dual setpoint thermostat is being modified by this `TemperatureAndHumidity` control, the maximum overcool range must be less than or equal to the temperature difference between the dual setpoint thermostat's cooling and heating setpoints:

$$\Delta T_{OvercoolRange,MAX} = MIN(\Delta T_{OvercoolRange}, \Delta T_{Setpoints}) \quad (19.207)$$

where:

$\Delta T_{OvercoolRange,MAX}$ is the maximum overcool range for the zone air (°C)

$\Delta T_{OvercoolRange}$ is a user input for the overcool range for the zone air (°C)

$\Delta T_{Setpoints}$ is the temperature difference between the cooling and heating setpoints (°C).

If a single cooling setpoint thermostat is being modified by this control, the maximum overcool range is equal to the user-defined overcool range.

The extent that the zone air relative humidity exceeds the user-entered dehumidifying relative humidity setpoint is given by:

$$\Delta\phi = MAX(0.0, \phi_{ZoneLagged} - \phi_{CSP}) \quad (19.208)$$

The actual cooling setpoint reduction (overcooling) is calculated for the condition when the zone air relative humidity exceeds the dehumidifying setpoint (i.e., $\Delta\phi > 0$), as described below:

$$\begin{aligned}
& \text{IF } (\Delta\phi > 0) \text{ THEN} \\
& \quad \Delta T_{\text{Overcool,Actual}} = \text{MIN}(\Delta T_{\text{OvercoolRange,MAX}}, \Delta\phi / \Delta\phi_{\text{adjust}}) \\
& \text{ELSE} \\
& \quad \Delta T_{\text{Overcool,Actual}} = 0 \\
& \text{ENDIF}
\end{aligned} \tag{19.209}$$

The cooling setpoint temperature is then adjusted as follows:

$$T_{CSP,adj} = (T_{CSP} - \Delta T_{\text{Overcool,Actual}}) \tag{19.210}$$

where:

$T_{CSP,adj}$ is the adjusted cooling setpoint temperature (°C)

T_{CSP} is the user input for zone air cooling setpoint temperature for the current time step (°C)

$\Delta\phi_{\text{adjust}}$ is the user-defined overcool control ratio (%/K)

$\Delta\phi$ is the difference between the zone air relative humidity and the user-defined dehumidifying setpoint (%)

$\phi_{\text{ZoneLagged}}$ is the zone air relative humidity calculated at the last system time step (%)

φ_{CSP} is the user input for the dehumidifying relative humidity setpoint at the current time step (%).

This adjusted cooling setpoint temperature is made every timestep for every zone immediately after the original thermostat setpoint is obtained from the user-defined setpoint schedule.

19.5.5 Humidistat

The input object ZoneControl:Humidistat provides a way for the zone to be controlled to a single relative humidity setpoint schedule, or dual humidity schedules (humidifying and dehumidifying with deadband). The schedules consist of relative humidities, expressed as a percentage (0-100), to be used for the zone moisture prediction calculation. Only one control statement can be specified for each zone. Individual relative humidity values can be defined for every time step, thus giving the user a full range of flexibility. For a single setpoint humidistat, if the control relative humidity is below the calculated load and the equipment specified can humidify then that equipment will try and meet the requirement. The opposite is true if the calculated value is above the setpoint and the equipment can dehumidify. For a dual setpoint humidistat, if the zone relative humidity is below the **humidifying** relative humidity setpoint and the equipment specified can humidify then that equipment will try and meet the zone's humidification load. The opposite is true if the zone relative humidity is above the **dehumidifying** relative humidity setpoint and the equipment can dehumidify.

If the ZoneControl:Humidistat is used by a furnace or unitary system then no other objects are required. The signal from the humidistat is used directly by that component. If the Zone Control:Humidistat is used to control a Humidifier or used in conjunction with the Controller:Simple object with control variable "TemperatureAndHumidityRatio", then either the "SetpointManager:SingleZone:Humidity:Minimum", "SetpointManager:MultiZone:Humidity:Minimum", "SetpointManager:SingleZone:Humidity:Maximum" or "SetpointManager:MultiZone:Humidity:Maximum" objects are required to determine a setpoint for those components to meet for the single setpoint humidistat. For a dual setpoint humidistat, a

minimum humidity setpoint manager object (“SetpointManager:SingleZone:Humidity:Minimum” or “SetpointManager:MultiZone:Humidity:Minimum”) and a maximum humidity setpoint manager object (“SetpointManager:SingleZone:Humidity:Maximum” or “SetpointManager:MultiZone:Humidity:Maximum”) are required to determine the setpoints for the corresponding humidification and dehumidification components. Note that the “SetpointManager:Scheduled” object can also be used to directly set humidity ratio setpoints on the exit node of the humidifier component.

For the single setpoint humidistat case, the model takes into account all of the moisture gains and/or losses from sources except the HVAC system contribution, and then calculates a moisture removal or addition rate based on the provided setpoint value, like the temperature predictor. The algorithm uses a 3rd Order derivative to predict zone moisture addition or removal to smooth the changes using the zone air capacitance. Positive values of moisture load mean that this amount of moisture must be added to the zone to reach the setpoint. Negative values represent the amount of moisture that must be removed by the system.

$$\text{MoistLoadHumidSetPoint} = \text{massflow} \cdot \text{HumidityRatio} = \text{kg air/s} \cdot \text{kg H}_2\text{O/kg air} = \text{kg H}_2\text{O/s} \quad (19.211)$$

This routine also calculates the zone required humidity ratio, Wsetpoint, which is required and takes into account the zone multiplier. At this time the Wsp is not stored in a derived type to make it available for SetpointManagers. It was setup to be analogous to the temperature thermostat.

For the dual setpoint humidistat case, the model takes into account all of the moisture gains and/or losses from sources except the HVAC system contribution, and then calculates moisture addition and removal rates based on the provided humidifying and dehumidifying setpoint values, like the temperature predictor. The algorithm uses a Third Order Backward Difference, Analytical Solution, or Euler Method in subroutine CalcPredictedHumidityRatio to predict zone moisture addition and removal to smooth the changes using the zone air capacitance. The program calculates the humidifying (addition) and dehumidifying (removal) moisture loads based on the specified humidifying and dehumidifying setpoints, respectively. The calculated humidifying moisture load is passed to subroutine CalcSingZoneMinHumSetPoint and CalcMultiZoneMinHumSetPoint in the SetpointManager module to calculate the requested supply air humidity ratio at the setpoint node (Ref. SetpointManager:SingleZone:Humidity:Minimum and SetpointManager:MultiZone:Humidity:Minimum objects). The calculated dehumidifying moisture load is passed to subroutine CalcSingZoneMaxHumSetPoint and CalcMultiZoneMaxHumSetPoint in the SetpointManager module to calculate the requested supply air humidity ratio at the setpoint node (Ref. SetpointManager:SingleZone:Humidity:Maximum and SetpointManager:MultiZone:Humidity:Maximum objects). At the same time, the dehumidifying load is also passed directly to a furnace or unitary system if it is defined for the simulation, and that system will operate to meet this load based on its configuration and control settings.

19.5.6 Thermal Comfort Zone Control

The input object ZoneControl:Thermostat:ThermalComfort provides a way for the zone to be controlled to a specified temperature based on a selected thermal comfort model. ZoneControl:Thermostat:ThermalComfort references a thermal comfort control type schedule and one or more thermal comfort control type objects which in turn reference one or more setpoint schedules.

The thermal comfort control type schedule and the list of thermal comfort control type/name

pairs are directly related. The schedule defines the type of thermal comfort control that is to be used during for each simulation time step. Valid control types are shown in Table 19.13.

Table 19.13: Thermal Comfort Zone Control Types

Control Type	Control Type Name/Object
0	No thermal comfort control
1	ThermostatSetpoint:ThermalComfort:Fanger:SingleHeating
2	ThermostatSetpoint:ThermalComfort:Fanger:SingleCooling
3	ThermostatSetpoint:ThermalComfort:Fanger:SingleHeatingOrCooling
4	ThermostatSetpoint:ThermalComfort:Fanger:DualSetpoint

If the schedule referenced in the ZoneControl statement has a value of 4 for a particular time step, this indicates that during that time step “ThermostatSetpoint:ThermalComfort:Fanger:DualSetpoint” control is to be used. The specific “ThermostatSetpoint:ThermalComfort:Fanger:DualSetpoint” control object to be used is specified in the list of thermal comfort control type/name pairs. Then the specific thermal comfort control type objects reference the thermal comfort PMV setpoint schedule to be used. Because only one thermal comfort control can be specified for each thermal comfort control type in a ZoneControl statement, there are only four pairs possible in a particular ZoneControl type/name list. This is because individual thermal comfort controls can be defined for specific times, thus giving the user a full range of flexibility. Since putting in the name of the thermal comfort control type directly in the schedule would be very cumbersome, the thermal comfort control types are assigned a number which is used in the schedule profile.

For more information see ZoneControl:Thermostat:ThermalComfort in the InputOutput Reference and Zone Fanger Thermal Comfort in the Engineering Documentation.

19.5.6.1 Zone Control Based on Fanger Thermal Comfort

The syntax for the current set (4) of zone thermal comfort control types is given below. In each case, the keyword is accompanied by an identifying name and either one or two schedule names (depending on whether the control type is a single or dual setpoint control). The schedule defines a PMV setpoint for the control type. The schedule would be defined through the standard schedule syntax described earlier in this document. For an uncontrolled thermal comfort zone, no Fanger thermal comfort object is specified or necessary. See the Input Output Reference for more details.

The control type schedule and the list of control type/name pairs are directly related. The schedule defines the type of control that is to be used during for each hour. Valid control types are shown in Table 19.14.

Table 19.14: Types of Fanger Thermal Comfort Zone Control

Control Type	Control Type Name/Object
0	No thermal comfort control
1	ThermostatSetpoint:ThermalComfort:Fanger:SingleHeating

Control Type	Control Type Name/Object
2	ThermostatSetpoint:ThermalComfort:Fanger:SingleCooling
3	ThermostatSetpoint:ThermalComfort:Fanger:SingleHeatingOrCooling
4	ThermostatSetpoint:ThermalComfort:Fanger:DualSetpoint

For the no thermal comfort control (uncontrolled) case, the control will revert to thermostat control if specified. If the thermal comfort control is specified as “uncontrolled” for a particular period and thermostat control is not specified in the input, then conditions will float.

For the ThermostatSetpoint:ThermalComfort:Fanger:SingleHeating case there would be a heating only thermal comfort setpoint temperature. The setpoint is calculated based on the selected thermal comfort model and varied throughout the simulation but only heating is allowed with this thermal comfort control type.

CASE (Single Thermal Comfort Heating Setpoint:Fanger)

TempControlType(ZoneNum) = SingleHeatingSetpoint

TempZoneThermostatSetPoint(ZoneNum) = Calculated Zone Setpoint from Fanger heating setpoint PMV

For the ThermostatSetpoint:ThermalComfort:Fanger:SingleCooling case there would be a cooling only thermal comfort setpoint temperature. The setpoint is calculated based on the selected thermal comfort model and varied throughout the simulation but only cooling is allowed with this thermal comfort control type.

CASE (Single Thermal Comfort Cooling Setpoint:Fanger)

TempControlType(ZoneNum) = SingleCoolingSetPoint

TempZoneThermostatSetPoint(ZoneNum) = Calculated Zone Setpoint from Fanger cooling setpoint PMV

For the ThermostatSetpoint:ThermalComfort:Fanger:SingleHeatingOrCooling there would be heating and cooling thermal comfort zone control objects. The setpoint is calculated based on the selected thermal comfort model and varied throughout the simulation for both heating and cooling. With this thermal comfort control type only 1 setpoint profile is needed or used.

CASE (Single Thermal Comfort Heating Cooling Setpoint:Fanger)

TempControlType(ZoneNum) = SingleHeatCoolSetPoint

TempZoneThermostatSetPoint(ZoneNum) = Calculated Zone Setpoint from Fanger heating and cooling setpoint PMV

For ThermostatSetpoint:ThermalComfort:Fanger:DualSetpoint there would be heating and cooling thermal comfort control objects. For this case both a heating and cooling setpoint can be calculated based on the selected thermal comfort model for any given time period. The thermal comfort setpoint temperature can be varied throughout the simulation for both heating and cooling.

CASE (Dual Thermal Comfort Setpoint with Deadband:Fanger)

TempControlType(ZoneNum) = DualSetPointWithDeadBand

ZoneThermostatSetPointLo(ZoneNum) = Calculated Zone Setpoint from Fanger heating setpoint PMV

ZoneThermostatSetPointHi(ZoneNum) = Calculated Zone Setpoint from Fanger cooling setpoint PMV

19.6 Zone Equipment and Zone Forced Air Units

19.6.1 Air Distribution Terminal Unit

19.6.1.1 Overview

The ZoneHVAC:AirDistributionUnit is a special piece of zone equipment – it connects centrally conditioned air with a zone. It encompasses the various types of air terminal units in EnergyPlus: *AirTerminal:DualDuct:ConstantVolume*, *AirTerminal:SingleDuct:VAV:Reheat*, etc. It is a generalized component that accesses the calculations for the different types of air terminal unit.

19.6.1.2 Model

The air distribution function is encapsulated in the module *ZoneAirEquipmentManager*. The object and module function only to invoke the individual air terminal unit simulations.

19.6.1.3 Inputs and Data

The data for this unit consists of the unit name, the air outlet node name (which should be the same as one of the zone inlet nodes), the type of air terminal unit (air distribution equipment), and the name of the air terminal unit.

All input data for air distribution units is stored in the array *AirDistUnit* in data module *DataDefineEquip*.

19.6.1.4 Calculation

There is no calculation associated with ZoneHVAC:AirDistributionUnit.

19.6.1.5 Simulation and Control

SimZoneAirLoopEquipment in module *ZoneAirEquipmentManager* calls the individual air terminal unit simulations.

19.6.2 Air Terminal Single Duct Mixer

19.6.2.1 Overview

The mixer object *AirTerminal:SingleDuct:Mixer* provides a means for using a ZoneHVAC equipment as a terminal unit by mixing central system conditioned air with the inlet or supply side air stream of the ZoneHVAC equipment. Usually the central system would be a Direct Outside Air System (DOAS) providing centrally conditioned ventilation air to the controlled zones. The inlet or supply side connection type is specified by user.

19.6.2.2 Model

The mixer uses the equations for adiabatic mixing of two moist air streams. Namely, dry air mass balance, water mass balance, and enthalpy balance. For inlet side mixer connection, the primary air and outlet air flow rates are known, and the condition of the primary and secondary air streams are also known. The mass balance yields the secondary air mass flow rate, and the outlet conditions

are determined from enthalpy and water mass balance. For the supply side mixer connection, the primary and secondary air stream conditions and flow rates are known so the outlet condition and flow rate is calculated.

19.6.2.3 Inputs and Data

The only input data are the name and type of the ZoneHVAC equipment unit plus the node names of the primary and the secondary air nodes and the outlet air node. No flow rate data is needed.

All input data for the inlet and supply side mixer units is stored in the data structure *SysAT-Mixer*.

19.6.2.4 Calculation

The following equations for the mixing of two moist air streams are used:

$$\dot{m}_{da1}h_1 + \dot{m}_{da2}h_2 = \dot{m}_{da3}h_3 \quad (19.212)$$

$$\dot{m}_{da1} + \dot{m}_{da2} = \dot{m}_{da3} \quad (19.213)$$

$$\dot{m}_{da1}W_1 + \dot{m}_{da2}W_2 = \dot{m}_{da3}W_3 \quad (19.214)$$

The mixed air temperature is determined using the following psychrometric function:

$$T_3 = PsyHFnTdbW(h_3, w_3) \quad (19.215)$$

where:

\dot{m}_{da} is the dry air mass flow rate (kg/s)

h is the specific enthalpy (J/kg)

T is the temperature (°C)

W is the humidity ratio (kg of water/kg of dry air).

For a mixer unit connected to the inlet side of a ZoneHVAC equipment, the outlet air mass flow rate has been set by the zone HVAC equipment. The air mass flow rate of one of the inlets - the primary air from the central system - is also known. So the air mass balance equation is used to obtain the secondary air mass flow rate.

The inlet conditions - specific enthalpy and humidity ratio - for both inlet air streams are known. Now that both inlet air streams' mass flow rate is known, the enthalpy and water mass balance equations are used to get the outlet conditions.

For a mixer unit connected to the supply side of a ZoneHVAC equipment, the conditions and flow rates of the primary air and secondary air streams are known, are taken from the inlet nodes' data. The balance equations are then used to calculate the outlet flow rate and conditions.

19.6.2.5 Simulation and Control

The mixer model is invoked from within the zone HVAC model. Basically the mixer becomes a subcomponent of the zone HVAC equipment model. This allows the zone unit to allow for the mixing of central supply air with its inlet or supply air stream of the ZoneHVAC equipment in calculating how much cooling or heating it needs to do in order to meet the zone load.

19.6.3 Simple Duct Leakage Model

19.6.3.1 Overview

The input object ZoneHVAC:AirDistributionUnit also provides access to a model for duct leakage that can be a significant source of energy inefficiency in forced-air HVAC systems. Evaluating duct leakage energy losses can involve considerable user effort and computer resources if an airflow network is defined through a detailed description of the system components and airflow paths (including leakage paths). A nonlinear pressure-based solver is used to solve for pressures and flow rates in the network. By making certain assumptions and approximations for certain well defined configurations, however, it is possible to obtain accurate results with a simple mass and energy balance calculation and thus avoid the input and calculation costs of doing a full pressure-based airflow network simulation.

The Simple Duct Leakage Model (SDLM) assumes a central VAV air conditioning system with a constant static pressure setpoint. The model assumes that the leaks are in the supply ducts and that the system returns air through a ceiling plenum that contains the ducts. Thus, the ducts leak into the return plenum, and this part of the supply does not reach the conditioned zones. With the additional assumptions described below, it is possible to model this configuration with heat and mass balance equations and avoid the use of a nonlinear pressure-based solver. In the EnergyPlus context, this means that use of AirflowNetwork is avoided and the leakage calculations are obtained in the course of the normal thermal simulation.

19.6.3.2 Principles and Description

Constant Flow Rate

The airflow rate through a duct leak is a function of the pressure difference between the duct and the surrounding space:

$$\dot{V}_{leak} = C_1 \cdot \Delta p_{duct-space}^n \quad (19.216)$$

The exponent n is 0.5 for leaks that look like orifices (holes that are large relative to the thickness of the duct wall); for leaks that resemble cracks (e.g., lap joints), n is approximately 0.6 to 0.65.

For a duct with constant flow rate and a linear pressure drop through the duct, the average static pressure in the duct will equal half of the duct static pressure drop. Assuming turbulent flow in the duct, the duct pressure drop is proportional to the square of the airflow through the duct. This can be expressed as:

$$\Delta p_{duct-space} = \frac{\Delta p_{duct}}{2} = C_2 \left(\frac{\dot{V}_{duct}^2}{2} \right) \quad (19.217)$$

Combining equations and assuming the leaks are large holes (n equals 0.5) gives:

$$\dot{V}_{leak} = C_1 \cdot \Delta p_{duct-space}^{0.5} = C_3 \cdot \dot{V}_{duct} \quad (19.218)$$

where:

$$C_3 = C_1 \cdot (C_2/2)^{0.5} \quad (19.219)$$

Thus the leakage fraction C_3 remains constant regardless of the duct flow rate or static pressure. This result depends on the following assumptions:

- the duct airflow is turbulent;
- the duct pressure varies linearly along the duct;
- the average duct pressure approximates the pressure drop across the duct;
- the leaks are large and have pressure exponent 0.5.

Effects of Constant Pressure Upstream and Variable Flow and Pressure Downstream

Commonly VAV systems maintain a constant static pressure at some point in the duct system upstream of the VAV terminal units. That is, airflow rate will vary depending on the cooling requirement, but a constant pressure will be maintained at the static pressure sensor. Consequently, the leakage flow for a leak upstream of the VAV boxes will be approximately constant. Or to put it another way, the leakage fraction will vary in proportion to the flow rate.

For leaks downstream of the VAV terminal units, the airflow through the duct and the pressure in the downstream duct will vary as the box damper modulates in response to the differential between the room temperature and the thermostat setpoint. In this case, the situation is similar to the constant flow case: for an orifice-like leak, the pressure difference across the leak will vary linearly with the air speed (or flow rate); i.e., the leakage fraction will be approximately constant.

SDLM

For SDLM, our leakage model is then:

- for leaks upstream of the terminal units, the leakage flow rate will be constant;
- for leaks downstream of the terminal units, the leakage fraction will be constant.

This model assumes, in addition to the assumptions given above, that the VAV system is controlled to a constant static pressure setpoint. In EnergyPlus, SDLM is not currently applicable to systems using static pressure reset. Using SDLM would require knowledge of static pressure as a function of system air flow rate.

19.6.3.3 Inputs and Data

User data for the SDLM is entered through The ZoneHVAC:AirDistributionUnit (ADU) object. There are 2 data items per ADU:

1. the upstream nominal leakage fraction;
2. the downstream fixed leakage fraction.

Both inputs are leakage fractions. Input (1) is the leakage fraction at design flow rate, which together can be used to determine the constant leakage flow rate upstream of the VAV boxes; this leakage fraction varies with the flow rate. Input (2) is a fixed leakage fraction and is constant as the flow rate varies.

19.6.3.4 Implementation

The various zone mass flow rates are related in the following manner.

$$\dot{m}_{s,us} = \dot{m}_{tu} + \dot{m}_{lk,us} \quad (19.220)$$

$$\dot{m}_{tu} = \dot{m}_{lk,ds} + \dot{m}_{s,z} \quad (19.221)$$

$$\dot{m}_{lk,us} = Frac_{us} \cdot \dot{m}_{s,us,max} \quad (19.222)$$

$$\dot{m}_{lk,ds} = Frac_{ds} \cdot \dot{m}_{tu} \quad (19.223)$$

where:

$\dot{m}_{s,us}$ is the constant zone supply air mass flow rate upstream of the leaks (kg/s)

\dot{m}_{tu} is the air mass flow rate through the terminal unit (kg/s)

$\dot{m}_{lk,us}$ is the upstream leakage air mass flow rate (kg/s)

$\dot{m}_{lk,ds}$ is the downstream leakage air mass flow rate (kg/s)

$\dot{m}_{s,us,max}$ is the maximum upstream supply air mass flow rate (program input) (kg/s)

$\dot{m}_{s,z}$ is the supply air mass flow rate delivered to the zone (kg/s)

$Frac_{us}$ is the design upstream leakage fraction (program input)

$Frac_{ds}$ is the constant downstream leakage fraction (program input)

\dot{m}_{tu} is calculated in the VAV terminal unit model in the usual manner: the mass flow rate is varied to meet the zone load. The limits on the mass flow rate variation are set by the $\dot{m}_{MaxAvail}$ and $\dot{m}_{MinAvail}$ values stored at the terminal unit's air inlet node. To account for upstream leakage the maximum air mass flow rate available is reset to:

$$\dot{m}'_{MaxAvail} = \dot{m}_{MaxAvail} - \dot{m}_{lk,us} \quad (19.224)$$

Downstream leakage must also be accounted for because not all of \dot{m}_{tu} will reach the zone. This is done by having \dot{m}_{tu} meet an adjusted zone load:

$$\dot{Q}_{z,adjusted} = \frac{1}{1 - Frac_{ds}} \dot{Q}_z \quad (19.225)$$

where \dot{Q}_z (W) is the actual zone load (met by $\dot{m}_{s,z}$) and $\dot{Q}_{z,adjusted}$ is the load used in the VAV terminal unit model to obtain \dot{m}_{tu} .

Once \dot{m}_{tu} is known, all the other flow rates can be calculated. $\dot{m}_{s,us}$ is assigned to the air distribution unit's air inlet node and $\dot{m}_{s,z}$ is assigned to the unit's air outlet node. Thus, air mass flow is not conserved through the unit: the two air leakage flow rates disappear. These two vanished flow rates are stored in the air distribution unit data structure. When the downstream return air plenum mass and energy balances are calculated, the leakage flow rate data is accessed and added back in as inlets to the return air plenum. Thus, the overall air system preserves a mass balance.

19.6.4 Fan Coil Unit

19.6.4.1 Overview

The input object `ZoneHVAC:FourPipeFanCoil` provides a model for a 4 pipe fan coil zonal hydronic unit that can supply heating and cooling to a zone. It contains a hot water or electric heating coil, a chilled water coil, and a fan. It can supply a fixed amount of outdoor air, but cannot operate in an economizer mode. The fan runs at constant speed – control is achieved by throttling the hot or cold water flow. The fan coil configuration and control is rather limited. The fan position is always *blow-through*, control is always by varying the water flow, never by holding the water flow constant and cycling the fan.

19.6.4.2 Model

The 4 pipe fan coil unit is modeled as a compound component consisting of 4 sub-components: an outdoor air mixer, a fan, a cooling coil, and a heating coil. In terms of EnergyPlus objects these are:

1. *OutdoorAir:Mixer*
2. *Fan:ConstantVolume*
3. *Coil:Cooling:Water*, *Coil:Cooling:Water:DetailedGeometry*, or *CoilSystem:Cooling:Water:HeatExchangerAssisted*
4. *Coil:Heating:Water* or *Coil:Heating:Electric*

The unit is a forward model: its inputs are defined by the state of its inlets: namely its 2 air streams – recirculated and outdoor air. The outputs of the model are the conditions of the outlet air stream: flow rate, temperature and humidity ratio. The unit data and simulation are encapsulated in the module *FanCoilUnits*.

19.6.4.3 Inputs and Data

The user describes the 4 pipe fan coil unit by inputting the names of the outdoor air mixer, the fan, the heating coil, and the cooling coil. The heating and cooling coil types must also be specified.

The unit is connected to the overall HVAC system by specifying node names for the unit air inlet (for recirculated air) node, air outlet node, outdoor air node, relief node, inlet hot water node,

and inlet chilled water node. The individual components comprising the fan coil must also be input and connected together properly. Specifically the outdoor air mixer mixed air node must be the same as the fan inlet node; the fan outlet node must be the same as the cooling coil air inlet node; the cooling coil air outlet node must be the same as the heating coil air inlet node; and the heating coil air outlet node must be the same as the unit air outlet node; the outdoor air mixer inlet nodes must match the unit inlet nodes; and the outdoor air mixer relief node must match the unit relief node.

The user needs to also specify (unless the unit is autosized) various maximum flow rates: the supply air flow rate, the outdoor air inlet flow rate, the maximum (and minimum) chilled water flow rate, and the maximum (and minimum) hot water flow rate. Heating and cooling convergence tolerances need to be specified or defaulted. And there is an on/off availability schedule for the unit.

All the input data for the fan coil unit is stored in the array *FanCoil*.

19.6.4.4 Calculation

Given the needed inputs, the output is calculated in subroutine *Calc4PipeFanCoil*. The temperature, humidity ratio and flow rate of the recirculated and outdoor air streams are taken from the inlet air nodes. The inlet hot and chilled water flow rates have been set by local controllers – temperatures are taken from the inlet water nodes. Then:

1. The outdoor air mixer is simulated (Call *SimOAMixer*);
2. the fan is simulated (Call *SimulateFanComponents*);
3. the cooling coil is simulated (Call *SimulateWaterCoilComponents* or *SimHXAssistedCooling-Coil*);
4. the heating coil is simulated (Call *SimulateWaterCoilComponents* or *SimulateHeatingCoil-Components*).

The load met (sensible cooling or heating) is calculated and passed back to the calling routine:

$$\dot{Q}_{sens,out} = \dot{m}_{tot} (\text{PsyHFnTdbW}(T_{out}, W_{in}) - \text{PsyHFnTdbW}(T_{in}, W_{in})) \quad (19.226)$$

where *PsyHFnTdbW* is the EnergyPlus function for calculating the specific enthalpy of air given the drybulb temperature and the humidity ratio. The subscript *in* indicates the conditions at the inlet recirculated air node.

19.6.4.5 Simulation and Control

From the result of the zone simulation we have the current heating/cooling demand on the unit $\dot{Q}_{z,req}$. The first step is to decide whether the unit is on for the current time step. If the load is less than 1 watt or the flow rate is less than .001 kg/s, the unit is off. If the availability schedule is off, the mass flow rate is set to zero, so the second condition holds. When the unit is off there will be no air flow through the unit and outlet conditions will be equal to inlet conditions.

$\dot{Q}_{z,req}$ is not the demand on the heating or cooling coil. To obtain the actual coil load, we need to calculate the unit output with no heating or cooling by the coils ($\dot{Q}_{unit,no\ hc}$). We obtain this by calling *Calc4PipeFanCoil* with the water flow rates set to zero. Then the coil loads are calculated:

$$\dot{Q}_{hc} = \dot{Q}_{z,hsp} - \dot{Q}_{unit,no\ hc} \quad (19.227)$$

$$\dot{Q}_{cc} = \dot{Q}_{z,csp} - \dot{Q}_{unit,no\ hc} \quad (19.228)$$

where \dot{Q}_{hc} is the heating coil load, $\dot{Q}_{z,hsp}$ is the current zone load to the heating setpoint, \dot{Q}_{cc} is the cooling coil load, and $\dot{Q}_{z,csp}$ is the current zone load to the cooling setpoint.

If the unit is on and $\dot{Q}_{cc} < 0$ and the thermostat type is not “single heating setpoint”, *ControlCompOutput* is called with the control node set to the cold water inlet node. *ControlCompOutput* is a general component control routine. In this case calls *Calc4PipeFanCoil* repeatedly while varying the cold water flow rate and minimizing $(\dot{Q}_{sens,out} - \dot{Q}_{z,csp})/\dot{Q}_{z,csp}$ to within the cooling convergence tolerance. Similarly if the unit is on and $\dot{Q}_{hc} > 0$ and the thermostat type is not “single cooling setpoint”, *ControlCompOutput* is called with the control node set to the hot water inlet node (for hydronic heating coil only). *ControlCompOutput* varies the hot water flow rate or the electric heating coil part-load ratio is varied to minimize $(\dot{Q}_{sens,out} - \dot{Q}_{z,hsp})/\dot{Q}_{z,hsp}$ to within the heating tolerance. *ControlCompOutput* executes a slow but safe interval halving algorithm to do its minimization. Once control is achieved, the total cooling/heating output is calculated:

$$\dot{Q}_{tot,out} = \dot{m} \cdot (PsyHFnTdbW(T_{out}, W_{out}) - PsyHFnTdbW(T_{in}, W_{in})) \quad (19.229)$$

19.6.4.5.1 Multi-Speed Fan In FanCoil

When modeling multi-speed fan in FanCoil unit, capacity is modulated using speed ratio or part load ratio. The supply air fan speed is varied while operating the coils at maximum water flow. When there is no system load to meet, the water control valve is fully closed. When the FanCoil fan is cycling between two consecutive fan speed levels a speed ratio is calculated, but when the FanCoil unit cycles between the minimum fan speed and off-position, then part load ratio is calculated. The fan may be off or run continuously at lowest speed to provide ventilation air depending the fan operating schedule specified. When the FanCoil is operating at the lowest fan speed (Speed = 1), the water flow rate is reported as the average for the time step by multiplying the maximum water flow by part load ratio. The speed ratio and part-load ratio are calculated such that the FanCoil unit satisfies the required system zone cooling or heating load. The set of equations used for the multi-speed fan capacity control methods in FanCoil unit are summarized next.

Cycling Between Speeds

When the supply fan is cycling between consecutive speeds, then the speed ratio (SR) and the average mass flow rate are calculated as follows:

$$SR_n = Abs(SystemLoad - FullLoadOutput_{n-1}) / Abs(FullLoadOutput_n - FullLoadOutput_{n-1}) \quad (19.230)$$

$$\dot{m} = \dot{m}_{on,n} SR_n + \dot{m}_{on,n-1} (1 - SR_n) \quad (19.231)$$

$$\dot{m}w = \dot{m}_{w,max} \quad (19.232)$$

Cycling OnOff at Lowest Speed

The average supply air flow rate calculation when the fan is running at the lowest fan speed level depends on the fan operating schedule and load. The fan coil unit part load ratio is given by:

$$PLR = Abs(SystemLoad - NoLoadOutput) / Abs(FullLoadOutput_1 - NoLoadOutput) \quad (19.233)$$

Continuous Fan

$$\dot{m} = \dot{m}_{on,1} PLR + \dot{m}_{off} (1 - PLR) \quad (19.234)$$

Cycling Fan:

$$\begin{aligned} \dot{m} &= \dot{m}_{on,1} PLR \\ \dot{m}_w &= \dot{m}_{w,max} PLR \end{aligned} \quad (19.235)$$

where:

SR_n is the speed ratio of the fan coil unit at speed n

PLR is the part load ratio of the fan coil unit at speed 1

\dot{m} is the average mass flow rate of supply air (kg/s)

$\dot{m}_{on,n-1}$ is the mass flow rate of supply air at fan speed level n-1 (kg/s)

$\dot{m}_{on,n}$ is the mass flow rate of supply air at fan speed level n (kg/s)

\dot{m}_{off} is the mass flow rate of supply air when the coils are off (kg/s)

\dot{m}_w is the average mass flow rate of chilled or hot water (kg/s)

$\dot{m}_{w,max}$ is the maximum or full mass flow rate of chilled or hot water (kg/s)

$SystemLoad$ is the system load to be met by the fan coil unit (W)

$FullLoadOutput_{n-1}$ is the fully load fan coil unit output at fan speed level n-1 (W)

$FullLoadOutput_n$ is the fully load fan coil unit output at fan speed level n (W).

19.6.4.5.2 ASHRAE 90.1

The ASHRAE90.1 control method uses a simple technique to adjust fan speed based on zone design sensible load. The specific section of the Standard is described as:

Section 6.4.3.10 "(Single Zone Variable-Air-Volume "Controls) of ASHRAE Standard 90.1-2010.
HVAC systems shall have variable airflow controls as follows:

- (a) Air-handling and fan-coil units with chilled-water cooling coils and supply fans with motors greater than or equal to 5 hp shall have their supply fans controlled by two-speed motors or variable-speed drives. At cooling demands less than or equal to 50%, the supply fan controls shall be able to reduce the airflow to no greater than the larger of the following:
 - One-half of the full fan speed, or
 - The volume of outdoor air required to meet the ventilation requirements of Standard 62.1.
- (b) Effective January 1, 2012, all air-conditioning equipment and air-handling units with direct expansion cooling and a cooling capacity at AHRI conditions greater than or equal to 110,000 Btu/h that serve single zones shall have their supply fans controlled by two-speed motors or variable-speed drives. At cooling demands less than or equal to 50%, the supply fan controls shall be able to reduce the airflow to no greater than the larger of the following:
 - Two-thirds of the full fan speed, or
 - The volume of outdoor air required to meet the ventilation requirements of Standard 62.1.

This control method assumes that a simulation sizing run is performed to determine the zone design sensible cooling and heating load $\dot{Q}_{z,design}$.

For fan coil units, the limit used to determine if reduced zone loads are met with reduced fan speed is the fan coil's Low Speed Supply Air Flow Ratio input.

$$\dot{Q}_{reduced} = \dot{Q}_{z,design} * Ratio_{fan,low\ speed} \quad (19.236)$$

If the zone load, $\dot{Q}_{z,req}$, is less than $\dot{Q}_{reduced}$ then the fan is maintained at the reduced speed while the water coils (or electric heating coil) are modulated to meet the zone load.

If the zone load is greater than the design zone sensible load, $\dot{Q}_{z,design}$, the fan will operate at the maximum supply air flow rate and the water or electric heating coils will modulate to meet the zone load.

If the zone load is between these two extremes, the fan and coil will modulate to meet the zone load.

An example of the ASHRAE 90.1 control method is provided in Figure 19.20. In this figure, the X-axis represents the zone cooling (-) or heating (+) load.

Figure 19.20: Single-Zone VAV Fan Control for Fan Coil Units

19.6.5 Window Air Conditioner

19.6.5.1 Overview

The input object ZoneHVAC:WindowAirConditioner provides a model for a window air conditioner unit that is a packaged unit that supplies cooling to a zone (it is part of zone equipment, not part of the air loop equipment). It contains a fan, a DX cooling coil, and an outdoor air inlet. The coil meets the cooling load by cycling on/off. The fan can operate continuously or cycle on/off in conjunction with the coil.

19.6.5.2 Model

The window air conditioner is modeled as a compound component consisting of 3 sub-components: an outdoor air mixer, a fan, and a DX coil. In terms of EnergyPlus objects these are OutdoorAir:Mixer, Fan:ConstantVolume or Fan:OnOff, and Coil:Cooling:DX:SingleSpeed or CoilSystem:Cooling:DX:HeatExchangerAssisted. The unit is a forward model: its inputs are defined by the state of its inlets: namely its 2 air streams – recirculated and outdoor air. The outputs of the model are the conditions of the outlet air stream: flow rate, temperature and humidity ratio. The model is also an averaged model: the performance of the unit is averaged over the time step. That is, the unit is assumed to cycle on/off during the time step and this on/off cycling is averaged over the simulation time step. The unit data and simulation are encapsulated in the module WindowAC.

19.6.5.3 Inputs and Data

The user describes the window air conditioner by inputting the names of the outdoor air mixer, the fan, and the cooling coil. The user can also choose fan placement – blow through or draw through; fan operation – cycling or continuous; and cooling coil type – normal DX or DX with heat exchanger assistance.

The connectivity of the unit needs to be specified: a recirculated (inlet) air node (same as a zone exhaust node); an air outlet node (same as a zone inlet node); an outdoor air inlet node; and a relief air node. The individual components comprising the window air conditioner must of course also be input and connected together properly. For instance, for a blow through fan configuration the outdoor air mixer mixed air node must be the same as the fan inlet node; the fan outlet node must be the same as the coil inlet node; the coil outlet node must be the same as the unit outlet node; the outdoor air mixer inlet nodes must match the unit inlet nodes; and the outdoor air mixer relief node must match the unit relief node.

The user also specifies the air conditioner flow rate delivered to the zone (when cycled on) and the outdoor air flow rate. The user also needs to specify an availability schedule for the unit (this is an on/off schedule).

Note that there is no input specifying the unit's design cooling capacity. This is an input in the DX coil object and is not repeated here.

All the input data for the window air conditioner is stored in the array *WindAC*.

19.6.5.4 Calculation

Given the needed inputs, the output is calculated in subroutine CalcCyclingWindowAC. The temperature, humidity ratio and flow rate of the recirculated and outdoor air streams are taken from the inlet air nodes. The part load ratio is specified by the calling routine. Then

- The outdoor air mixer is simulated (Call SimOAMixer);
- For blow-through fan position:
 - the fan is simulated (Call SimulateFanComponents);
 - the coil is simulated (Call SimDXCoil or SimHXAssistedCoolingCoil).

For draw-through fan position, the simulation order of the fan and coil is reversed. Note that data is never explicitly passed between the sub-components. This is all handled automatically by the node connections and the data stored on the nodes.

19.6.5.5 Simulation and Control

From the result of the zone simulation we have the heating/cooling demand on the unit $\dot{Q}_{z,req}$. The first step is to decide whether the unit is on for the current time step. For a unit with a cycling fan, the entire unit is assumed to be off if there is no cooling load, the cooling load is very small (less than 1 watt), the unit is scheduled off, or the zone temperature is in the deadband. For a unit with a continuous flow the fan operates if the unit is scheduled on, whether or not there is a cooling demand. The coil however only operates if there is a cooling demand and the zone temperature is not in the deadband.

If the unit is determined to be on, the next step is to find the unit part load fraction that will satisfy the cooling load. This is done in *ControlCycWindACOutput*. In this routine *CalcCyclingWindowAC* is first called with part load fraction equal to 0, then with part load fraction equal to 1. These calls establish the minimum and maximum cooling output possible by the unit given the current conditions. An initial estimate of the part load fraction is then made:

$$PLF = (\dot{Q}_{z,req} - \dot{Q}_{out,min}) / |\dot{Q}_{out,max} - \dot{Q}_{out,min}| \quad (19.237)$$

Since the unit's cooling output is a nonlinear function of the part load fraction, this *PLF* will not give exactly the desired $\dot{Q}_{z,req}$. To obtain the exact *PLF* that will give $\dot{Q}_{z,req}$, it is necessary to iteratively call *CalcCyclingWindowAC*, varying *PLF* until the desired cooling output is obtained, within the error tolerance specified by the user in the input.

Once *PLF* is determined, *ControlCycWindACOutput* is exited. One last call to *CalcCyclingWindowAC* is made to establish the final outlet conditions at the unit's air outlet node. Finally, the inlet and outlet node conditions are used to calculate the reporting variables: sensible and total cooling output.

$$\dot{Q}_{sens,out} = \dot{m} \cdot (PsyHFnTdbW(T_{out}, W_{in}) - PsyHFnTdbW(T_{in}, W_{in})) \quad (19.238)$$

$$\dot{Q}_{total,out} = \dot{m} \cdot (PsyHFnTdbW(T_{out}, W_{out}) - PsyHFnTdbW(T_{in}, W_{in})) \quad (19.239)$$

where *PsyHFnTdb* is the EnergyPlus function giving enthalpy as a function of temperature and humidity ratio.

19.6.6 Packaged Terminal Air Conditioner

19.6.6.1 Overview

The input object *ZoneHVAC:PackagedTerminalAirConditioner* provides a model for a packaged terminal air conditioner (PTAC) that is a compound object made up of other components. Each PTAC consists of an outdoor air mixer, direct expansion (DX) cooling coil, heating coil (gas, electric, hot water, or steam) and a supply air fan. While Figure 19.21 shows the PTAC with draw through fan placement, blow through fan placement can also be modeled by positioning the supply air fan between the outdoor air mixer and DX cooling coil. The packaged terminal air conditioner coordinates the operation of these components and is modeled as a type of zone equipment (Ref. *ZoneHVAC:EquipmentList* and *ZoneHVAC:EquipmentConnections*).

The PTAC conditions a single zone and is controlled by a thermostat located in that zone. The PTAC operates to meet the zone sensible cooling or sensible heating requirements as dictated by the thermostat schedule. The model calculates the required part-load ratio for the air conditioner's

Figure 19.21: Schematic of a Packaged Terminal Air Conditioner with Draw Through Fan Placement

coils and the supply air fan to meet the cooling/heating requirements. The heating or cooling energy provided by the PTAC is delivered to the zone via the zone air inlet node.

The PTAC is able to model supply air fan operation in two modes: cycling fan – cycling coil (i.e., AUTO fan) and continuous fan – cycling coil (i.e., fan ON). Supply air fan operation is coordinated with the use of a supply air fan operating mode schedule. Schedule values of 0 denote cycling fan operation (AUTO fan). Schedule values other than 0 denote continuous fan operation (fan ON). Fan:OnOff must be used to model AUTO fan (i.e. if schedule values of 0 occur in the supply air fan operating mode schedule), while Fan:OnOff or Fan:ConstantVolume can be used to model fan ON (i.e. if schedule values of 0 do not occur in the supply air fan operating mode schedule). The supply air fan operating mode schedule specified for the PTAC overrides the operating mode specified in the DX cooling coil object.

Output variables reported by the PTAC object include the supply air fan part-load ratio, the air conditioner's part-load ratio (cooling or heating), and the electric consumption of the PTAC. Additional output variables report the total zone heating rate and the total zone cooling rate provided by the air conditioner. The sensible and latent components of zone cooling are also available as output variables. Reporting of other variables of interest for the PTAC (DX coil cooling rate, coil heating rate, crankcase heater power, fan power, etc.) is done by the individual system components (fan, DX cooling coil and heating coil).

19.6.6.2 Model Description

As described previously, the PTAC conditions a single zone and is controlled by a zone thermostat (ZoneControl:Thermostatic). Each simulation time step, EnergyPlus performs a zone air heat

balance to determine if cooling or heating is required to meet the thermostat setpoints, excluding any impacts from PTAC operation. PTAC performance is then modeled with all heating/cooling coils off but the supply air fan operates as specified by the user. If the zone air heat balance plus the impact of PTAC operation with coils off results in no requirement for heating or cooling by the PTAC coils, or if the PTAC is scheduled off (via its availability schedule), then the PTAC coils do not operate and the air conditioner's part-load ratio output variable is set to 0. If the model determines that cooling or heating is required and the PTAC is scheduled to operate, the model calculates the average air flow rate through the unit and the part-load ratio of the cooling and heating coils in order to meet the thermostat setpoint temperature.

The remainder of this section describes the calculations performed during the latter situation, when cooling or heating coil operation is required. For any HVAC simulation time step, the PTAC can only be cooling or heating, not both. Because the PTAC cycles its coil(s) on and off to meet the required load, the coil(s) operate for a portion of the time step and are off for the rest of the time step. If the user specifies continuous fan operation (i.e. supply air fan operating mode schedule value is greater than 0), then the supply air fan continues to operate at a user-specified flow rate even during periods when the coils cycle off. If the user specifies AUTO fan operation (i.e. supply air fan operating mode schedule value is equal to 0), then the supply air fan cycles on and off with the coils. The model accounts for these variations in air flow through the PTAC within a simulation time step when it determines the total cooling or heating energy delivered to the zone, the average supply air conditions and air flow rate, and the energy consumed by the air conditioner.

19.6.6.3 Cooling Operation

If EnergyPlus determines that the air conditioner must supply cooling to the zone in order to meet the zone air temperature setpoint, then the model first calculates the PTAC's sensible cooling rate to the zone under two conditions: when the unit runs at full-load (steady-state) conditions and when the DX cooling coil is OFF. If the supply air fan cycles on/off with the compressor, then the sensible cooling rate is zero when the cooling coil is OFF. However if the fan is configured to run continuously regardless of coil operation, then the sensible cooling rate will not be zero when the cooling coil is OFF. Calculating the sensible cooling rate involves modeling the supply air fan (and associated fan heat), the outdoor air mixer, and the DX cooling coil. The heating coil is also modeled, but only to pass the air properties and mass flow rate from its inlet node to its outlet node. For each of these cases (full load and DX cooling coil OFF), the sensible cooling rate delivered to the zone by the PTAC is calculated as follows:

$$\dot{Q}_{cooling,max} = (\dot{m}_{SA,full\ load}) (h_{out,full\ load} - h_{zone\ air})_{HRmin} \quad (19.240)$$

$$\dot{Q}_{cooling,min} = (\dot{m}_{SA,coil\ off}) (h_{out,coil\ off} - h_{zone\ air})_{HRmin} \quad (19.241)$$

where:

$\dot{Q}_{cooling,max}$ = maximum PTAC sensible cooling rate with cooling coil ON (W)

$\dot{m}_{SA,full\ load}$ = supply air mass flow rate at full-load (steady-state) conditions (kg/s)

$h_{out,full\ load}$ is the enthalpy of air exiting the PTAC at full-load conditions (J/kg)

$h_{zone\ air}$ is the enthalpy of zone (exhaust) air (J/kg)

HR_{min} are the enthalpies evaluated at a constant humidity ratio, the minimum humidity ratio of the PTAC exiting air or the zone (exhaust) air

$\dot{Q}_{cooling,min}$ is the minimum PTAC sensible cooling rate with cooling coil OFF (W)

$\dot{m}_{SA,coil\ off}$ is the supply air mass flow rate with the cooling coil OFF (kg/s)

$h_{out,coil\ off}$ is the enthalpy of air exiting the PTAC with the cooling coil OFF (J/kg).

With the calculated PTAC sensible cooling rates and the zone sensible cooling load to be met, the compressor part-load ratio for the PTAC is approximately equal to:

$$PartLoadRatio = MAX \left(0.0, \frac{ABS \left(\dot{Q}_{zone,cooling} - \dot{Q}_{cooling,min} \right)}{ABS \left(\dot{Q}_{cooling,max} - \dot{Q}_{cooling,min} \right)} \right) \quad (19.242)$$

where:

$PartLoadRatio$ is the compressor part-load ratio required to meet the zone load

$\dot{Q}_{zone,cooling}$ is the required zone sensible cooling rate to meet setpoint (W).

Since the part-load performance of the DX cooling coil is frequently non-linear (Ref: DX Cooling Coil Model), and the supply air fan heat varies based on cooling coil operation for the case of cycling fan/cycling coil (AUTO fan), the actual part-load ratio for the cooling coil compressor and fan are determined through iterative calculations (successive modeling of the individual PTAC component models) until the PTAC's cooling output (including on/off cycling effects) matches the zone cooling load requirement.

If the PTAC has been specified with cycling fan/cycling coil (AUTO fan), then the user-defined supply air flow rate during cooling operation (volumetric flow rate converted to mass flow rate) is multiplied by the final $PartLoadRatio$ value to determine the average supply air mass flow rate for the HVAC system simulation time step. For this case, the air conditions (temperature, humidity ratio and enthalpy) at nodes downstream of the cooling coil represent the full-load (steady-state) values when the coil is operating. If the supply air fan is specified to run continuously (fan ON), then the supply air mass flow rate is calculated as the average of the air mass flow rate when the compressor is on and the air mass flow rate when the compressor is off. In this case, the air conditions at nodes downstream of the cooling coil are calculated as the average conditions over the simulation time step (i.e., the weighted average of full-load conditions when the coil is operating and mixed inlet air conditions when the coil is OFF). Additional discussion regarding the calculation of the average supply air flow and supply air conditions is provided later in this section.

19.6.6.4 Heating Operation

Calculations of the PTAC's sensible heating rate delivered to the zone at full load and with the heating coil OFF are identical to the calculations described above for cooling operation.

$$\dot{Q}_{heating,max} = (\dot{m}_{SA,full\ load}) (h_{out,full\ load} - h_{zone\ air})_{HRmin} \quad (19.243)$$

$$\dot{Q}_{heating,min} = (\dot{m}_{SA,coil\ off}) (h_{out,coil\ off} - h_{zone\ air})_{HRmin} \quad (19.244)$$

where:

$\dot{Q}_{heating,max}$ is the maximum PTAC sensible heating rate with heating coil ON (W)

$\dot{Q}_{heating,min}$ is the minimum PTAC sensible heating rate with heating coil OFF (W).

With the calculated PTAC sensible heating rates and the zone sensible heating load to be met, the heating coil part-load ratio for the PTAC is approximately equal to:

$$PartLoadRatio = MAX \left(0.0, \frac{ABS \left(\dot{Q}_{zone,heating} - \dot{Q}_{heating,min} \right)}{ABS \left(\dot{Q}_{heating,max} - \dot{Q}_{heating,min} \right)} \right) \quad (19.245)$$

where:

PartLoadRatio is the heating coil part-load ratio required to meet the zone load

$\dot{Q}_{zone,heating}$ is the required zone sensible heating rate to meet setpoint (W).

Iterative calculations (successive modeling of the individual PTAC component models) are used to determine the final heating part-load ratio to account for the non-linear performance of the heating coil at part-load conditions and the variation in supply air fan heat for the case of cycling fan/cycling coil (AUTO fan). If heating coil operation at full load is unable to meet the entire zone heating load (e.g., the heating coil capacity is insufficient or the coil is scheduled OFF), the air conditioner's part-load ratio is set to 1 to meet the zone heating load to the extent possible.

19.6.6.5 Single Zone VAV load based control:

The packaged terminal air conditioner can also be used to simulate a system capable of maintaining a low fan speed through a range of low to moderate loads. This control scheme is similar to single zone variable-air-volume (VAV) control where the fan speed is maintained at a minimum level and the coil is modulated to a point where the system outlet air temperature reaches a user specified limit. As the outlet air temperature limit is reached and loads increase, the fan speed increases to maintain thermostat control. When the fan speed reaches the maximum flow limit, the system outlet air temperature may exceed the user specified limit, if the coil is capable of providing more capacity, to meet increased load. This model is active only for constant fan operating mode. Cycling fan operating may be used, however, during time of cycling fan operating mode, the model reverts to control specified above for cooling or heating operation. Additionally, only specific coil types are allowed for the Single Zone VAV capacity control method.

Allowed coil types are:

Cooling coils:

- Coil:Cooling:DX:SingleSpeed

Heating coils:

- Coil:Heating:Water
- Coil:Heating:Fuel
- Coil:Heating:Electric
- Coil:Heating:DX:SingleSpeed (Packaged Terminal Heat Pump only)

Other coil types may be used when selecting the Single Zone VAV control method, however, these coils will not be modeled using the Single Zone VAV load based control method and instead will be modeled using the Load Based control method described in a previous section.

Figure 19.22 shows two implementations of the Single Zone VAV model using the ZoneHVAC:PackagedTerminalAirConditioner and ZoneHVAC:PackagedTerminalHeatPump objects serving a single zone. The supply air temperature limits are autosized. The supply air temperature

limits are intended to reflect the model requirement to allow low speed fan operation at zone loads less than or equal to 50% of the design load. The zone cooling and heating loads identified in the figure are actual simulation data taken from the zone sizing information representative of the control zones used for each system. If the load on the unit is zero the air flow rate remains at the minimum. If the zone load is greater than 50% of the design load, the air flow rate increases to allow more capacity up to the point where the maximum supply air flow rate is achieved. When supplemental heaters are active, the air flow rate will be at the maximum. The figure on the left has a 24°C cooling and 18°C heating set point temperature. The figure on the right, 23.5°C and 22.5°C, respectively.

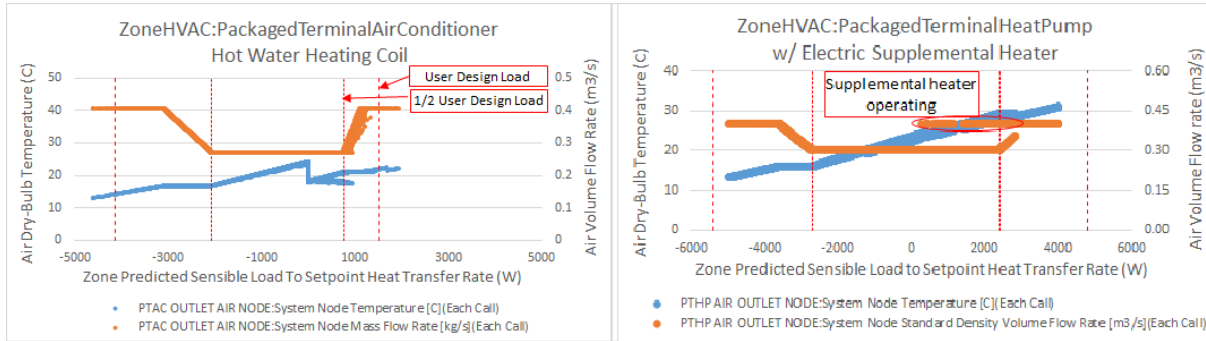

Figure 19.22: Example of the EnergyPlus Packaged Terminal Unit Single Zone VAV Model

Supply air temperature limits are autosizable and calculated with respect to the zone temperatures at the design cooling and heating peak load conditions. Once the temperature limits are reached and the zone load continues to increase, the fan speed is increased while limiting the maximum outlet air temperature up to the maximum fan speed. At this point, the maximum temperature limits are ignored and the coils are allowed to provide excess temperatures when needed to meet increasing loads. When a supplemental heating coil is used, this coil should be active only when maximum fan speed is reached and will supplement any additional heating required to meet the zone load. The supplemental heating coil also has no maximum temperature limit while attempting to meet high heating loads.

19.6.6.6 Average Air Flow Calculations

The packaged terminal air conditioner operates based on user-specified (or autosized) air flow rates. The PTAC's supply air flow rate during cooling operation may be different than the supply air flow rate during heating operation. In addition, the supply air flow rate when no cooling or heating is required but the supply air fan remains ON can be different than the air flow rates when cooling or heating is required. The outdoor air flow rates can likewise be different in these various operating modes. The model takes these different flow rates into account when modeling the air conditioner, and the average air flow rate for each simulation time step is reported on the inlet/outlet air nodes of the various PTAC components in proportion to the calculated part-load ratio of the coil.

The average supply air and outdoor air mass flow rates through the air conditioner for the HVAC simulation time step are calculated based on the part-load ratio of the DX cooling coil or heating coil (whichever coil is operating) as follows:

$$\dot{m}_{SA,avg} = \dot{m}_{SA,coil\ on} (PartLoadRatio) + \dot{m}_{SA,coil\ off} (1 - PartLoadRatio) \quad (19.246)$$

$$\dot{m}_{OA,avg} = \dot{m}_{OA,coil\ on} (PartLoadRatio) + \dot{m}_{OA,coil\ off} (1 - PartLoadRatio) \quad (19.247)$$

where:

$\dot{m}_{SA,avg}$ is the average supply air mass flow rate during the time step (kg/s)

$\dot{m}_{SA,coil\ on}$ is the supply air mass flow rate when the coil is ON (kg/s)

PartLoadRatio is the part-load ratio of the coil (heating or cooling)

$\dot{m}_{SA,coil\ off}$ is the supply air mass flow rate when the coil is OFF (kg/s)

$\dot{m}_{OA,avg}$ is the average outdoor air mass flow rate during the time step (kg/s)

$\dot{m}_{OA,coil\ on}$ is the average outdoor air mass flow rate when the coil is ON (kg/s)

$\dot{m}_{OA,coil\ off}$ is the average outdoor air mass flow rate when the coil is OFF (kg/s).

The supply air and outdoor air flow rates when the DX cooling coil or the heating coil is ON are specified by the user (i.e., supply air volumetric flow rate during cooling operation, supply air volumetric flow rate during heating operation, outdoor air volumetric air flow rate during cooling operation, and outdoor air volumetric air flow rate during heating operation) and are converted from volumetric to mass flow rate. If the user has specified cycling fan operation (i.e. supply air fan operating mode schedule value is equal to 0), then the supply air and outdoor air mass flow rates when the coil is OFF are zero. If the user has specified constant fan operation (i.e. supply air fan operating mode schedule value is greater than 0), then the user-defined air flow rates when no cooling or heating is needed are used when the coil is OFF.

There is one special case. If the supply air fan operating mode schedule value specifies constant fan operation and the user also specifies that the supply air volumetric flow rate when no cooling or heating is needed is zero (or field is left blank), then the model assumes that the supply air and outdoor air mass flow rates when the coil is OFF are equal to the corresponding air mass flow rates when the cooling or heating coil was last operating (ON).

19.6.6.7 Calculation of Outlet Air Conditions

When the supply air fan cycles on and off with the PTAC coils (AUTO fan), the calculated outlet air conditions (temperature, humidity ratio, and enthalpy) from the heating coil or the DX cooling coil at full-load (steady-state) operation are reported on the appropriate coil outlet air node. The air mass flow rate reported on the air nodes is the average air mass flow rate proportional to the part-load ratio of the coil (see Average Air Flow Calculations above).

When the supply air fan operates continuously while the PTAC coils cycle on and off (fan ON), the air mass flow rate reported on the air nodes is the average air mass flow rate proportional to the part-load ratio of the coil (see Average Air Flow Calculations above). Since the air flow rate can be different when the coil is ON compared to when the coil is OFF, then the average outlet air conditions from the heating coil or the DX cooling coil are reported on the appropriate coil outlet air node.

For hot water or steam coils, the water or steam mass flow rate is also proportional to the part-load ratio of the coil regardless of the supply air fan operating mode. Refer to the sections in the document that describe the heating and DX cooling coils for further explanation on how they report their outlet air (and water or steam) conditions.

19.6.6.8 Calculation of Zone Heating and Cooling Rates

At the end of each HVAC simulation time step, this compound object reports the heating or cooling rate and energy delivered to the zone, as well as the electric power and consumption by the air conditioner. In terms of thermal energy delivered to the zone, the sensible, latent and total energy transfer rate to the zone is calculated as follows:

$$\dot{Q}_{Total} = (\dot{m}_{SA,avg}) (h_{out,avg} - h_{zone\ air}) \quad (19.248)$$

$$\dot{Q}_{Sensible} = (\dot{m}_{SA,avg}) (h_{out,avg} - h_{zone\ air})_{HRmin} \quad (19.249)$$

$$\dot{Q}_{Latent} = \dot{Q}_{Total} - \dot{Q}_{Sensible} \quad (19.250)$$

where:

\dot{Q}_{Total} is the total energy transfer rate to the zone (W)

$\dot{Q}_{Sensible}$ is the sensible energy transfer rate to the zone (W)

\dot{Q}_{Latent} is the latent energy transfer rate to the zone (W)

$\dot{m}_{SA,avg}$ is the average mass flow rate of the supply air stream (kg/s)

$h_{out,avg}$ is the enthalpy of the air being supplied to the zone (J/kg).

Since each of these energy transfer rates can be calculated as positive or negative values, individual reporting variables are established for cooling and heating and only positive values are reported. The following calculations in pseudo code are representative of what is done for each of the energy transfer rates:

```
IF ( $\dot{Q}_{Total} < 0.0$ ) THEN
   $\dot{Q}_{TotalCooling} = ABS(\dot{Q}_{Total})$ 
   $\dot{Q}_{TotalHeating} = 0.0$ 
ELSE
   $\dot{Q}_{TotalCooling} = 0.0$ 
   $\dot{Q}_{TotalHeating} = \dot{Q}_{Total}$ 
END IF
```

where:

$\dot{Q}_{TotalCooling}$ is the output variable ‘Packaged Terminal Air Conditioner Total Zone Cooling Rate’ (W).

$\dot{Q}_{TotalHeating}$ is the output variable ‘Packaged Terminal Air Conditioner Total Zone Heating Rate’ (W).

In addition to heating and cooling rates, the heating and cooling energy supplied to the zone is also calculated for the time step being reported. The following example for total zone cooling energy is representative of what is done for the sensible and latent energy as well as the heating counterparts.

$$Q_{TotalCooling} = \dot{Q}_{TotalCooling} \cdot TimeStepSys \cdot 3600 \quad (19.251)$$

where:

$Q_{TotalCooling}$ is the output variable ‘Packaged Terminal Air Conditioner Total Zone Cooling Energy’ (J)

$TimeStepSys$ is the HVAC system simulation time step (hr).

19.6.7 Packaged Terminal Heat Pump

19.6.7.1 Overview

The input object `ZoneHVAC:PackagedTerminalHeatPump` provides a model for a packaged terminal heat pump (PTHP) that is a compound object made up of other components. Each PTHP consists of an outdoor air mixer, direct expansion (DX) cooling coil, DX heating coil, supply air fan, and a supplemental heating coil. While Figure 19.23 shows the PTHP with draw through fan placement, blow through fan placement can also be modeled by moving the supply air fan before the DX cooling coil. The packaged terminal heat pump coordinates the operation of these components and is modeled as a type of zone equipment (Ref. `ZoneHVAC:EquipmentList` and `ZoneHVAC:EquipmentConnections`).

Figure 19.23: Schematic of a Packaged Terminal Heat Pump (Draw Through Fan Placement)

The PTHP conditions a single zone and is controlled by a thermostat located in that zone. The PTHP operates to meet the zone sensible cooling or sensible heating requirements as dictated by the thermostat schedule. The model calculates the required part-load ratio for the heat pump's coils and the supply air fan to meet the cooling/heating requirements. The heating or cooling energy provided by the PTHP is delivered to the zone via the zone air inlet node.

The PTHP is able to model supply air fan operation in two modes: cycling fan – cycling coil (i.e., AUTO fan) and continuous fan – cycling coil (i.e., fan ON). `Fan:OnOff` must be used to model AUTO fan, while `Fan:OnOff` or `Fan:ConstantVolume` can be used to model fan ON.

Output variables reported by the PTHP object include the supply air fan part-load ratio, the compressor part-load ratio, and the electric consumption of the PTHP. Additional output variables report the total zone heating rate and the total zone cooling rate provided by the heat pump. The

sensible and latent components of zone cooling are also available as output variables. Reporting of other variables of interest for the PTHP (DX coil cooling rate, DX coil heating rate, crankcase heater power, fan power, etc.) is done by the individual system components (fan, DX cooling coil, DX heating coil, and supplemental heating coil).

19.6.7.2 Model Description

As described previously, the PTHP conditions a single zone and is controlled by a zone thermostat (ZoneControl:Thermostat). Each simulation time step, EnergyPlus performs a zone air heat balance to determine if cooling or heating is required to meet the thermostat setpoints, excluding any impacts from PTHP operation. PTHP performance is then modeled with all heating/cooling coils off but the supply air fan operates as specified by the user. If the zone air heat balance plus the impact of PTHP operation with coils off results in no requirement for heating or cooling by the PTHP coils, or if the PTHP is scheduled off (via its availability schedule), then the PTHP coils do not operate and the compressor part-load ratio output variable is set to 0. If the model determines that cooling or heating is required and the PTHP is scheduled to operate, the model calculates the average air flow rate through the unit and the part-load ratio of the cooling and heating coils in order to meet the thermostat setpoint temperature.

The remainder of this section describes the calculations performed during the latter situation, when cooling or heating coil operation is required. For any HVAC simulation time step, the PTHP can only be cooling or heating, not both. Because the PTHP cycles its coil(s) on and off to meet the required load, the coil(s) operate for a portion of the time step and are off for the rest of the time step. If the user specifies continuous fan operation (supply air fan operating mode schedule value > 0), then the supply air fan continues to operate at a user-specified flow rate even during periods when the coils cycle off. If the user specifies AUTO fan operation (supply air fan operating mode schedule value $= 0$), then the supply air fan cycles on and off with the coils. The model accounts for these variations in air flow through the PTHP within a simulation time step when it determines the total cooling or heating energy delivered to the zone, the average supply air conditions and air flow rate, and the energy consumed by the heat pump.

19.6.7.3 Cooling Operation

If EnergyPlus determines that the heat pump must supply cooling to the zone in order to meet the zone air temperature setpoint, then the model first calculates the PTHP's sensible cooling rate to the zone under two conditions: when the unit runs at full-load (steady-state) conditions and when the DX cooling coil is OFF. If the supply air fan cycles on/off with the compressor, then the sensible cooling rate is zero when the cooling coil is OFF. However if the fan is configured to run continuously regardless of coil operation, then the sensible cooling rate will not be zero when the cooling coil is OFF. Calculating the sensible cooling rate involves modeling the supply air fan (and associated fan heat), the outdoor air mixer, and the DX cooling coil. The DX heating coil and the gas or electric supplemental heating coil are also modeled, but only to pass the air properties and mass flow rate from their inlet nodes to their outlet nodes. For each of these cases (full load and DX cooling coil OFF), the sensible cooling rate delivered to the zone by the PTHP is calculated as follows:

$$\dot{Q}_{cooling,max} = (\dot{m}_{SA,full\ load})(h_{out,full\ load} - h_{zone\ air})_{HRmin} \quad (19.252)$$

$$\dot{Q}_{cooling,min} = (\dot{m}_{SA,coil\ off})(h_{out,coil\ off} - h_{zone\ air})_{HRmin} \quad (19.253)$$

where:

$\dot{Q}_{cooling,max}$ is the maximum PTHP sensible cooling rate with cooling coil ON (W)

$\dot{Q}_{SA,full\ load}$ is the supply air mass flow rate at full-load (steady-state) conditions (kg/s)

$h_{out,full\ load}$ is the enthalpy of air exiting the PTHP at full-load conditions (J/kg)

$h_{zone\ air}$ is the enthalpy of zone (exhaust) air (J/kg)

HR_{min} are the enthalpies evaluated at a constant humidity ratio, the minimum humidity ratio of the PTHP exiting air or the zone (exhaust) air

$\dot{Q}_{cooling,min}$ is the minimum PTHP sensible cooling rate with cooling coil OFF (W)

$\dot{Q}_{SA,coil\ off}$ is the supply air mass flow rate with the cooling coil OFF (kg/s)

$h_{out,coil\ off}$ is the enthalpy of air exiting the PTHP with the cooling coil OFF (J/kg).

With the calculated PTHP sensible cooling rates and the zone sensible cooling load to be met, the compressor part-load ratio for the PTHP is approximately equal to:

$$PartLoadRatio = MAX \left(0.0, \frac{ABS(\dot{Q}_{zone,cooling} - \dot{Q}_{cooling,min})}{ABS(\dot{Q}_{cooling,max} - \dot{Q}_{cooling,min})} \right) \quad (19.254)$$

where:

$PartLoadRatio$ is the compressor part-load ratio required to meet the zone load

$\dot{Q}_{zone,cooling}$ is the required zone sensible cooling rate to meet setpoint (W).

Since the part-load performance of the DX cooling coil is frequently non-linear (Ref: DX Cooling Coil Model), and the supply air fan heat varies based on cooling coil operation for the case of cycling fan/cycling coil (AUTO fan), the actual part-load ratio for the cooling coil compressor and fan are determined through iterative calculations (successive modeling of the individual PTHP component models) until the PTHP's cooling output (including on/off cycling effects) matches the zone cooling load requirement within the cooling convergence tolerance that is specified.

If the PTHP is specified to operate with cycling fan/cycling coil (AUTO fan), then the user-defined supply air flow rate during cooling operation (volumetric flow rate converted to mass flow rate) is multiplied by the final PartLoadRatio value to determine the average supply air mass flow rate for the HVAC system simulation time step. For this case, the air conditions (temperature, humidity ratio and enthalpy) at nodes downstream of the cooling coil represent the full-load (steady-state) values when the coil is operating. If the supply air fan is specified to operate continuously (fan ON), then the supply air mass flow rate is calculated as the average of the air mass flow rate when the compressor is on and the air mass flow rate when the compressor is off. In this case, the air conditions at nodes downstream of the cooling coil are calculated as the average conditions over the simulation time step (i.e., the weighted average of full-load conditions when the coil is operating and mixed inlet air conditions when the coil is OFF). Additional discussion regarding the calculation of the average supply air flow and supply air conditions is provided later in this section.

19.6.7.4 Heating Operation

Calculations of the PTHP's sensible heating rate delivered to the zone at full load and with the DX heating coil OFF are identical to the calculations described above for cooling operation.

$$\dot{Q}_{heating,max} = (\dot{m}_{SA,full\ load})(h_{out,full\ load} - h_{zone\ air})_{HRmin} \quad (19.255)$$

$$\dot{Q}_{heating,min} = (\dot{m}_{SA,coil\ off})(h_{out,coil\ off} - h_{zone\ air})_{HRmin} \quad (19.256)$$

where:

$\dot{Q}_{heating,max}$ is the maximum PTHP sensible heating rate with DX heating coil ON (W)

$\dot{Q}_{heating,min}$ is the minimum PTHP sensible heating rate with DX heating coil OFF (W).

With the calculated PTHP sensible heating rates and the zone sensible heating load to be met, the compressor part-load ratio for the PTHP is approximately equal to:

$$PartLoadRatio = MAX \left(0.0, \frac{ABS \left(\dot{Q}_{zone,heating} - \dot{Q}_{heating,min} \right)}{ABS \left(\dot{Q}_{heating,max} - \dot{Q}_{heating,min} \right)} \right) \quad (19.257)$$

where:

$PartLoadRatio$ is the compressor part-load ratio required to meet the zone load

$\dot{Q}_{zone,heating}$ is the required zone sensible heating rate to meet setpoint (W).

Iterative calculations (successive modeling of the individual PTHP component models) are used to determine the final heating part-load ratio to account for the non-linear performance of the DX heating coil at part-load conditions and the variation in supply air fan heat for the case of cycling fan/cycling coil (AUTO fan). If DX heating coil operating at full load is unable to meet the entire zone heating load (e.g., the DX heating coil capacity is insufficient or the coil is scheduled OFF, or the outdoor temperature is below the PTHP's minimum outdoor dry-bulb temperature for compressor operation), the supplemental heating coil is activated to meet the remaining zone heating load to the extent possible.

19.6.7.5 Single Zone VAV Load Based Control

The packaged terminal heat pump can also be used to simulate a system capable of maintaining a low fan speed through a range of low to moderate loads. This control scheme is similar to single zone variable-air-volume (VAV) control where the fan speed is maintained at a minimum level and the coil is modulated to a point where the system outlet air temperature reaches a user specified limit. This model is active only for constant fan operating mode. Cycling fan operating may be used, however, during time of cycling fan operating mode, the model reverts to control specified above for cooling or heating operation. See the description for Packaged Terminal Air Conditioner.

19.6.7.6 Average Air Flow Calculations

The packaged terminal heat pump operates based on user-specified (or autosized) air flow rates. The PTHP's supply air flow rate during cooling operation may be different than the supply air flow rate during heating operation. In addition, the supply air flow rate when no cooling or heating is required but the supply air fan remains ON can be different than the air flow rates when cooling or heating is required. The outdoor air flow rates can likewise be different in these various operating modes. The model takes these different flow rates into account when modeling the heat pump, and the average air flow rate for each simulation time step is reported on the inlet/outlet air nodes of the various PTHP components in proportion to the calculated part-load ratio of the DX coil compressor.

The average supply air and outdoor air mass flow rates through the heat pump for the HVAC simulation time step are calculated based on the part-load ratio of the DX cooling coil or DX heating coil (whichever coil is operating) as follows:

$$\dot{m}_{SA,avg} = \dot{m}_{SA,comp\ on}(PartLoadRatio) + \dot{m}_{SA,comp\ off}(1 - PartLoadRatio) \quad (19.258)$$

$$\dot{m}_{OA,avg} = \dot{m}_{OA,comp\ on}(PartLoadRatio) + \dot{m}_{OA,comp\ off}(1 - PartLoadRatio) \quad (19.259)$$

where:

$\dot{m}_{SA,avg}$ is the average supply air mass flow rate during the time step (kg/s)

$\dot{m}_{SA,comp\ on}$ is the supply air mass flow rate when the DX coil compressor is ON (kg/s)

$PartLoadRatio$ is the part-load ratio of the DX coil compressor (heating or cooling)

$\dot{m}_{SA,comp\ off}$ is the supply air mass flow rate when the DX coil compressor is OFF (kg/s)

$\dot{m}_{OA,avg}$ is the average outdoor air mass flow rate during the time step (kg/s)

$\dot{m}_{OA,comp\ on}$ is the average outdoor air mass flow rate when the DX coil compressor is ON (kg/s)

$\dot{m}_{OA,comp\ off}$ is the average outdoor air mass flow rate when the DX coil compressor is OFF (kg/s).

The supply air and outdoor air flow rates when the DX cooling or DX heating coil compressor is ON are specified by the user (e.g., supply air volumetric flow rate during cooling operation, supply air volumetric flow rate during heating operation, outdoor air volumetric air flow rate during cooling operation, and outdoor air volumetric air flow rate during heating operation) and are converted from volumetric to mass flow rate. If the user has specified cycling fan operation (supply air fan operating mode schedule value = 0), then the supply air and outdoor air mass flow rates when the DX compressor is OFF are zero. If the user has specified constant fan operation (supply air fan operating mode schedule value > 0), then the user-defined air flow rates when no cooling or heating is needed are used when the DX compressor is OFF.

There is one special case. If the user has specified constant fan operation (supply air fan operating mode schedule value > 0) and they specify that the supply air volumetric flow rate when no cooling or heating is needed is zero (or field is left blank), then the model assumes that the supply air and outdoor air mass flow rates when the DX coil compressor is OFF are equal to the corresponding air mass flow rates when the compressor was last operating (ON).

19.6.7.7 Calculation of Outlet Air Conditions

When the supply air fan cycles on and off with the PTHP coils (AUTO fan), the calculated outlet air conditions (temperature, humidity ratio, and enthalpy) from the DX heating or DX cooling coil at full-load (steady-state) operation are reported on the appropriate coil outlet air node. The air mass flow rate reported on the air nodes is the average air mass flow rate proportional to the part-load ratio of the DX coil compressor (see Average Air Flow Calculations above).

When the supply air fan operates continuously while the PTHP coils cycle on and off (fan ON), the air mass flow rate reported on the air nodes is the average air mass flow rate proportional to the part-load ratio of the DX coil compressor (see Average Air Flow Calculations above). Since the air flow rate can be different when the coil is ON compared to when the coil is OFF, then the average outlet air conditions from the DX heating or DX cooling coil are reported on the appropriate coil outlet air node.

Refer to the sections in the document that describe the DX heating and DX cooling coils for further explanation on how they report their outlet air conditions.

19.6.7.8 Calculation of Zone Heating and Cooling Rates

At the end of each HVAC simulation time step, this compound object reports the heating or cooling rate and energy delivered to the zone, as well as the electric power and consumption by the heat pump. In terms of thermal energy delivered to the zone, the sensible, latent and total energy transfer rate to the zone is calculated as follows:

$$\dot{Q}_{Total} = (\dot{m}_{SA,avg}) (h_{out,avg} - h_{zone\ air}) \quad (19.260)$$

$$\dot{Q}_{Sensible} = (\dot{m}_{SA,avg}) (h_{out,avg} - h_{zone\ air})_{HRmin} \quad (19.261)$$

$$\dot{Q}_{Latent} = \dot{Q}_{Total} - \dot{Q}_{Sensible} \quad (19.262)$$

where:

\dot{Q}_{Total} is the total energy transfer rate to the zone (W)

$\dot{Q}_{Sensible}$ is the sensible energy transfer rate to the zone (W)

\dot{Q}_{Latent} is the latent energy transfer rate to the zone (W)

$\dot{m}_{SA,avg}$ is the average mass flow rate of the supply air stream (kg/s)

$h_{out,avg}$ is the enthalpy of the air being supplied to the zone (J/kg).

Since each of these energy transfer rates can be calculated as positive or negative values, individual reporting variables are established for cooling and heating and only positive values are reported. The following calculations shown in pseudo code are representative of what is done for each of the energy transfer rates:

```
IF ( $\dot{Q}_{Total} < 0.0$ ) THEN
     $\dot{Q}_{TotalCooling} = \text{ABS}(\dot{Q}_{Total})$ 
     $\dot{Q}_{TotalHeating} = 0.0$ 
ELSE
     $\dot{Q}_{TotalCooling} = 0.0$ 
     $\dot{Q}_{TotalHeating} = \dot{Q}_{Total}$ 
END IF
```

where:

$\dot{Q}_{TotalCooling}$ is the output variable ‘Packaged Terminal Heat Pump Total Zone Cooling Rate’ (W)

$\dot{Q}_{TotalHeating}$ is the output variable ‘Packaged Terminal Heat Pump Total Zone Heating Rate’ (W).

In addition to heating and cooling rates, the heating and cooling energy supplied to the zone is also calculated for the time step being reported. The following example for total zone cooling energy is representative of what is done for the sensible and latent energy as well as the heating counterparts.

$$Q_{TotalCooling} = \dot{Q}_{TotalCooling} * TimeStepSys * 3600. \quad (19.263)$$

where:

(J) $Q_{TotalCooling}$ is the output variable ‘Packaged Terminal Heat Pump Total Zone Cooling Energy’

$TimeStepSys$ is the HVAC system simulation time step (hr).

19.6.8 Zone Single Speed Water-To-Air Heat Pump

19.6.8.1 Overview

The input object ZoneHVAC:WaterToAirHeatPump provides a zone equipment model for a water-to-air heat pump that is a “virtual” component consisting of an on/off fan component, a water-to-air heat pump cooling coil, a water-to-air heat pump heating coil, and a gas or electric supplemental heating coil. The specific configuration of the blowthru heat pump is shown in Figure 19.24. For a drawthru heat pump, the fan is located between the water-to-air heat pump heating coil and the supplemental heating coil. In addition, a water-to-air heat pump has a water loop connection on its source side. The water loop can be served by a condenser loop (like GHE for Ground source systems), or by a cooling tower/ boiler plant loop (for water loop systems).

There are two models for zone water-to-air heat pump cooling and heating coils, i.e. Single-Speed and Variable-Speed Equation Fit models. Cooling and heating coils are modeled using the Equation Fit model described here.

19.6.8.2 Single Speed Equation-Fit Model

This section describes the equation-fit model for Water-to-Air heat pump (Object names: Coil:Cooling:WaterToAirHeatPump:EquationFit and Coil:Heating:WaterToAirHeatPump:EquationFit). This documentation is derived from the M.S. dissertation of Tang (2005) which is available on the Oklahoma State University web site . The model uses five non-dimensional equations or curves to predict the heat pump performance in cooling and heating mode. The methodology involves using the generalized least square method to generate a set of performance coefficients from the catalog data at indicated reference conditions. Then the respective coefficients and indicated reference conditions are used in the model to simulate the heat pump performance. The variables or inlet conditions that influenced the water-to-air heat pump performance are load side inlet water temperature, source side inlet temperature, source side water flow rate and load side water flow rate. The governing equations for the cooling and heating mode are as following:

Cooling Mode:

$$\frac{Q_{total}}{Q_{total,ref}} = A1 + A2 \left[\frac{T_{wb}}{T_{ref}} \right] + A3 \left[\frac{T_{w,in}}{T_{ref}} \right] + A4 \left[\frac{\dot{V}_{air}}{\dot{V}_{air,ref}} \right] + A5 \left[\frac{\dot{V}_w}{\dot{V}_{w,ref}} \right] \quad (19.264)$$

$$\frac{Q_{sens}}{Q_{sens,ref}} = B1 + B2 \left[\frac{T_{db}}{T_{ref}} \right] + B3 \left[\frac{T_{wb}}{T_{ref}} \right] + B4 \left[\frac{T_{w,in}}{T_{ref}} \right] + B5 \left[\frac{\dot{V}_{air}}{\dot{V}_{air,ref}} \right] + B6 \left[\frac{\dot{V}_w}{\dot{V}_{w,ref}} \right] \quad (19.265)$$

$$\frac{Power_c}{Power_{c,ref}} = C1 + C2 \left[\frac{T_{wb}}{T_{ref}} \right] + C3 \left[\frac{T_{w,in}}{T_{ref}} \right] + C4 \left[\frac{\dot{V}_{air}}{\dot{V}_{air,ref}} \right] + C5 \left[\frac{\dot{V}_w}{\dot{V}_{w,ref}} \right] \quad (19.266)$$

Heating Mode:

Source Side (water)**Load Side (air)**

Figure 19.24: Source Side and Load Side Configuration of a Zone WaterToAir Heat Pump

$$\frac{Q_h}{Q_{h,ref}} = E1 + E2 \left[\frac{T_{db}}{T_{ref}} \right] + E3 \left[\frac{T_{w,in}}{T_{ref}} \right] + E4 \left[\frac{\dot{V}_{air}}{\dot{V}_{air,ref}} \right] + E5 \left[\frac{\dot{V}_w}{\dot{V}_{w,ref}} \right] \quad (19.267)$$

$$\frac{Power_h}{Power_{h,ref}} = F1 + F2 \left[\frac{T_{db}}{T_{ref}} \right] + F3 \left[\frac{T_{w,in}}{T_{ref}} \right] + F4 \left[\frac{\dot{V}_{air}}{\dot{V}_{air,ref}} \right] + F5 \left[\frac{\dot{V}_w}{\dot{V}_{w,ref}} \right] \quad (19.268)$$

Assuming no losses, the source side heat transfer rate for cooling and heating mode is calculated as following;

$$Q_{source,c} = Q_{total} + Power_c \quad (19.269)$$

$$Q_{source,h} = Q_h - Power_h \quad (19.270)$$

where:

$A1 - F5$ are equation fit coefficients for the cooling and heating mode

T_{ref} is 283K

$T_{w,in}$ is the entering water temperature (K)

T_{db} is the entering air dry-bulb temperature (K)

T_{wb} is the entering air wet-bulb temperature (K)

\dot{V}_{air} is the load side air volumetric flow rate (m³/s)

\dot{V}_w is the source side water volumetric flow rate (m³/s)

Q_{total} is the total cooling capacity (W)

Q_{sens} is the sensible cooling capacity (W)

$Power_c$ is the power consumption in cooling mode (W)

$Q_{source,c}$ is the source side heat transfer rate in cooling mode (W)

Q_h is the total heating capacity (W)

$Power_h$ is the power consumption in heating mode (W)

$Q_{source,h}$ is the source side heat transfer rate in heating mode (W).

The inlet conditions or variables are divided by the reference conditions. This formulation allows the coefficients to fall into smaller range of values. Moreover, the value of the coefficient indirectly represents the sensitivity of the output to that particular inlet variable. The reference conditions used when generating the performance coefficients must be the same as the reference conditions used later in the model. The reference temperature T_{ref} is fixed at 283K. Temperature unit of Kelvin is used instead of Celsius to keep the ratio of the water inlet temperature and reference temperature positive should the water inlet temperature drop below the freezing point.

For cooling mode, the reference conditions; reference load side air volumetric flow rate ($\dot{V}_{air,ref}$), reference source side water volumetric flow rate ($\dot{V}_{w,ref}$), reference sensible capacity ($Q_{sens,ref}$) and reference power input ($Power_{c,ref}$) are the conditions when the heat pump is operating at the highest cooling capacity or reference cooling capacity ($Q_{total,ref}$) indicated in the manufacturer's catalog. Note that the reference conditions for heating mode might differ from the reference conditions specified for the cooling mode.

19.6.8.3 Coefficient Estimation Procedure

The generalized least square method is used to generate the coefficients. This method utilizes an optimization method which calculates the coefficients that will give the least amount of differences between the model outputs and the catalog data. A set of coefficients for the cooling mode is generated which includes A1-A5 for total cooling capacity, B1-B6 for sensible cooling capacity, and C1-C5 for power consumption. The same procedure is repeated for the heating mode to generate the coefficients E1-E5 (total heating capacity) and F1-F5 (power consumption). An information flow chart showing the inputs, reference conditions, performance coefficients and outputs are shown in Figure 19.25.

19.6.9 Zone Air DX Dehumidifier

19.6.9.1 Overview

This model, object name ZoneHVAC:Dehumidifier:DX, simulates the thermal performance and electric power consumption of conventional mechanical dehumidifiers. These systems use a direct expansion (DX) cooling coil to cool and dehumidify an airstream. Heat from the DX system's condenser section is rejected into the cooled/dehumidified airstream, resulting in warm dry air being supplied from the unit. In EnergyPlus, this object is modeled as a type of zone equipment (ref. ZoneHVAC:EquipmentList and ZoneHVAC:EquipmentConnections).

The model assumes that this equipment dehumidifies and heats the air. If used in tandem with another system that cools and dehumidifies the zone air, then the zone dehumidifier should be specified as the lowest cooling priority in the ZoneHVAC:EquipmentList object for best control of zone temperature and humidity levels. With this zone equipment prioritization, the other cooling and dehumidification system would operate first to meet the temperature setpoint (and possibly meet the high humidity setpoint as well). If additional dehumidification is needed, then the zone dehumidifier would operate. The sensible heat generated by the dehumidifier is carried over to the zone air heat balance for the next HVAC time step.

19.6.9.2 Model Description

The user must input water removal, energy factor and air flow rate at rated conditions (26.7°C, 60% RH). Three performance curves must also be specified to characterize the change in water removal and energy consumption at part-load conditions:

1. Water removal curve (function of inlet air temperature and relative humidity)
 2. Energy factor curve (function of inlet air temperature and relative humidity)
 3. Part load fraction correlation (function of part load ratio)
- The water removal modifier curve is a biquadratic curve with two independent variables: dry-bulb temperature and relative humidity of the air entering the dehumidifier. The output of this curve is multiplied by the Rated Water Removal to give the water removal rate at the specific entering air conditions at which the dehumidifier is operating (i.e., at temperature/relative humidity different from the rating point conditions). If the output of this curve is negative, then a warning message is issued and it is reset to 0.0.

Figure 19.25: Information Flow Chart for Water-to-Air Heat Pump Equation Fit Model (Tang 2005)

Figure 19.26: Mechanical Dehumidifier Schematic

$$WaterRemovalModFac = a + b(T_{in}) + c(T_{in})^2 + d(RH_{in}) + e(RH_{in})^2 + f(T_{in})(RH_{in}) \quad (19.271)$$

where:

T_{in} is the dry-bulb temperature of the air entering the dehumidifier (°C)

RH_{in} is the relative of the air entering the dehumidifier (% , 0-100).

- The energy factor modifier curve is a biquadratic curve with two independent variables: dry-bulb temperature and relative humidity of the air entering the dehumidifier. The output of this curve is multiplied by the Rated Energy Factor to give the energy factor at the specific entering air conditions at which the dehumidifier is operating (i.e., at temperature/relative humidity different from the rating point conditions). If the output of this curve is negative, then a warning message is issued and it is reset to 0.0.

$$EFModFac = a + b(T_{in}) + c(T_{in})^2 + d(RH_{in}) + e(RH_{in})^2 + f(T_{in})(RH_{in}) \quad (19.272)$$

- The part load fraction (PLF) correlation curve is a quadratic or a cubic curve with the independent variable being part load ratio (PLR = water removal load to be met / dehumidifier steady-state water removal rate). The part load ratio is divided by the output of this curve to determine the dehumidifier runtime fraction. The part load fraction correlation accounts for efficiency losses due to compressor cycling.

$$PartLoadFrac = PLF = a + b(PLR) + c(PLR)^2 \quad (19.273)$$

or

$$PartLoadFrac = a + b(PLR) + c(PLR)^2 + d(PLR)^3 \quad (19.274)$$

where:

$$PLR = \text{part} - \text{load ratio} = \left(\frac{\text{water removal load to be met}}{\text{dehumidifier steady} - \text{state water removal rate}} \right) \quad (19.275)$$

The part load fraction correlation should be normalized to a value of 1.0 when the part load ratio equals 1.0 (i.e., no efficiency losses when the dehumidifier runs continuously for the simulation timestep). For PLR values between 0 and 1 ($0 <= PLR < 1$), the following rules apply:

$$0.7 \leq PLF \leq 1.0 \quad (19.276)$$

and

$$PLF \geq PLR \quad (19.277)$$

If $PLF < 0.7$ a warning message is issued, the program resets the PLF value to 0.7, and the simulation proceeds. The runtime fraction of the dehumidifier is defined as PLR/PLF . If $PLF < PLR$, then a warning message is issued and the runtime fraction of the dehumidifier is set to 1.0.

Mechanical dehumidifier typically have long runtimes with minimal compressor cycling. So, a typical part load fraction correlation might be:

$$PLF = 0.95 + 0.05(PLR) \quad (19.278)$$

If the user wishes to model no efficiency degradation due to compressor cycling, the part load fraction correlation should be defined as follows:

$$PLF = 1.0 + 0.0(PLR) \quad (19.279)$$

All three part-load curves are accessed through EnergyPlus' built-in performance curve equation manager (Curve:Quadratic, Curve:Cubic and Curve:Biquadratic). It is not imperative that the user utilize all coefficients shown in curve equations above if their performance equation has fewer terms (e.g., if the user's PartLoadFrac performance curve is linear instead of quadratic, simply enter the values for a and b, and set coefficient c equal to zero).

For any simulation time step when there is a water removal load to be met, the dehumidifier is available to operate (via availability schedule), and the inlet air dry-bulb temperature is within the minimum and maximum dry-bulb temperature limits specified in the input file for this object, the water removal rate for the dehumidifier is calculated as follows:

$$\dot{m}_{water,ss} = \frac{\rho_{water} \left(\dot{V}_{water,rated} \right) (WaterRemovalModFac)}{(24 \text{ hr/day}) (3600 \text{ sec/hr}) (1000 \text{ L/m}^3)} \quad (19.280)$$

where:

$\dot{m}_{water,ss}$ is the dehumidifier steady-state water removal rate (kg/s)

ρ_{water} is the density of water (kg/m³)

$\dot{V}_{water,rated}$ is the rated water removal rate (user input) (L/day).

The Zone Dehumidifier Part-Load Ratio (output variable) is then calculated, with the result constrained to be from 0.0 to 1.0:

$$PLR = \frac{\text{water removal load to be met}}{\dot{m}_{\text{water},ss}}, \quad 0.0 \leq PLR \leq 1.0 \quad (19.281)$$

The steady-state and average electrical power consumed by the dehumidifier are calculated next using the following equations:

$$P_{\text{dehumid},ss} = \frac{\dot{V}_{\text{water},rated} (\text{WaterRemovalModFac}) (1000)}{EF_{\text{rated}} (EF\text{ModFac}) (24)} \quad (19.282)$$

$$P_{\text{dehumid},avg} = P_{\text{dehumid},ss} (RTF) + (P_{\text{off-cycle}} (1 - RTF)) \quad (19.283)$$

where the 1000 and 24 are for conversion between kW and W, and days and hours, and:

$P_{\text{dehumid},ss}$ is the dehumidifier steady-state electric power (W)

$P_{\text{dehumid},avg}$ is the zone dehumidifier electric power (W)

$$RTF = \frac{PLR}{PLF} = \text{ZoneDehumidifier Runtime Fraction} \quad (19.284)$$

EF_{rated} is the user input for rated energy factor (L/kWh)

$P_{\text{off-cycle}}$ is the user input for off-cycle parasitic electric load (W).

If the dehumidifier is unavailable to operate for the time period (via the specified availability schedule) then Zone Dehumidifier Electric Power is set equal to zero.

The average water removal rate (kg/s) for the simulation time step is then calculated:

$$\dot{m}_{\text{water},avg} = \dot{m}_{\text{water},ss} (PLR) = \text{Zone Dehumidifier Removed Water Mass Flow Rate} \quad (19.285)$$

The Zone Dehumidifier Sensible Heating Rate (output variable) is calculated as follows:

$$\dot{Q}_{\text{sensible},avg} = \dot{m}_{\text{water},avg} (h_{fg}) + P_{\text{dehumid},avg} \quad (19.286)$$

where h_{fg} is the enthalpy of vaporization of air (J/kg).

The Zone Dehumidifier Sensible Heating Rate (W) is calculated during each HVAC simulation time step, and the results are averaged for the timestep being reported. However, this sensible heating is carried over to the zone air heat balance for the next HVAC time step (i.e., it is reported as an output variable for the current simulation time step but actually impacts the zone air heat balance on the following HVAC time step).

The air mass flow rate through the dehumidifier is determined using the Rated Air Flow Rate (m^3/s) entered in the input, PLR, and converting to mass using the density of air at rated conditions (26.7°C, 60% RH) and local barometric pressure accounting for altitude is:

$$p = 101325 * (1 - 2.25577E - 05 * Z)^{5.2559} \quad (19.287)$$

where p is the pressure in Pa and Z is the altitude in m.

$$\dot{m}_{\text{air},avg} = \rho_{\text{air}} (\dot{V}_{\text{air},rated}) (PLR) \quad (19.288)$$

where:

$\dot{m}_{air,avg}$ is the average air mass flow rate through dehumidifier (kg/s)

$\dot{V}_{air,rated}$ is the rated air flow rate (user input) (m³/s)

ρ_{air} is the density of air at 26.7°C , 60% RH and local barometric pressure (kg/m³).

The dry-bulb temperature and humidity ratio of the air leaving the dehumidifier are calculated as follows:

$$T_{out} = T_{in} + \frac{P_{dehumid,ss} + \dot{m}_{water,ss} h_{fg}}{\rho_{air} \dot{V}_{air,rated} C_p} \quad (19.289)$$

$$w_{out} = w_{in} - \frac{\dot{m}_{water,avg}}{\dot{m}_{air,avg}} \quad (19.290)$$

where:

T_{out} is the zone dehumidifier outlet air temperature which represents the outlet air temperature when the dehumidifier is operating (°C)

T_{in} is the inlet air dry-bulb temperature (°C)

C_p is the heat capacity of air (J/kg)

w_{in} is the inlet air humidity ratio (kg/kg)

w_{out} is the outlet air humidity ratio (kg/kg)

If the dehumidifier does not operate for a given HVAC simulation time step, then the outlet air dry-bulb temperature and humidity ratio are set equal to the corresponding inlet air values.

Since the sensible heating rate impacts the zone air heat balance on the following HVAC time step and is passed to the heat balance via an internal variable, the dry-bulb temperature of the dehumidifier's HVAC outlet air node (System Node Temperature) will always be set equal to the dehumidifier's HVAC inlet air node temperature. Therefore, when the dehumidifier operates the Zone Dehumidifier Outlet Air Temperature (output variable) will not be equal to the System Node Temperature for the dehumidifier's HVAC outlet node.

Finally, the following additional output variables are calculated:

$$Q_{sensible} = \dot{Q}_{sensible,avg} * TimeStepSys * 3600 \quad (19.291)$$

$$E_{Dehumid} = P_{Dehumid,avg} * TimeStepSys * 3600 \quad (19.292)$$

$$P_{off-cycle,avg} = P_{off-cycle} (1 - RTF) \quad (19.293)$$

$$E_{off-cycle} = P_{off-cycle,avg} * TimeStepSys * 3600 \quad (19.294)$$

$$m_{water} = \dot{m}_{water,avg} * TimeStepSys * 3600 \quad (19.295)$$

$$\dot{V}_{water,avg} = \frac{\dot{m}_{water,avg}}{\rho_{water}} \quad (19.296)$$

$$V_{water} = \dot{V}_{water,avg} * TimeStepSys * 3600 \quad (19.297)$$

where:

$Q_{sensible}$ is the output variable 'Zone Dehumidifier Sensible Heating Energy' (J)

$E_{dehumid}$ is the output variable ‘Zone Dehumidifier Electric Energy’ (J)

$P_{off-cycle,avg}$ is the output variable ‘Zone Dehumidifier Off Cycle Parasitic Electric Power’ (W)

$E_{off-cycle}$ is the output variable ‘Zone Dehumidifier Off Cycle Parasitic Electric Energy’ (J)

m_{water} is the output variable ‘Zone Dehumidifier Removed Water Mass’ (kg)

$\dot{V}_{water,avg}$ is the output variable ‘Zone Dehumidifier Condensate Volume Flow Rate’ (m³/s)

V_{water} is the output variable ‘Zone Dehumidifier Condensate Volume’ (m³).

19.6.10 Energy Recovery Ventilator

The input object ZoneHVAC:EnergyRecoveryVentilator provides a model for a stand alone energy recovery ventilator (ERV) that is a single-zone HVAC component used for exhaust air heat recovery (see Figure 19.27). This compound object consists of three required components: a generic air-to-air heat exchanger (see object HeatExchanger:AirToAir:SensibleAndLatent), a supply air fan, and an exhaust air fan (see object Fan:OnOff). An optional controller (see object ZoneHVAC:EnergyRecoveryVentilator:Controller) may be used to simulate economizer (free cooling) operation.

Figure 19.27: Schematic of the Energy Recovery Ventilator:Stand Alone compound object

This compound object models the basic operation of supply and exhaust air fans and an air-to-air heat exchanger. The stand alone ERV operates whenever the unit is scheduled to be available (Availability schedule). The stand alone ERV object can be used in conjunction with an economizer feature whereby heat exchange is suspended whenever free cooling is available (i.e., air flow is fully bypassed around a fixed-plate heat exchanger or the rotation of a rotary heat exchanger is stopped).

To model a stand alone ERV connected to a single zone, the input data file should include the following objects:

- ZoneHVAC:EnergyRecoveryVentilator
- HeatExchanger:AirToAir:SensibleAndLatent
- Fan:OnOff (supply air)
- Fan:OnOff (exhaust air)
- ZoneHVAC:EnergyRecoveryVentilator:Controller (if economizer [free cooling] operation is desired)
- SetpointManager:Scheduled (if supply air outlet temperature control is used, Ref. HeatExchanger:AirToAir:SensibleAndLatent)
- ZoneHVAC:EquipmentConnections
- ZoneHVAC:EquipmentList
- OutdoorAir:NodeList

19.6.10.1 Model Description

The purpose of this compound component is to simply call the individual component models and optional controller for each energy recovery ventilator. Since this equipment is not associated with an air loop, the compound object sets the supply and exhaust air mass flow rates through the ventilator. This compound object is also used to report the total, sensible and latent energy supplied to the zone, as well as the total electrical energy consumed by all of the individual components (supply air fan, exhaust air fan and heat exchanger parasitics).

During each simulation time step, the air mass flow rate at the supply air and exhaust air inlets is set based on the stand alone ERV's availability schedule and the specified volumetric air flow rates as follows:

IF (Availability Schedule Value > 0) THEN

$$\dot{m}_{Supply} = \rho \dot{V}_{Supply} \quad (19.298)$$

$$\dot{m}_{Exhaust} = \rho \dot{V}_{Exhaust} \quad (19.299)$$

ELSE

$$\dot{m}_{Supply} = \dot{m}_{Exhaust} = 0.0 \quad (19.300)$$

END IF

where:

\dot{m}_{Supply} is the mass flow rate of the supply air stream (kg/s)

$\dot{m}_{Exhaust}$ is the mass flow rate of the exhaust air stream (kg/s)

ρ is the density of dry air at local barometric pressure (adjusted for altitude) and 20 °C (kg/m³)

\dot{V}_{Supply} is the volumetric flow rate of the supply air stream (m³/s)

$\dot{V}_{Exhaust}$ is the volumetric flow rate of the exhaust air stream (m³/s)

With the supply and exhaust inlet air mass flow rates set, the compound object then calls the generic air-to-air heat exchanger model to determine its supply air and exhaust air exiting conditions

based on the inputs specified in the heat exchanger object. The supply air and exhaust air fans are then modeled to determine the final conditions of the air streams exiting the stand alone energy recovery ventilator. The heat exchanger and fan models are described in detail elsewhere in this document (reference: HeatExchanger:AirToAir:SensibleAndLatent and Fan:OnOff).

The sensible heat transfer rate to the zone by the stand alone ventilator is then calculated as follows:

$$\dot{Q}_{Sensible} = \dot{m}_{Supply} (h_{SupplyOutlet} - h_{ExhaustInlet})_{HRmin} \quad (19.301)$$

where:

$\dot{Q}_{Sensible}$ is the sensible energy transfer rate to the zone (W)

\dot{m}_{Supply} is the mass flow rate of the supply air stream (kg/s)

$h_{SupplyOutlet}$ is the enthalpy of the air being supplied to the zone (J/kg)

$h_{ExhaustInlet}$ is the enthalpy of the air being exhausted from the zone through the ventilator (J/kg)

HR_{min} is the enthalpies evaluated at a constant humidity ratio, the minimum humidity ratio of the supply air outlet or the exhaust air inlet.

The resulting sensible energy transfer rate is passed to the zone equipment manager and added to the zone load to be met by other heating or cooling equipment. Since the stand alone ERV is intended to reduce the outdoor air load through heat exchange and not meet that load completely, the stand alone heat exchanger must be modeled first in the list of zone equipment. This is accomplished by setting the stand alone ERV priority for cooling and heating higher than that of other zone cooling or heating equipment (reference: ZoneHVAC:EquipmentList).

When economizer (free cooling) operation is desired, a controller is coupled to the stand alone ERV by providing the name of the controller object in the ERV controller input field. This controller determines when the air-side economizer is active (i.e., air flow is fully bypassed around a fixed-plate heat exchanger or the rotation of a rotary heat exchanger is stopped) based on the controller inputs (Ref. ZoneHVAC:EnergyRecoveryVentilator:Controller).

At the end of each HVAC simulation time step, this compound object reports the heating or cooling rate and energy delivered to the zone, as well as the electric power and consumption by the ventilator. In terms of thermal energy delivered to the zone, the sensible, latent and total energy transfer rate to the zone is calculated as follows:

$$\dot{Q}_{Total} = \dot{m}_{Supply} (h_{SupplyOutlet} - h_{ExhaustInlet}) \quad (19.302)$$

$$\dot{Q}_{Sensible} = \dot{m}_{Supply} (h_{SupplyOutlet} - h_{ExhaustInlet})_{HRmin} \quad (19.303)$$

$$\dot{Q}_{Latent} = \dot{Q}_{Total} - \dot{Q}_{Sensible} \quad (19.304)$$

where:

\dot{Q}_{Total} is the total energy transfer rate to the zone (W)

$\dot{Q}_{Sensible}$ is the sensible energy transfer rate to the zone (W)

\dot{Q}_{Latent} is the latent energy transfer rate to the zone (W)

\dot{m}_{Supply} is the mass flow rate of the supply air stream (kg/s)

$h_{SupplyOutlet}$ is the enthalpy of the air being supplied to the zone (J/kg)

$h_{ExhaustInlet}$ is the enthalpy of the air being exhausted from the zone through the ventilator (J/kg)

HR_{min} is the enthalpies evaluated at a constant humidity ratio, the minimum humidity ratio of the supply air outlet or the exhaust air inlet.

Since each of these energy transfer rates can be calculated as positive or negative values, individual reporting variables are established for cooling and heating and only positive values are reported. The following calculations are representative of what is done for each of the energy transfer rates:

IF ($\dot{Q}_{Total} < 0.0$) THEN

$$\dot{Q}_{TotalCooling} = ABS(\dot{Q}_{Total}) \quad (19.305)$$

$$\dot{Q}_{TotalHeating} = 0.0 \quad (19.306)$$

ELSE

$$\dot{Q}_{TotalCooling} = 0.0 \quad (19.307)$$

$$\dot{Q}_{TotalHeating} = ABS(\dot{Q}_{Total}) \quad (19.308)$$

END IF

where:

$\dot{Q}_{TotalCooling}$ is the output variable ‘Zone Ventilator Total Cooling Rate’ (W)

$\dot{Q}_{TotalHeating}$ is the output variable ‘Zone Ventilator Total Heating Rate’ (W).

In addition to heating and cooling rates, the heating and cooling energy supplied to the zone is also calculated for the time step being reported. The following example for total cooling energy is representative of what is done for the sensible and latent energy as well as the heating counterparts.

$$Q_{TotalCooling} = \dot{Q}_{TotalCooling} * TimeStepSys * 3600 \quad (19.309)$$

where:

$Q_{TotalCooling}$ is the output variable ‘Zone Ventilator Total Cooling Energy’ (J)

$TimeStepSys$ is the HVAC system simulation time step (hr).

19.6.11 Zone Evaporative Cooler Unit

The input object ZoneHVAC:EvaporativeCoolerUnit provides a zone equipment model for evaporative cooling. This is a compound object that combines a fan and one or two evaporative coolers in a zone unit. The fan and evaporative cooler component models are described elsewhere. In this section we describe how the zone unit is controlled.

19.6.11.1 Controls

There are three choices for control methods.

ZoneTemperatureDeadbandOnOffCycling. This control method operates the cooler unit in a manner similar to how a normal, real-world thermostat operates. The control uses input for throttling temperature range, $\Delta T_{throttle}$, the most recent result for zone air node temperature, T_{zone} , and the current cooling setpoint temperature, T_{set} . The controller also stores the history of whether

or not the unit was operating during the previous timestep to model hysteresis control where the unit retains its mode when it passes through the throttling range (to avoid short cycling).

The following algorithm is used to determine if the unit will operate.

If $[T_{zone} < (T_{set} - 0.5 * \Delta T_{throttle})]$ is true, then do not operate cooler unit.

If $[T_{zone} > (T_{set} + 0.5 * \Delta T_{throttle})]$ is true, then operate the cooler unit (at full speed).

If zone air temperature is within the throttling range, $(T_{set} - 0.5\Delta T_{throttle}) < T_{zone} < (T_{set} + 0.5\Delta T_{throttle})$, then continue to operate the cooler if it was running during the previous timestep and do not operate the cooler if it was not running during the previous timestep.

Whenever the unit is operating, it runs at the full design air mass flow rate regardless if the fan is constant or variable speed but the unit cycles to meet the current cooling load.

ZoneCoolingLoadOnOffCycling. This control method operates the cooler similar to how a thermostat would behave, but instead of using temperatures it uses the predicted zone load to cooling setpoint. The control uses input for the threshold value for a load that is considered a significant, \dot{Q}_{thresh} , and the result from the Predictor for the zone's load to cooling setpoint, $\dot{Q}_{CoolLoad}$. The following algorithm is used to determine if the unit will operate.

If $[\dot{Q}_{CoolLoad} \leq \dot{Q}_{thresh}]$ is true, then do not operate cooler unit.

If $[\dot{Q}_{CoolLoad} > \dot{Q}_{thresh}]$ is true, then operate the cooler unit (at full speed).

Whenever the unit is operating, it runs at the full design air mass flow rate regardless if the fan is constant or variable speed but the unit cycles to meet the current cooling load.

ZoneCoolingLoadVariableSpeedFan. This control method also operates the cooler using the predicted zone load to cooling setpoint but instead of on/off cycling, it modulates the fan speed to meet the cooling load. This control method is only applicable to cooler units with variable speed supply fans. The control uses input for the threshold value for a load that is considered a significant, \dot{Q}_{thresh} , and the result from the Predictor for the zone's cooling load to setpoint, $\dot{Q}_{CoolLoad}$. The following algorithm is used to determine if the unit will operate.

If $[\dot{Q}_{CoolLoad} \leq \dot{Q}_{thresh}]$ is true, then do not operate cooler unit.

If $[\dot{Q}_{CoolLoad} > \dot{Q}_{thresh}]$ is true, then operate the cooler unit.

When the unit operates, the model first operates the unit at the highest fan speed, a fan speed ratio of 1.0, and determines the sensible cooling provided by the unit to the zone, $\dot{Q}_{FullOutput}$. If $\dot{Q}_{FullOutput} \leq \dot{Q}_{CoolLoad}$, then the unit operates at full fan speed because the cooler cannot meet the entire zone cooling load. If $\dot{Q}_{FullOutput} > \dot{Q}_{CoolLoad}$, then the model solves for a fan speed ratio between 0.0 and 1.0 that satisfies $|\left(\dot{Q}_{Output} - \dot{Q}_{CoolLoad}\right)| < 0.01$ using the non-linear numerical method called root solver.

19.6.12 Hybrid Unitary HVAC Equipment

19.6.12.1 Overview

The input object ZoneHVAC:HybridUnitaryHVAC provides a model for hybrid unitary HVAC systems – packaged forced air equipment with multiple discrete operating modes. Equipment in this category may utilize a wide variety technologies including, but not limited to: indirect evaporative cooling, desiccant dehumidification, heat recovery, vapor compression, adsorption, or ventilation cooling. Each hybrid system packages multiple technologies into a single integrated system. There

are a multitude of unique hybrid system architectures, and each unique system may have numerous unique operating modes.

ZoneHVAC:HybridUnitaryHVAC is a black-box model designed to allow empirical representation of a wide variety of hybrid unitary systems. The model does not require information about internal system architecture, however it requires extensive data to describe the performance of a product in every operating mode. The model is intended for forced air equipment and can represent unitary systems that consume electricity, water, and up to two additional fuel types.

19.6.12.2 Model

ZoneHVAC:HybridUnitaryHVAC will operate to provide cooling, heating, ventilation, humidification, or dehumidification for a zone. A ZoneHVAC:HybridUnitaryHVAC object is assigned to a zone using ZoneHVAC:EquipmentList and ZoneHVAC:EquipmentConnections. The object must be assigned a supply air node (which must be a zone inlet node), a return air node (which must be a zone outlet node), and an outdoor air node. In the case when the hybrid system modeled does not utilize either return air or outdoor air, a return air node and an outdoor air node must still be assigned. The resulting mass flow rate on those nodes will be zero.

The zone sensible cooling or heating load is determined in each time step according to temperature set points specified in a ZoneControl:Thermostat object. The zone humidification or dehumidification load is determined in each time step according to relative humidity set points specified in a ZoneControl:Humidistat object (Ref: Zone Controls). The intended zone ventilation rate is specified in a DesignSpecification:OutdoorAir object (Ref: Design Outdoor Air Calculation).

The performance of a hybrid system is not directly given as a result of the loads and the environmental conditions. A hybrid system may have numerous discrete operating modes, within which other variables may be adjusted in fine intervals. There may be many settings in which a hybrid system could feasibly operate at a given time. Therefore, ZoneHVAC:HybridUnitaryHVAC is structured as a constrained optimization problem that is solved in each time step. The feasible settings are the unique combinations of operating mode, outdoor air fraction, and supply air mass flow rate that satisfy constraints. In each time step the hybrid model will choose to operate at one or more settings so as to best satisfy the sensible load, latent load, and scheduled ventilation rate while minimizing resource consumption.

Inequality constraints for the optimization include the ranges of indoor and outdoor psychrometric conditions within which each mode is allowed to operate, and the allowable ranges for supply air temperature and absolute humidity generated by the system. These inequality constraints are specified directly as inputs to each ZoneHVAC:HybridUnitaryHVAC object. The scheduled ventilation rate, the zone sensible load, and the zone latent load act as soft inequality constraints.

EnergyPlus simulations occur on user defined time steps, accordingly, the hybrid system may operate in multiple settings within each time step. The portion of each time step spent in a setting is described as the part runtime fraction for that setting. If no combination of settings and part runtime fractions will satisfy all of the soft constraints the system will choose the combination of settings and part runtime fractions that most nearly satisfies all soft constraints.

During any time step that the combination of settings can satisfy all of the soft constraints with part runtime fractions that sum to less than one, the system will operate in a standby mode (Mode 0) for the remainder of the timestep. If the indoor and outdoor psychrometric conditions are beyond the constraints that limit each operating mode, or if no setting will satisfy the constraints on supply air temperature and absolute humidity, the system will operate in standby mode (Mode

0).

19.6.12.3 Inputs and Data

The model requires extensive empirical data to describe system performance in each operating mode as a function of several independent variables. Uncontrolled independent variables include outdoor air conditions and indoor air conditions. Controlled independent variables within each mode include supply air flow rate and outdoor air fraction. Dependent variables include supply air temperature, supply air humidity, electricity use, fuel uses, water use, fan electricity use, and external static pressure. The dependent variables are mapped with lookup tables. Independent variables (xk) for the model include:

- x1 = outside air temperature (dry bulb) ($^{\circ}\text{C}$) = T_{OSA}
- x2 = outside humidity ratio (g H₂O/g dry air) = ω_{OSA}
- x3 = return air temperature (dry bulb) ($^{\circ}\text{C}$) = T_{RA}
- x4 = return air humidity ratio (g H₂O/g dry air) = ω_{RA}
- x5 = normalized supply air mass flow rate (–) = $\dot{m}_{SA}/\dot{m}_{SA,max}$
- x6 = outside air fraction (–) = OSAF

Dependent variables (yi) for the model include:

- y1 = supply air temperature (dry bulb) ($^{\circ}\text{C}$) = T_{SA}
- y2 = supply air humidity ratio (gH₂O/g dry air) = ω_{SA}
- y3 = total electric power (kJ/kg) = $\dot{W}_{elec}/\dot{m}_{SA,max}$
- y4 = supply fan electric power (kJ/kg) = $\dot{W}_{fan\ elec}/\dot{m}_{SA,max}$
- y5 = second fuel consumption (kJ/kg) = $\dot{W}_{fuel}/\dot{m}_{SA,max}$
- y6 = third fuel consumption (kJ/kg) = $\dot{W}_{fuel}/\dot{m}_{SA,max}$
- y7 = water consumption (liters/kg) = $\dot{V}_{water}/\dot{m}_{SA,max}$
- y8 = external static pressure (Pa) = PESF

The relationship between the independent variables and each dependent variable must be specified as lookup tables using **Table:Lookup** objects. A table must be created for each relevant dependent variable in each operating mode. Every operating mode must have a table for supply air temperature and a table for supply air humidity ratio. If tables are omitted for other dependent variables the model will assume that they are not relevant for the associated operating mode. The model can accommodate up to 26 discrete operating modes, including a standby mode.

To permit scaling of performance data, all extensive dependent variables are normalized by the system maximum supply air mass flow rate. To rescale performance data, extensive parameters are multiplied by a desired maximum supply air flow rate, which is specified as an input to each ZoneHVAC:HybridUnitaryHVAC object.

19.6.12.4 Calculation

The constrained optimization problem solved in each time step can be stated explicitly as:

19.6.12.4.1 Minimize:

$$\dot{W}_{resource}(t) = f(T_{OSA}(t), \omega_{OSA}(t), T_{RA}(t), \omega_{RA}(t), [mode_i(t), \dot{m}_{SAi}(t), OSAF_i(t), RF_i(t)]_{i=1}^N) \quad (19.310)$$

19.6.12.4.2 Subject to:

soft constraints:

$$\dot{Q}_{sensible}(t) \geq \dot{Q}_{sensible}^{requested}(t) \quad (19.311)$$

$$\dot{Q}_{latent}(t) \geq \dot{Q}_{latent}^{requested}(t) \quad (19.312)$$

$$\dot{m}_{ventilation}(t) \geq \dot{m}_{ventilation}^{requested}(t) \quad (19.313)$$

constraints on supply air temperature and humidity ratio:

$$T_{SA}^{min}(t) \leq T_{SA}(\check{t}) \leq T_{SA}^{max}(t) \quad (19.314)$$

$$\omega_{SA}^{min}(t) \leq \omega_{SA}(\check{t}) \leq \omega_{SA}^{max}(t) \quad (19.315)$$

limits for each operating mode j :

$$T_{OSA}^{min,j} \leq T_{OSA}(t) \leq T_{OSA}^{max,j} \quad (19.316)$$

$$\omega_{OSA}^{min,j} \leq \omega_{OSA}(t) \leq \omega_{OSA}^{max,j} \quad (19.317)$$

$$RH_{OSA}^{min,j} \leq RH_{OSA}(t) \leq RH_{OSA}^{max,j} \quad (19.318)$$

$$T_{RA}^{min,j} \leq T_{RA}(t) \leq T_{RA}^{max,j} \quad (19.319)$$

$$\omega_{RA}^{min,j} \leq \omega_{RA}(t) \leq \omega_{RA}^{max,j} \quad (19.320)$$

$$RH_{RA}^{min,j} \leq RH_{RA}(t) \leq RH_{RA}^{max,j} \quad (19.321)$$

$$\dot{m}_{SA}^{min,j} \leq \dot{m}_{SA}(\check{t}) \leq \dot{m}_{SA}^{max,j} \quad (19.322)$$

$$OSAF_{OSA}^{min,j} \leq OSAF_{OSA}(\check{t}) \leq OSAF_{OSA}^{max,j} \quad (19.323)$$

Since the model may select multiple settings within each time step, the outputs reported are weighted averages of the outputs determined for each setting independently.

Intensive output variables are determined as a supply air mass weighted time step average.

Supply air temperature is determined as a supply air mass weighted time step average:

$$\overline{T_{SA}}(t) = \frac{\sum_{i=1}^N RF_i(t) \cdot \dot{m}_{SAi}(t) \cdot T_{SAi}(t)}{\sum_{i=1}^N RF_i(t) \cdot \dot{m}_{SAi}(t)} \quad (19.324)$$

Supply air humidity ratio is determined as a supply air mass weighted time step average:

$$\overline{\omega_{SA}}(t) = \frac{\sum_{i=1}^N RF_i(t) \cdot \dot{m}_{SAi}(t) \cdot \omega_{SAi}(t)}{\sum_{i=1}^N RF_i(t) \cdot \dot{m}_{SAi}(t)} \quad (19.325)$$

Outdoor air fraction is determined as a supply air mass weighted time step average:

$$\overline{OAF}_{SA}(t) = \frac{\sum_{i=1}^N RF_i(t) \cdot \dot{m}_{SAi}(t) \cdot OAF_i(t)}{\sum_{i=1}^N RF_i(t) \cdot \dot{m}_{SAi}(t)} \quad (19.326)$$

Extensive output variables are determined as time weighted time step averages.

Supply air mass flow rate is determined as a time weighted time step average of the supply air mass flow rate in each setting:

$$\overline{\dot{m}_{SA}}(t) = \frac{\sum_{i=1}^N RF_i(t) \cdot \dot{m}_{SAi}(t)}{\sum_{i=1}^N RF_i(t)} \quad (19.327)$$

System electric power, fan power, fuel consumption, and water consumption are determined as time weighted time step averages of each resource use in each setting.

$$\overline{\dot{W}_{resource}}(t) = \frac{\sum_{i=1}^N RF_i(t) \cdot \dot{W}_{resource}(t)}{\sum_{i=1}^N RF_i(t)} \quad (19.328)$$

In this way, calculations of cooling capacity and other metrics can proceed according to typical functions at the time step scale. For example:

$$\begin{aligned} \dot{Q}_{SystemSensible}(t) = & \overline{\dot{m}_{SA}}(t) \cdot \\ & \frac{1}{2} (C_{p,RA}(t) + \overline{OAF}(t) \cdot (C_{p,OA}(t) - C_{p,RA}(t)) + \overline{C_{p,SA}}(t)) \cdot \\ & (T_{RA}(t) + \overline{OAF}(T_{OA}(t) - T_{RA}(t)) - \overline{T_{SA}}(t)) \end{aligned} \quad (19.329)$$

and:

$$\dot{Q}_{SystemLatent}(t) = \frac{\lambda \overline{\dot{m}_{SA}}(t)}{1 + \overline{\omega_{SA}}(t)} (\omega_{RA}(t) + \overline{OAF}(\omega_{OA}(t) - \omega_{RA}(t)) - \omega_{SA}(t)) \quad (19.330)$$

and:

$$\dot{Q}_{SystemSensible}(t) = \frac{\overline{\dot{m}_{SA}}(t)}{2} (C_{p,RA}(t) - C_{p,SA}(t)) (T_{RA}(t) - \overline{T_{SA}}(t)) \quad (19.331)$$

and:

$$\dot{Q}_{ZoneLatent}(t) = \frac{\overline{\dot{m}_{SA}}(t)}{1 + \overline{\omega_{SA}}(t)} \lambda (\omega_{RA}(t) - \overline{\omega_{SA}}(t)) \quad (19.332)$$

where:

- $\dot{Q}_{SystemSensible}(t)$ is the system sensible cooling capacity for time step
- $\dot{Q}_{SystemLatent}(t)$ is the system latent cooling capacity for time step
- $\dot{Q}_{ZoneSensible}(t)$ is the zone sensible cooling capacity for time step

- $\dot{Q}_{ZoneLatent}(t)$ is the zone latent cooling capacity for time step
- $\overline{\dot{m}_{SA}}(t)$ is the time weighted average supply air mass flow rate for time step
- $C_{p,RA}(t)$ is the specific heat capacity of return air for time step
- $C_{p,OA}(t)$ is the specific heat capacity of outdoor air for time step
- $\overline{C_{p,SA}}(t)$ is the supply air mass weighted average specific heat capacity of supply air for time step
- λ is the latent heat of vaporization for water
- $\overline{OAF}(t)$ is the supply air mass weighted average outdoor air fraction for time step
- $T_{RA}(t)$ is the return air temperature for time step
- $T_{OA}(t)$ is the outdoor air temperature for time step
- $\overline{T_{SA}}(t)$ is the supply air mass weighted average supply air temperature for time step
- $\omega_{RA}(t)$ is the return air humidity ratio for time step
- $\omega_{OA}(t)$ is the outdoor air humidity ratio for time step
- $\overline{\omega_{SA}}(t)$ is the supply air mass weighted average supply air humidity ratio for time step.

19.6.13 Unit Heater

(Note: Some of this information also appears in the Input Output Reference for EnergyPlus. It is repeated here for clarity.)

The input object ZoneHVAC:UnitHeater provides a model for unit heaters that are zone equipment units which are assembled from other components and are a simplification of unit ventilators. They contain only a fan and a heating coil. These components are described elsewhere in this document. The unit heater input simply requires the names of these components, which have to be described elsewhere in the input. The input also requires the name of an availability schedule, maximum airflow rate, and maximum and minimum hot water volumetric flow rates. The unit is connected to the zone inlet and exhaust nodes by specifying unit inlet and outlet node names. Note that the unit air inlet node should be the same as a zone exhaust node and the unit outlet node should be the same as a zone inlet node.

19.6.13.1 Controls

While the control of the heating coil is similar to the fan coil units and the unit ventilator, the overall control of the unit heater is much different. There are four different modes in which a unit heat can operate based on the user input:

OFF: In this mode, the unit has been scheduled off. All flow rates are set to zero, and the temperatures are set to zone conditions.

NO LOAD OR COOLING/"NO" for "Supply Air Fan Operation During No Heating" input field : In this mode, the unit is available, but there is no heating load. With "No" specified for

“Supply Air Fan Operation During No Heating” and the supply fan operating mode schedule value of 0, the fan will only run when there is a heating load. Since there is no heating load in this mode and the fan is in cycling operating mode, all flow rates are set to zero, and the temperatures are set to zone conditions. Since the unit heater is designed only to provide heating, the presence of a cooling load signifies that the unit should not be running.

NO LOAD OR COOLING/”YES” for “Supply Air Fan Operation During No Heating” input field: In this mode, the unit is available and the fan is controlled to be running continuously. For OnOff fan type the supply fan operating mode schedule value should be greater than 0. If it is scheduled to be available and the supply fan operating mode schedule value is greater than 0, then the fan runs and circulates air to the space. While no direct heating is provided, any heat added by the fan is introduced into the space with the circulation of the air. If the fan is scheduled off, the fan will not run (this is identical to “NO” control with no load).

With “Yes” specified for “Supply Air Fan Operation During No Heating”, and the supply fan operating mode schedule value is 0 (for onOff fan type), then supply fan will not run. Since there is no heating load in this mode and the fan is in cycling mode, all flow rates are set to zero. This control mode allows to schedule the supply fan operation by specifying different operating modes during the day regardless of the heating load.

HEATING: In this mode, the unit and fan are on/available, and there is a heating load. The heating coil is modulated (constant fan speed) to meet the heating load. When the fan is not cycling then the control of the heating coil and its flow rate is identical to the fan coil unit. The flow rate of air through the unit is controlled by the user input and schedules. In the case of OnOff fan the fan cycles with heating coil if the current timestep supply fan operating mode schedule value is 0, or the supply fan runs continuously for the entire timestep if the current timestep fan operating mode schedule value is greater than 0. When the fan is cycling the average supply air flow rate is proportional to the heating load at current time step, or else when the fan is scheduled to run continuously the fan supplies the maximum flow rate specified.

19.6.14 Unit Ventilator

(Note: Some of this information also appears in the Input Output Reference for EnergyPlus. It is repeated here for clarity.)

The input object ZoneHVAC:UnitVentilator provides a model for unit ventilators that are zone equipment units which are assembled from other components. They contain a built-in outdoor air mixer, a fan, a heating coil, and a cooling coil. These components are described elsewhere in this document, except the built-in outdoor air mixer which is contained within the unit ventilator statement. The unit ventilator input simply requires the names of these other three components, which have to be described elsewhere in the input. The input also requires the name of an availability schedule, maximum airflow rate, outdoor air control information (control type and schedules), an outdoor airflow rate, and maximum and minimum hot and cold water mass flow rates. The unit is connected to the zone inlet and exhaust nodes and the outdoor air by specifying unit inlet, outlet, outdoor air and exhaust (relief) air node names. Note that if the Unit Ventilator is not connected to central dedicated outdoor air (DOA), then the unit air inlet node should be the same as a zone exhaust air node and the unit air outlet node should be the same as a zone air inlet node. The three node name input fields: *Outdoor Air Node Name*, *Exhaust Air Node Name*, and *Mixed Air Node Name* are required fields only when the built-in outdoor air mixer is used to provide outdoor air. If the Unit Ventilator is connected to a central dedicated outdoor air (DOA) via

AirTerminal:SingleDuct:Mixer, then the above three node name input fields are not required and must be left blank. In the later case the Unit Ventilator node connection to the zone air exhaust node and the zone air inlet node are described in *AirTerminal:SingleDuct:Mixer* object. In general, the unit ventilator input is very similar to the fan coil unit input, and the unit is connected to a hot water loop (demand side) through its hot water coil and to a chilled water loop (demand side) through its cooling coil.

19.6.14.1 Controls and Outdoor Air

The main difference between the fan coil and unit ventilator input is that the unit ventilator has a built-in outdoor air mixer with its own specialized controls. The outdoor air control type can be selected from one of the following options: “variable percent”, “fixed temperature” or “fixed amount”. In fixed temperature control, the amount of outdoor air is varied between the minimum outdoor air fraction (specified by a schedule) and 100% outdoor air to obtain a mixed air temperature as close as possible to the temperature schedule defined in the input. Variable percent control will also vary the amount of outdoor air between the minimum and maximum fractions (both specified in input by the user) to meet the load without the use of a coil if possible. In fixed amount control, the outdoor air flow rate is fixed to the specified value by the user. In this control strategy, the maximum outdoor air flow rate and schedule are automatically set to be equal to the minimum outdoor air flow rate and schedule. These control types are based on the 2004 ASHRAE Systems and Equipment Handbook (pp. 31.1-31.3) description of unit ventilator systems. The three outdoor air control strategies are also valid and available when the Unit Ventilator is connected to central DOA.

The unit is controlled to meet the zone (remaining) heating or cooling demand. If there is a heating demand, the cooling coil is off and the hot water flow through the heating coil is throttled to meet the demand. The hot water control node must be specified (same as the hot water coil inlet node) as well as maximum and minimum possible hot water volumetric flow rates. If there is a cooling demand from the zone, the hot water coil is off and the chilled water flow through the cooling coil is throttled to meet the load. The cooling coil control node must be specified (same as the cooling coil inlet node) and the maximum and minimum chilled water volumetric flow rates must be given. Finally both heating and cooling require a convergence tolerance, which is the tolerance denoting how closely the fan coil unit will meet the heating or cooling load. The tolerance is always relative to the zone load.

Overall, control of the unit must consider the outdoor air for continuously running and cycling fans. For cycling fan operating mode, the outdoor air mass rate is capped by the actual supply air flow rate if the former is greater than the latter; otherwise, uses the amount calculated by the outdoor air control. Here is a more detailed description of the overall unit control:

OFF: Unit is schedule off or there is no load on it. All flow rates are set to zero and the temperatures are set to zone conditions (except for the outdoor air inlet). Outdoor air requirements will not override this condition.

HEATING/NO COIL/VARIABLE PERCENT: The unit is on, there is a heating load, no heating coil is present or it has been scheduled off, and variable percent outdoor air control type has been specified. In this case, the variable percent outdoor air controls what happens with the outdoor air. If the outside temperature is greater than the return temperature, then the outdoor air is set to the maximum as defined by the user input. If the outdoor air temperature is less than the return temperature from the zone, then the outdoor air is set to the minimum outdoor air flow

rate as defined by the user. Since a coil is not present to further condition the supply air, the zone simply receives whatever temperature air results from the outdoor air controls.

HEATING/NO COIL/FIXED TEMPERATURE: The unit is on, there is a heating load, no heating coil is present or it has been scheduled off, and fixed temperature has been specified. The unit ventilator tries to use outdoor air as best as possible to meet the temperature goal. If it cannot meet this goal because the temperature goal is not between the zone return temperature and the outdoor air temperature, then the unit ventilator will either use the maximum or minimum outdoor air flow rate.

HEATING/NO COIL/FIXED AMOUNT: The unit is on, there is a heating load, no heating coil is present or it has been scheduled off, and fixed amount control has been specified. The unit ventilator fixes the outdoor air flow rate as defined by the user and sets the maximum and minimum outdoor air flow rate to be equal in order to avoid the variation of outdoor air flow rate between the maximum and minimum values. Since a coil is not present to further condition the supply air, the zone simply receives whatever temperature air results from the outdoor air controls.

HEATING/WITH COIL/VARIABLE PERCENT: The unit is on, there is a heating load, and variable percent control is specified. The outdoor air fraction is set to the minimum outdoor air fraction (schedule based), and the heating coil is activated. The heating coil attempts to meet the remaining load on the zone being served by the unit ventilator.

HEATING/WITH COIL/FIXED AMOUNT: The unit is on, there is a heating load, a heating coil is present and is scheduled on, and fixed amount control has been specified. The unit ventilator fixes the outdoor air flow rate as defined by the user and sets the maximum and minimum outdoor air flow rate to be equal in order to avoid the variation of outdoor air flow rate between the maximum and minimum values. The heating coil then attempts to meet any remaining zone heating load.

COOLING/NO COIL/VARIABLE PERCENT: The unit is on, there is a cooling load, no coil is present or it has been scheduled off, and variable percent outdoor air control type has been specified. In this case, the variable percent outdoor air controls what happens with the outdoor air. If the outside temperature is greater than the return temperature, then the outdoor air is set to the minimum as defined by the user input. If the outdoor air temperature is less than the return temperature from the zone, then the outdoor air is varied up to the maximum flow rate to try to meet whatever cooling load is present. Since a coil is not present to further condition the supply air, the zone simply receives whatever temperature air results from the outdoor air controls.

COOLING/NO COIL/FIXED TEMPERATURE: The unit is on, there is a cooling load, no cooling coil is present or it has been scheduled off, and fixed temperature has been specified. The unit ventilator tries to use outdoor air as best as possible to meet the temperature goal. If it cannot meet this goal because the temperature goal is not between the zone return temperature and the outdoor air temperature, then the unit ventilator will either use the maximum or minimum outdoor air flow rate in the same fashion as the variable percent outdoor air control.

COOLING/NO COIL/FIXED AMOUNT: The unit is on, there is a cooling load, no cooling coil is present or it has been scheduled off, and fixed amount control has been specified. The unit ventilator fixes the outdoor air flow rate as defined by the user and sets the maximum and minimum outdoor air flow rate to be equal in order to avoid the variation of outdoor air flow rate between the maximum and minimum values. Since a coil is not present to further condition the supply air, the zone simply receives whatever temperature air results from the outdoor air controls.

COOLING/WITH COIL/VARIABLE PERCENT: The unit is on, there is a cooling load, a coil is present and is scheduled on, and variable percent outdoor air control type has been

specified. In this case, the variable percent outdoor air controls what happens with the outdoor air. If the outside temperature is greater than the return temperature, then the outdoor air is set to the minimum as defined by the user input. If the outdoor air temperature is less than the return temperature from the zone, then the outdoor air is varied up to the maximum flow rate to try to meet whatever cooling load is present. The coil then attempts to meet any remaining zone load.

COOLING/WITH COIL/FIXED TEMPERATURE: The unit is on, there is a cooling load, a cooling coil is present and is scheduled on, and fixed temperature has been specified. The unit ventilator tries to use outdoor air as best as possible to meet the temperature goal. If it cannot meet this goal because the temperature goal is not between the zone return temperature and the outdoor air temperature, then the unit ventilator will either use the maximum or minimum outdoor air flow rate in the same fashion as the fixed temperature outdoor air control for the “no coil” conditions. The cooling coil then attempts to meet any remaining zone load.

COOLING/WITH COIL/FIXED AMOUNT: The unit is on, there is a cooling load, a cooling coil is present and is scheduled on, and fixed amount control has been specified. The unit ventilator fixes the outdoor air flow rate as defined by the user and sets the maximum and minimum outdoor air flow rate to be equal in order to avoid the variation of outdoor air flow rate between the maximum and minimum values. The cooling coil then attempts to meet any remaining zone cooling load.

Note: the unit ventilator controls are strictly temperature based and do not factor humidity into the equation (not an enthalpy economy cycle but rather a simple return air economy cycle). In addition, temperature predictions are not strict energy balances here in the control routine though in the mixing routine an energy balance is preserved.

19.6.15 Variable Refrigerant Flow Terminal Unit

Variable refrigerant flow zone terminal units are used exclusively with variable refrigerant flow (VRF) air conditioning systems (ref: AirConditioner:VariableRefrigerantFlow and ZoneTerminalUnitList). The terminal units operate to satisfy a heating or cooling load in a zone based on a zone thermostat temperature set point. A direct-expansion (DX) cooling and/or DX heating coil is specified depending on the operating mode required. Outdoor ventilation air is modeled with the use of an outside air mixer object. Outside air may be provided to the zone only when the coil is operating or can be supplied continuously even when the coil is not operating. A supply air fan is also required and can be modeled as either draw through as shown in Figure 19.28 or as blow through where the fan inlet node would be connected to the outside air mixer mixed air node. If an outside air mixer is not used, the fan inlet node would be connected to the zone exhaust node.

19.6.15.1 Overview

As described previously, the terminal units operate to satisfy a heating or cooling load in a zone based on a zone thermostat temperature set point (Zone Control:Thermostatic). Each simulation time step, EnergyPlus performs a zone air heat balance to determine if cooling or heating is required to meet the zone thermostat set points, excluding any impacts from zone terminal unit operation.

Terminal unit performance is then modeled with all heating/cooling coils off but the supply air fan operates as specified by the user. If the zone air heat balance plus the impact of terminal unit operation with coils off results in no requirement for heating or cooling by the terminal unit coils, or if the terminal unit is scheduled off (via its availability schedule), then the terminal unit coils

Figure 19.28: Zone Terminal Unit Schematic

do not operate and the terminal unit's part-load ratio output variable is set to 0. If the model determines that cooling or heating is required and the terminal unit is scheduled to operate, the model calculates the part-load ratio of the cooling and heating coils in order to meet the thermostat set point temperature.

The following sections describe the performance calculations for cooling-mode and heating-mode.

19.6.15.2 Model Description

Zone terminal units meet a zone load as determined by a zone thermostat. The DX coils within a zone terminal unit will operate to meet a sensible zone load and all terminal units are controlled to either meet a zone sensible cooling load or a zone sensible heating load. This model does not provide for simultaneous cooling and heating.

Given a zone load, the model calculates the part-load ratio of the terminal unit such that the terminal unit's "net" sensible capacity is equal to the zone load (if sufficient capacity is available). If it is determined that the part-load ratio of the zone terminal unit will be equal to 1, the DX cooling coil's capacity is calculated in the same manner as described for single-speed DX cooling coils (ref: Coil:Cooling:DX:SingleSpeed). When it is determined that the part-load ratio of the zone terminal unit will be less than 1, the DX cooling coil's capacity will be modulated through a reduction in refrigerant flow rate and an iterative solution technique will be used to calculate the performance of the DX cooling coil. For DX heating coils, capacity is calculated in the same manner as described for single-speed DX heating coils (ref: Coil:Heating:DX:SingleSpeed).

The "net" sensible full load cooling capacity is then compared to the zone sensible load. If the "net" sensible full load capacity is less than or equal to the absolute value of the zone sensible load, the DX coil operates at the *maximum* available capacity and, as a result, the zone air heat balance adjusts the zone air temperature. If the "net" sensible full load capacity is greater than the absolute value of the zone sensible load, an iterative solution technique is used to determine the total capacity required to meet the zone sensible load. This iteration loop entails successive modeling of DX coil performance and the loop iterates on the required total capacity until the operating "net" sensible capacity is equal to the zone sensible load.

To calculate the coil part-load ratio the model first calculates the "net" sensible capacity using the cooling/heating air flow rate and a very small PLR (default = 1E-20 and cannot be modified by the user). This allows the model to include fan heat in the result if constant fan operating mode is selected. If the resulting "net" system capacity is greater than the zone load, the terminal unit operates at PLR = 0 using the no load air flow rate. For loads greater than this, the model then calculates the "net" sensible capacity at PLR = 1 using the cooling/heating air flow rate. If the zone load exceeds the calculated "net" sensible capacity the terminal unit operates at PLR = 1, otherwise the model iterates to find the operating PLR between 0 (actually 1E-20) and 1.

19.6.15.3 Average Air Flow Calculations

The variable refrigerant flow (VRF) terminal unit operates based on user-specified (or autosized) air flow rates. The VRF terminal unit's supply air flow rate during cooling operation may be different than the supply air flow rate during heating operation. In addition, the supply air flow rate when no cooling or heating is required but the supply air fan remains ON can be different than the air flow rates when cooling or heating is required. The outside air flow rates can likewise be different in these various operating modes. The model takes these different flow rates into account when

Figure 19.29: Variable Refrigerant Flow Terminal Unit Capacity Control

modeling the terminal unit, and the average air flow rate for each simulation time step is reported on the inlet/outlet air nodes of the various VRF terminal unit components in proportion to the calculated cycling ratio of the heat pump condenser. If the compressor does not cycle for a specific simulation time step then the heating or cooling air flow rate as specified by the user is assumed for the entire time step.

The average supply air and outdoor air mass flow rates through the terminal unit for the HVAC simulation time step are calculated based on the cycling ratio of the heat pump condenser as follows:

$$\dot{m}_{SA,avg} = \dot{m}_{SA,coil\ on}(CyclingRatio) + \dot{m}_{SA,coil\ off}(1 - CyclingRatio) \quad (19.333)$$

$$\dot{m}_{OA,avg} = \dot{m}_{OA,coil\ on}(CyclingRatio) + \dot{m}_{OA,coil\ off}(1 - CyclingRatio) \quad (19.334)$$

where:

$\dot{m}_{SA,avg}$ is the average supply air mass flow rate during the time step (kg/s)

$\dot{m}_{SA,coil\ on}$ is the supply air mass flow rate when the coil is ON (kg/s)

$CyclingRatio$ is the cycling ratio of the heat pump condenser (heating or cooling)

$\dot{m}_{SA,coil\ off}$ is the supply air mass flow rate when the coil is OFF (kg/s)

$\dot{m}_{OA,avg}$ is the average outside air mass flow rate during the time step (kg/s)

$\dot{m}_{OA,coil\ on}$ is the average outside air mass flow rate when the coil is ON (kg/s)

$\dot{m}_{OA,coil\ off}$ is the average outside air mass flow rate when the coil is OFF (kg/s).

The supply air and outside air flow rates when the DX cooling coil or the DX heating coil is ON are specified by the user (i.e., supply air volumetric flow rate during cooling operation, supply air volumetric flow rate during heating operation, outside air volumetric air flow rate during cooling operation, and outside air volumetric air flow rate during heating operation) and are converted from

volumetric to mass flow rate. If the user has specified cycling fan/cycling coil operation (i.e. supply air fan operating mode schedule value is equal to 0), then the supply air and outside air mass flow rates when the coil is OFF are zero. If the user has specified constant fan/cycling coil operation (i.e. supply air fan operating mode schedule value is greater than 0), then the user-defined air flow rates when no cooling or heating is needed are used when the coil is OFF.

There is one special case. If the supply air fan operating mode schedule value specifies constant fan operation and the user also specifies that the supply air volumetric flow rate when no cooling or heating is needed is zero (or field is left blank), then the model assumes that the supply air and outside air mass flow rates when the coil is OFF are equal to the corresponding air mass flow rates when the cooling or heating coil was last operating (ON).

19.6.15.4 Calculation of Outlet Air Conditions

When the supply air fan cycles on and off with the terminal unit coils (AUTO fan), the calculated outlet air conditions (temperature, humidity ratio, and enthalpy) from the DX heating coil or the DX cooling coil at full-load (steady-state) operation are reported on the appropriate coil outlet air node. The air mass flow rate reported on the air nodes is the average air mass flow rate proportional to the cycling ratio of the coil (see Average Air Flow Calculations above).

When the supply air fan operates continuously while the terminal unit coils cycle on and off (fan ON), the air mass flow rate reported on the air nodes is the average air mass flow rate proportional to the cycling ratio of the coil (see Average Air Flow Calculations above). Since the air flow rate can be different when the coil is ON compared to when the coil is OFF, then the average outlet air conditions from the DX heating coil or the DX cooling coil are reported on the appropriate coil outlet air node.

19.6.15.5 Calculation of Zone Heating and Cooling Rates

At the end of each HVAC simulation time step, this compound object reports the heating or cooling rate and energy delivered to the zone. In terms of thermal energy delivered to the zone, the sensible, latent and total energy transfer rate to the zone is calculated as follows:

$$\dot{Q}_{Total} = (\dot{m}_{SA,avg}) (h_{out,avg} - h_{zone\ air}) \quad (19.335)$$

$$\dot{Q}_{Sensible} = (\dot{m}_{SA,avg}) (h_{out,avg} - h_{zone\ air})_{HRmin} \quad (19.336)$$

$$\dot{Q}_{Latent} = \dot{Q}_{Total} - \dot{Q}_{Sensible} \quad (19.337)$$

where:

\dot{Q}_{Total} is the total energy transfer rate to the zone (W)

$\dot{Q}_{Sensible}$ is the sensible energy transfer rate to the zone (W)

\dot{Q}_{Latent} is the latent energy transfer rate to the zone (W)

$\dot{m}_{SA,avg}$ is the average mass flow rate of the supply air stream (kg/s)

$h_{out,avg}$ is the enthalpy of the air being supplied to the zone (J/kg).

The terminal unit's energy transfer rate is used by the program in the zone air heat balance to determine the final zone air conditions. If the terminal unit is capable of meeting the zone thermostat set point temperature, then these report variables are indicative of the zone loads and

may be compared directly to the report variables for predicted zone loads (ref: Output:Variable, e.g., Zone Predicted Sensible Load to Setpoint Heat Transfer Rate).

Since each of these energy transfer rates can be calculated as positive or negative values, individual reporting variables are established for cooling and heating and only positive values are reported. The following calculations are representative of what is done for each of the energy transfer rates:

IF ($\dot{Q}_{Total} < 0.0$) THEN

$$\dot{Q}_{TotalCooling} = ABS(\dot{Q}_{Total}) \quad (19.338)$$

$$\dot{Q}_{TotalHeating} = 0.0 \quad (19.339)$$

ELSE

$$\dot{Q}_{TotalCooling} = 0.0 \quad (19.340)$$

$$\dot{Q}_{TotalHeating} = \dot{Q}_{Total} \quad (19.341)$$

ENDIF

where:

$\dot{Q}_{TotalCooling}$ is the output variable ‘Zone VRF Air Terminal Total Cooling Rate’ (W)

$\dot{Q}_{TotalHeating}$ is the output variable ‘Zone VRF Air Terminal Total Heating Rate’ (W).

In addition to heating and cooling rates, the heating and cooling energy supplied to the zone is also calculated for the time step being reported. The following example for total zone cooling energy is representative of what is done for the sensible and latent energy as well as the heating counterparts.

$$Q_{TotalCooling} = \dot{Q}_{TotalCooling} * TimeStepSys * 3600 \quad (19.342)$$

where:

$Q_{TotalCooling}$ is the output variable ‘Zone VRF Air Terminal Total Cooling Energy’ (J)

$TimeStepSys$ is the HVAC system simulation time step (hr).

19.6.16 Ventilated Slab

19.6.16.1 Model Overview

The input object ZoneHVAC:VentilatedSlab provides a model for ventilated slab systems that in general use outdoor air to “precool” slabs with colder nighttime air. This method of precooling the thermal mass of a space can be very effective when nighttime temperatures are low and the mass of the system is high enough to provide a significant amount of cooling potential during the day to counteract internal heat gains within a zone. Nearly all ventilated slabs are simple systems such as that shown in the right side of Figure 19.30. The fan is shown in a blow through position, but the model will allow either a blow or draw through configuration.

It should be noted that in Figure 19.30 the use of “unit ventilator” and “low temperature radiant system” do not imply that the user must also specify these elements in the input file. The ventilated slab model combines aspects of these two existing EnergyPlus features into a single model that the user specifies through the input shown in the Input/Output Reference.

Figure 19.30: Basic System for the Ventilated Slab Module

The ventilated slab system has been implemented in a fashion that is similar to the “unit ventilator” system in EnergyPlus. The unit ventilator is a system that allows the user to bring in outdoor air (ventilation) that may or may not be tempered with a heating or cooling coil as shown the left side of Figure 19.30. The air can be delivered to the slab only (Figure 19.31), to the slab then to the space (Figure 19.32), and to several slabs in different areas in series (Figure 19.33). The model essentially combines the functionality of the low temperature radiant system (using air as a transport medium rather than water) and the unit ventilator. In some cases, the system may not meet all the zone heating and cooling load because it is operated not by setpoint of the zone but control temperature range and coil outlet air temperature set by user input.**Note that no coils are shown in Figure 19.33 for diagram simplicity but the implementation of the system shown in Figure 19.33 includes coils as in Figure 19.31 and Figure 19.32.

Figure 19.31: Model with Air Delivered to Slab (Slab Only Mode)

19.6.16.2 Connections to the Heat Balances

The ventilated slab systems shown in the above diagrams connect or will connect to the various EnergyPlus heat balance equations in a variety of ways. All of the systems send outside or conditioned air through a slab or building element. This portion of the system acts in a fashion that is identical to the low temperature radiant systems. These surfaces that have the air being blown through them will impact the zone and air heat balances through the normal surface heat balances

Figure 19.32: Zone Supply Model using Ventilated Slab (Slab and Zone mode)

Figure 19.33: Multiple Slabs model with Several Zones (Series Slabs Mode)

that interact with this surface. The ventilated slab will participate in the surface heat balances by exchanging radiation with other surfaces in the zone and in the air heat balances via convection to the zone air. So, the ventilated slab is handled identically to the low temperature radiant systems with respect to the zone and air heat balances. This information is valid for all of the systems shown in the figures above.

Figure 19.32 shows that the air, instead of being circulated through the slab and then sent back to the ventilation portion of the system, gets circulated through the space after it gets sent through the slab. When this system is selected in EnergyPlus, it will have an additional impact on the zone air heat balance because air will be introduced into the space at conditions different than the zone air. Thus, it will have an energy impact on the air directly through the circulation of air from the slab to the zone and then back to the ventilated slab system. It will still have an impact on the slab surface convection and radiation as with the other systems.

For more information on the impact on the zone and air heat balances by the ventilated slab system, please consult the low temperature radiant system documentation and the EnergyPlus code.

19.6.17 CoolTower

19.6.17.1 Overview

The Cool Tower (object ZoneCoolTower:Shower) is available for modeling a cooltower (which is sometimes referred to as a wind tower or a shower cooling tower) which is a component that is intended to model a passive downdraught evaporative cooling (PDEC) that is designed to capture the wind at the top of a tower and cool the outdoor air using water evaporation before delivering it to a space. The air flow in these systems is natural as the evaporation process increases the density of the air causing it to fall through the tower and into the space without the aid of a fan. A cooltower typically consists of a water spray or an evaporative pad, a shaft, and a water tank or reservoir. Wind catchers to improve the wind-driven performance at the top of the tower are optional. Water is pumped over an evaporative device by water pump which is the only component consumed power for this system. This water cools and humidifies incoming air and then the cool, dense air naturally falls down through shaft and leaves through large openings at the bottom of cooltowers.

The shower cooling tower shown in Figure 19.34 is controlled by a schedule and the specification of maximum water flow rate and volume flow rate as well as minimum indoor temperature. The actual flow rate of water and air can be controlled as users specify the fractions of water loss and flow schedule. The required input fields include effective tower height and exit area to obtain the temperature and flow rate of the air exiting the tower. A schedule and rated power for the water pump are also required to determine the power consumed. The component typically has a stand-alone water system that is not added to the water consumption from mains. However, users are required to specify the water source through an optional field, the name of water supply storage tank, in case any water comes from a water main.

The cooltower model employing a model of the inertial shower cooling tower is intended to establish the actual mass flow rate of the air that leaves the cooltower and the evaporation rate consumed during the processes within the cooltower. Like infiltration, ventilation, and earth tubes, the air is assumed to be immediately mixed with the zone air. The determination of simultaneous heat and mass transfer that occurs during natural evaporative cooling in cooltower is complicated. Therefore, some assumptions have been made to obtain the conditions of the air and water. All

Figure 19.34: Typical Cooltower Configuration

cooltowers are executed at the start of each time step called by HVAC manager, and the conditions of air temperature and humidity ratio in the zone will be corrected with any other air that enters the zone.

All temperatures in the following descriptions are in degrees C, mass flow rates are in kg/s, and volume flow rates are in m³/s.

19.6.17.2 Model Description

The user must input the required information according to the Input Output Reference Manual (ref: ZoneCoolTower:Shower). The cooltower model requires a unique identifying name, an availability schedule, and the name of the zone being served. The schedule name must refer to a valid schedule type (range 0-1) and contain values of fractional cooltower operation as well as water pump operation. For the determination of the exit temperature and actual air volume flow rate, four additional inputs are required: effective tower height, exit area, fraction of flow schedule, and fraction of water loss. These define the conditions of the exit air, obtaining the conditions of outdoor air from the weather data and thus allow EnergyPlus to correct both the temperature and humidity level in the zone. The power consumed by the water pump can be directly determined by the schedule and rated power that the user inputs. The component is also controlled by the specification of minimum indoor temperature, maximum volume flow rate, and maximum water flow rate. These allow the model to prevent overcooling the zone or overestimation of the air volume flow rate. In addition, the user must input a flow control type according to the information that the user is able to obtain.

19.6.17.3 Simulation and Control

The cooltower model first determines the temperature and volume flow rate of the exit air. Both parameters can be directly determined in case of water flow schedule control when the water flow rate is known. With the outdoor temperatures obtained from weather data, the exit air temperature (T_{out}) can be directly determined as functions of outdoor dry bulb temperature (DB), outdoor wet bulb temperature (WB), effective tower height (H) and water flow rate (WF) in l/min by using following equation:

$$T_{out} = DB - (DB - WB)(1 - \exp(-0.8H))(1 - \exp(-0.15WF)) \quad (19.343)$$

The volume flow rate of the exit air (Q) can also be directly obtained as functions of water flow rate and effective tower height from the following equation:

$$Q = 0.0125WF \cdot H^{0.5} \quad (19.344)$$

If the calculated air volume flow rate is greater than maximum air volume flow rate in this control, which leads to overestimation of actual volume flow rate of the exit air, the calculated air volume flow rate is replaced with the maximum.

For the simulation of wind-driven flow control where the water flow rate is unknown, the model determines velocity of the outlet air (V_{out}) as functions of effective tower height and wind speed of outdoor air (WS) as:

$$V_{out} = 0.7H^{0.5} + 0.47(WS - 1) \quad (19.345)$$

The air volume flow rate (Q) is then calculated by:

$$Q_{estimate} = A \cdot V_{out} \quad (19.346)$$

where A is opening area at the bottom of cooltower.

Substituting the air flow rate to the previous equation for Q , water flow rate is obtained using:

$$WF = \frac{Q}{0.0125 \cdot H^{0.5}} \quad (19.347)$$

Once water flow rate is determined, the model checks the limit of water flow rate that the user inputs, so that the model prevents overestimation of actual volume flow rate of the exit air. If the calculated water flow rate is greater than the maximum water flow rate, the maximum will be chosen. The model also replaces the calculated air volume flow rate with the maximum volume flow rate from the user input when the calculated is greater than the maximum. Then, the model calculates the air volume flow rate and exit temperature using the previous equation for Q and T_{out} .

This cooltower model allows the user to specify water loss due to drift or blow down and the loss of air flow (example: a cooltower which delivers air to both the interior and exterior of the building). If the user inputs the fraction of water loss or flow schedule that means some amount of the air actually goes to outside, the fractional values will be applied to previously calculated ones so that the model calculates both actual water flow rate (WF_{actual}) and air volume flow rate (Q_{actual}) as follows:

$$WF_{actual} = WF(1.0 + Fraction) \quad (19.348)$$

$$Q_{actual} = Q(1.0 - Fraction) \quad (19.349)$$

The model then determines the exit humidity ratio (ω_{out}) from the relation of mass balances below:

$$\omega_{in}(\dot{m}_{air} + \dot{m}_{water}) = \omega_{out} \cdot \dot{m}_{air} \quad (19.350)$$

In this case, actual mass flow rate at the inlet and outlet of cooltower cannot be correctly calculated with limited information. Thus, the model estimates initial conditions of the air based on the outdoor temperatures, the calculated exit air temperature, enthalpy of outdoor air (H_{in}) and outdoor barometric pressure (P). Assuming no enthalpy changes and pressure drops between inlet air and the initialized air, the humidity ratio and mass flow of the initialized air can be obtained by using EnergyPlus psychrometric functions and the following equation:

$$\omega_{in} = PsyWRnTdbTwbPb(T_{db_{in}}, T_{wb_{in}}, P) \quad (19.351)$$

$$\omega_{initial} = PsyWRnTdbH(T_{out}, H_{in}, P) \quad (19.352)$$

$$\rho_{initial_{air}} = PsyRhoAirFnPbTdbW(T_{out}, \omega_{initial}, P) \quad (19.353)$$

$$\dot{m}_{air} = \rho_{initial_{air}} \cdot Q_{actual} \quad (19.354)$$

where $\omega_{initial}$ and $\rho_{initial}$ are the humidity ratio and air density of the initialized air and ω_{in} is the humidity ratio of outdoor air.

Therefore, the humidity ratio of exit air, ω_{out} , is:

$$\omega_{out} = \frac{\omega_{in}(\dot{m}_{air} + \dot{m}_{water})}{\dot{m}_{air}} \quad (19.355)$$

Once the humidity ratio at the exit is determined, the model can obtain the actual density (ρ_{air}), specific heat ($c_{p,air}$), and mass flow rate ($\dot{m}_{cooltower}$) of the air leaving cooltower by using EnergyPlus psychrometric function and following equation:

$$c_{p,air} = PsyCpAirFnW(\omega_{out}) \quad (19.356)$$

$$\rho_{air} = PsyRhoAirFnPbTdbW(T_{out}, \omega_{out}, P) \quad (19.357)$$

$$\dot{m}_{cooltower} = \rho_{air} \cdot Q_{actual} \quad (19.358)$$

Assuming that the water temperature equals to outdoor wet bulb temperature, the model eventually determines density of the water and evaporation rate as bellows.

$$\rho_{water} = RhoH2O(T_{wb_{in}}) \quad (19.359)$$

$$Q_{water} = \frac{\dot{m}_a(\omega_{out} - \omega_{in})}{\rho_{water}} \quad (19.360)$$

19.6.18 Earthtube

The earth tube model (input object ZoneEarthtube) provides a simple earth tube model that uses a complex ground heat transfer model to establish the temperature of the soil at the depth of the earth tube. The following information defines the basis for the model including the assumptions and mathematical equations. It supplements the information for the ZoneEarthtube input object given in the Input/Output Reference for EnergyPlus.

Input Requirements

- Pipe : Pipe radius(m), Pipe thickness(m), Pipe length(m)
- Distance between the pipe outer surface and undisturbed soil (m),
- Pipe thermal conductivity (W/m-°C),
- Air velocity inside pipe(m/s), Depth of the radial center of pipe below ground (m)
- Soil : Soil density(kg/m³), Soil specific heat(J/kg-°C),
- Soil thermal Conductivity(W/m-°C), Absorption coefficient, Fraction of evaporation rate

Assumption(s)

- Convection flow inside the pipe is hydrodynamically and thermally developed.
- Soil temperature in the pipe vicinity is uniform after the particular distance from the center of the pipe(thickness of the annulus), so that pipe surface temperature is uniform after the distance 'r' from the center of the pipe, where 'r' is the pipe radius.

- The temperature profile in the pipe vicinity is not affected by the presence of the pipe, so that pipe surface temperature is uniform at axial direction.
- The soil surrounding the pipe has homogeneous thermal conductivity.
- Pipe has uniform cross section area at axial direction.

Wind velocity (m/s), u , is the annual average value. This is calculated from EnergyPlus weather data by averaging individual wind velocity values of the whole year. The convective heat transfer coefficient at the soil surface ($\text{W}/\text{m}^2\text{-}^\circ\text{C}$), h_s , is function of wind speed u . According to McAdams(1954), h_s can be approximated by the following correlation (Krarti, 1995):

$$h_s = 5.7 + 3.8u \quad (19.361)$$

In case of h_e and h_r , they can be determined by the following equations.

$$h_e = h_s (1 + 0.0168af) \quad (19.362)$$

$$h_r = h_s (1 + 0.0168ar_af) \quad (19.363)$$

where a is equal to $103 \text{ Pa}/^\circ\text{C}$.

Average air temperature ($^\circ\text{C}$), T_{ma} , is also calculated from EnergyPlus weather data by averaging individual air temperature values of the whole year.

The appropriate value of hemispherical emittance of the ground surface, ε is 0.93~0.96. Radiation constant (W/m^2), ΔR , depends on soil radiative properties, air relative humidity, and effective sky temperature. An appropriate value of ΔR according to Krarti (1995) is $63 \text{ W}/\text{m}^2$.

The absorption coefficient, β , depends on the soil absorptance and shading condition. The coefficient β is approximately equal to one minus the soil surface albedo. Albedo depends on soil cover and moisture content. Albedo = 0.1 corresponds to wet soils, albedo = 0.2 to moderate soils, and albedo = 0.3 to dry soils.

Average solar radiation (W/m^2), S_m , is determined from EnergyPlus weather data by averaging individual global horizontal solar radiation values of the whole year.

The fraction of evaporation rate, f , also depends mainly on the soil cover and the soil moisture level. Based on the results reported by Penman, it is recommended to estimate the fraction f as follows. For bare soil, f is directly proportional to soil moisture content. For instance, $f = 1$ corresponds to saturated soils, $f = 0.6\sim 0.8$ to wet soils, $f = 0.4\sim 0.5$ to moist soils, $f = 0.1\sim 0.2$ to arid soils. For dry soils, $f = 0$, since no evaporation occurs. For covered soils, the fraction f is obtained by multiplying 0.7 by the value of f for bare soil depending on the soil moisture content (Krarti, 1995).

Relative humidity, r_a , is also calculated from EnergyPlus weather data by averaging individual relative humidity values of the whole year.

The soil thermal diffusivity (m^2/s), α_s , and conductivity ($\text{W}/\text{m-}^\circ\text{C}$), k_s , varies with the density and moisture content. From Table 3.3, pg. 26 of ASHRAE's Ground Source Heat Pumps–Design of Geothermal Systems for Commercial and Institutional Buildings, 1997, the following values are recommended under different conditions.

Soil Type	Moisture Content Dry Density [kg/m ³]	5% k [W/m-K]	5% α [m ² /s]	10% k [W/m-K]	10% α [m ² /s]	15% k [W/m-K]	15% α [m ² /s]	20% k [W/m-K]	20% α [m ² /s]
Coarse	1922	2.77	1.34E-06	2.94	1.24E-06	3.29	1.18E-06		
100%	1602	1.90	1.18E-06	2.34	1.18E-06	2.51	1.08E-06	2.68	8.82E-07

	5% water	1922	2.596	1.344E-06
Light sand	15% water	1281	1.558	8.065E-07
	5% water	1281	1.385	9.677E-07

Annual angular frequency, w , is equal to 1.992×10^{-7} rad/s and the dampening depth (m), D , is calculated from the following equation:

$$D = \sqrt{\frac{2\alpha_s}{w}} \quad (19.364)$$

The value of δ is evaluated as follows:

$$\delta = \frac{1+i}{D} \quad (19.365)$$

The amplitude of the air temperature (°C), T_{va} , can be evaluated from EnergyPlus weather data by dividing the difference between the maximum and minimum air temperature value of the whole year by two. Similarly, amplitude of the solar radiation (W/m²), S_v , can also be determined from weather data by dividing the difference between the maximum and minimum solar radiation value of the whole year by two.

Phase angle between the insolation and the air temperature (rad), φ_I , is calculated by subtracting insolation phase angle from air temperature phase angle. Phase angle of insolation and air temperature is the point from the beginning of the year at which the insolation and air temperature respectively reaches the minimum value among the whole year.

Phase constant of the air (sec), t_{0a} , is the time elapsed from the beginning of the year at which the air temperature reaches the minimum value in the year.

By using all the input parameters and variables described above, average soil surface temperature ($^{\circ}\text{C}$), T_m , amplitude of the soil surface temperature variation ($^{\circ}\text{C}$), A_s , phase constant of the soil surface (sec), t_0 , and phase angle difference between the air and soil surface temperature (rad), Φ_s , can be evaluated as follows:

$$T_m = \frac{1}{h_e} [h_r T_{ma} - \varepsilon \Delta R + \beta S_m - 0.0168 h_s f b (1 - r_a)] \quad (19.366)$$

$$A_s = \left\| \frac{h_r T_{va} - \beta S_v e^{i\phi_I}}{(h_e + \delta k_s)} \right\| \quad (19.367)$$

$$t_0 = t_{0a} + \frac{\phi_s}{w} \quad (19.368)$$

$$\phi_s = -\text{Arg} \left[\frac{h_r T_{va} - \beta S_v e^{i\phi_I}}{(h_e + \delta k_s)} \right] \quad (19.369)$$

(Note: T_m , A_s , and t_0 are calculated by the CalcSoilSurfTemp program and are inputs to EnergyPlus. The remainder of this section describes what has been implemented in EnergyPlus.)

The symbols $\|$ and Arg denote the modulus and the argument of a complex number respectively. In order to calculate A_s and Φ_s , the complex number under consideration can be rearranged into the following form:

$$\begin{aligned} \frac{h_r T_{va} - \beta S_v e^{i\phi_I}}{h_e + \delta k_s} &= \frac{(h_e + \frac{k_s}{D})(h_r T_{va} - \beta S_v \cos \phi_I) + \frac{k_s}{D}(-\beta S_v \sin \phi_I)}{(h_e + \frac{k_s}{D})^2 + (\frac{k_s}{D})^2} \\ &\quad + i \frac{(h_e + \frac{k_s}{D})(-\beta S_v \sin \phi_I) - \frac{k_s}{D}(h_r T_{va} - \beta S_v \cos \phi_I)}{(h_e + \frac{k_s}{D})^2 + (\frac{k_s}{D})^2} \end{aligned} \quad (19.370)$$

Assuming a homogeneous soil of constant thermal diffusivity, the temperature at any depth z and time t can be estimated by the following expression:

$$T_{z,t} = T_m - A_s \exp \left[-z \left(\frac{\pi}{365 \alpha_s} \right)^{1/2} \right] \cos \left\{ \frac{2\pi}{365} \left[t - t_0 - \frac{z}{2} \left(\frac{365}{\pi \alpha_s} \right)^{1/2} \right] \right\} \quad (19.371)$$

In this expression, the unit of time, t , and phase constant of the soil surface, t_0 , should be converted into days. Similarly, the unit of soil thermal diffusivity, α_s , should also be converted into m^2/days .

By integrating the expression with respect to depth, the average temperature of a vertical soil profile ranging between depth z_1 and z_2 ($^{\circ}\text{C}$) can be determined as follows:

$$T_{z_1, z_2, t} = T_m + \frac{A_s}{(z_2 - z_1) \gamma \sqrt{2}} \left\{ e^{-\gamma z_1} \cos \left[\frac{2\pi}{365} (t - t_0 - z_1 L - 45.6) \right] - e^{-\gamma z_2} \cos \left[\frac{2\pi}{365} (t - t_0 - z_2 L - 45.6) \right] \right\} \quad (19.372)$$

where:

$$\gamma = (\pi / 365 \alpha_s)^{1/2} \quad (19.373)$$

$$L = \frac{1}{2}(365/\pi\alpha_s)^{1/2} \quad (19.374)$$

As the final step with regard to the heat transfer between soil and earth tube system, thermal conductivity of air ($\text{W/m}^\circ\text{C}$), k_{air} , and kinetic viscosity of air (m^2/s), ν , should be calculated first:

$$k_{air} = 0.02442 + (10^{-4}(0.6992T_a)) \quad (19.375)$$

$$\nu = 10^{-4}(0.1335 + 0.000925T_a) \quad (19.376)$$

By using the values of thermal conductivity of air, k_{air} , and kinetic viscosity of air, ν , the convective heat transfer coefficient at the inner pipe surface ($\text{W/m}^2\text{-}^\circ\text{C}$), h_c , can be evaluated. It is a function of Reynolds number, Re , and Nusselt number, Nu , where:

$$h_c = \frac{\text{Nu}k_{air}}{2r_1} \quad (19.377)$$

$$\text{Nu} = \frac{(f_a/2)(\text{Re} - 1000) \text{Pr}}{1 + 12.7(f_a/2)^{1/2}(\text{Pr}^{2/3} - 1)} \quad (19.378)$$

$$f_a = (1.58 \ln \text{Re} - 3.28)^{-2} \quad (19.379)$$

$$\text{Re} = \frac{2r_1 V_a}{\nu} \quad (19.380)$$

$$\text{Pr} = \frac{\nu}{\alpha_{air}} \quad (19.381)$$

where r_1 is inner pipe radius (m) and V_a is average pipe air velocity (m/s).

After determining the convective heat transfer coefficient, R_c , R_p and R_s are respectively calculated as follows:

$$R_c = \frac{1}{2\pi r_1 h_c} \quad (19.382)$$

$$R_p = \frac{1}{2\pi k_p} \ln \frac{r_1 + r_2}{r_1} \quad (19.383)$$

$$R_s = \frac{1}{2\pi k_s} \ln \frac{r_1 + r_2 + r_3}{r_1 + r_2} \quad (19.384)$$

where R_c is thermal resistance due to convection heat transfer between the air in the pipe and the pipe inner surface ($\text{m}^\circ\text{C/W}$), R_p is thermal resistance due to conduction heat transfer between the pipe inner and outer surface ($\text{m}^\circ\text{C/W}$), and R_s is thermal resistance due to conduction heat transfer between the pipe outer surface and undisturbed soil ($\text{m}^\circ\text{C/W}$). In addition, r_2 is pipe thickness (m), r_3 is distance between the pipe outer surface and undisturbed soil (m), and L is pipe length (m).

Finally, the heat transfer between the soil and the air inside the pipe is equal to the amount of heat losses as air flows along the pipe (Jacovides and Mihalakakou, 1995).

$$U_t [T_a(y) - T_{z,t}] dy = -\dot{m}_a C_a [dT_a(y)] \quad (19.385)$$

with

$$U_t = \frac{1}{R_t} \quad (19.386)$$

$$R_t = R_c + R_p + R_s \quad (19.387)$$

where U_t is overall heat transfer coefficient of the whole earth tube system (W/m²·°C), $T_a(y)$ is air temperature of the pipe at the distance y from the pipe inlet (°C), and \dot{m}_a is mass flow rate of ambient air through pipe (kg/s). C_a is specific heat of air (J/kg·°C) and R_t is total thermal resistance between pipe air and soil (m²·°C/W).

Initial condition of inlet air temperature is equal to the ambient air temperature. Outlet air temperature is finally evaluated by solving the heat transfer equation above.

Table 19.17: Nomenclature for Earthtube Model

Variable	Description	Units
A_s	amplitude of the soil surface temperature variation	°C
C_a	specific heat of air	J/kg·°C
h_c	convective heat transfer coefficient at the inner pipe surface	W/m ² ·°C
h_s	convective heat transfer coefficient at the soil surface	W/m ² ·°C
k_{air}	thermal conductivity of the air	W/m·°C
k_p	pipe thermal conductivity	W/m·°C
k_s	soil thermal conductivity	W/m·°C
L	pipe length	m
\dot{m}_a	mass flow rate of ambient air through pipe	kg/s
r_a	relative humidity	
R_c	thermal resistance due to convection heat transfer between the air in the pipe and the pipe inner surface	m ² ·°C/W
R_p	thermal resistance due to conduction heat transfer between the pipe inner and outer surface	m ² ·°C/W
R_s	thermal resistance due to conduction heat transfer between the pipe outer surface and undisturbed soil	m ² ·°C/W
R_t	total thermal resistance between pipe air and soil	m ² ·°C/W

Table 19.17: Nomenclature for Earthtube Model

Variable	Description	Units
ΔR	radiation constant	63 W/m ²
r_1	inner pipe radius	m
r_2	pipe thickness	m
r_3	distance between the pipe outer surface and undisturbed soil	m
S_m	average solar radiation	W/m ²
S_v	amplitude of the solar radiation	W/m ²
t	time elapsed from beginning of calendar year	days
$T_a(y)$	air temperature of the pipe at the distance y from the pipe inlet	°C
T_m	average soil surface temperature	°C
T_{ma}	average air temperature	°C
t_o	phase constant of the soil surface	sec, days
t_{oa}	phase constant of the air	sec, days
T_{va}	amplitude of the air temperature	°C
$T_{z,t}$	ground temperature at time t and depth z	°C
$T_{z1,z2,t}$	soil profile temperature at time t , averaged over depths between z_1 and z_2	°C
u	wind velocity above the ground surface	m/s
U_t	overall heat transfer coefficient of the whole earth tube system	W/m-°C
V_a	average pipe air velocity	m/s
z	depth of the radial center of pipe below soil surface	m
z_1	upper bounds of some vertical profile in soil	m
z_2	lower bounds of some vertical profile in soil	m
α_s	soil thermal diffusivity	m ² /s; m ² /days
β	soil absorption coefficient (= 1 - soil albedo)	
ε	hemispherical emittance of the ground surface	
φ_I	phase angle between the insolation and the air temperature	rad
ϕ_s	phase angle difference between the air and soil surface temperature	rad
ν	kinetic viscosity of air	m ² /s

19.6.19 Thermal Chimney Model

The ZoneThermalChimney input object is available for modeling a thermal chimney which is a device that uses stack driven air movement to ventilate spaces within a building. These systems have been used successfully in buildings as small as the size of an outhouse up to large commercial buildings. The air within a thermal chimney is heated naturally using solar energy. The air increases in temperature which causes its density to drop. This drop in density results in a natural vertical movement of air and a local drop in pressure. The drop in pressure is relieved by drawing air from the building interior, and the heat gained within the thermal chimney does not enter the occupied portion of the building. These systems are often used in support of natural ventilation systems. The EnergyPlus model will seek to model the air heat balance effects of the thermal chimney, balance air movements caused by the thermal chimney, and report other appropriate system variables. The new model will be linked into the air heat balance in a fashion similar to the current infiltration and simple ventilation models but will not be linked to an HVAC air loop. Any flow through the thermal chimney will be accounted for in the air mass balance in the HVAC calculations. However, other sophisticated ventilation strategies can be handled by other existing EnergyPlus components.

textbfInput Requirements

- Distance from the top of thermal chimney to each inlet (m),
- Relative ratio of air flow rates passing through each inlet,
- Width of the absorber wall (m),
- Discharge coefficient,
- Cross sectional area of air channel outlet (m²),
- Cross sectional areas of each air channel inlet (m²)

•

Assumptions

- Surface temperature of the glass cover is uniformly distributed.
- Surface temperature of the absorber wall is uniformly distributed.
- The inlet temperature of the air channel in the thermal chimney is equal to the room air temperature.
- Resistance to the air flow due to the surface friction is negligible.
- The discharged amount of interior air induced by the thermal chimney is replaced by the outdoor air infiltration.

The mathematical model currently available for thermal chimneys has the capability to handle the thermal chimney having only one inlet. In other words, it is unlikely that thermal chimneys with multiple inlets due to multiple stories utilizing the common thermal chimney can be mathematically modeled without computational fluid dynamics. Therefore, if the thermal chimney to be modeled has multiple inlets, it will be assumed that it will have only one inlet. For this assumption, the user will be required to specify the relative ratio of air flow rates passing through each inlet to compute the overall length of the thermal chimney (m), L , overall room air temperature (K), T_r , and overall cross sectional area of air channel inlet (m^2), A_i , as follows:

$$L = \frac{L_1 r_1 E_1 + L_2 r_2 E_2 + L_3 r_3 E_3 + \cdots + L_n r_n E_n}{r_1 E_1 + r_2 E_2 + r_3 E_3 + \cdots + r_n E_n} \quad (19.388)$$

$$T_r = T_{r1} r_1 + T_{r2} r_2 + T_{r3} r_3 + \cdots + T_{rn} r_n \quad (19.389)$$

$$A_i = A_{i1} + A_{i2} + A_{i3} + \cdots + A_{in} \quad (19.390)$$

where A_{in} is the cross sectional area of nth air channel inlet (m^2), L_n is the distance from the top of thermal chimney to nth inlet (m), E_n is the room air specific enthalpy corresponding to nth inlet (J/kg), r_n is the relative ratio of air flow rate passing through nth inlet and T_{rn} is the room air temperature corresponding to nth inlet (K). Among them, room air specific enthalpy, E_n , and room air temperature corresponding to each inlet, T_{rn} , are directly calculated inside EnergyPlus. In addition, the relative ratios should meet the following expression:

$$r_1 + r_2 + r_3 + \cdots + r_n = 1 \quad (19.391)$$

After merging the multiple inlets into a single inlet condition based on the description above, the following algorithm which is widely used is employed for the modeling of the thermal chimney.

The key output parameter in the thermal chimney model is the enhanced amount of natural ventilation rate caused by the presence of a thermal chimney. In order to determine the enhanced ventilation, the discharge air temperature from a thermal chimney should be calculated, which, in turn, should be computed based on the information on the absorber wall temperature, glass cover temperature and the vertical air temperature distribution within the thermal chimney. Among them, energy balances for the absorber wall and the glass cover are carried out using the existing

Figure 19.35: Basic Composition of Thermal Chimney

algorithm currently available in EnergyPlus, which has the similar approach to the Trombe wall. On the other hand, the vertical air temperature distribution and the resultant discharge air temperature of the thermal chimney are computed using the separate thermal chimney algorithm described in the following paragraphs.

Once the glass cover temperature and the absorber wall temperature are computed using the existing modeling algorithm in EnergyPlus, the energy balance for the fluid (air inside the thermal chimney) can be expressed as:

$$h_{wf}(T_w - \overline{T_f}) = h_{gf}(\overline{T_f} - T_g) + \frac{\dot{m}C_p}{w} \frac{dT_f}{dx} \quad (19.392)$$

where \dot{m} is the total mass flow rate of the air (kg/s), C_p is the specific heat of air (J/kg-°C), w is the width of the absorber wall (m) and x is the elemental length of the absorber wall (m).

Since the initial condition of inlet air temperature in this differential equation is equal to the room air temperature (i.e. $x = 0$, $T_{f,i} = T_r$), the outlet air temperature, $T_{f,o}$, can be finally evaluated.

Finally, the total air flow rate caused by the thermal chimney (m³/s), Q , can be evaluated from the following expression:

$$Q = C_d A_o \sqrt{\frac{2\left(\frac{T_{f,o} - T_r}{T_r}\right)gL}{(1 + A_r)^2}} \quad (19.393)$$

$$A_r = A_o/A_i \quad (19.394)$$

where C_d is the discharge coefficient, A_o and A_i is the cross sectional areas of air channel outlet and inlet (m²), respectively, $T_{f,o}$ is the outlet air temperature (K), T_r is the room air temperature (K) and L is the total length of the thermal chimney (m).

Since multiple inlets are merged into a single inlet in the beginning, the air flow rate passing through each inlet due to the existence of the thermal chimney can be finally determined as follows:

$$Q_1 = Qr_1, \quad Q_2 = Qr_2, \quad Q_3 = Qr_3, \quad \dots, \quad Q_n = Qr_n$$

where Q_n is the air flow rate passing through nth inlet (m³/s) and r_n is the relative ratio of air flow rate passing through nth inlet.

The discharged amount of interior air from each zone caused by the presence of the thermal chimney is assumed to be replaced by the outdoor air infiltration.

Table 19.18: Nomenclature of Thermal Chimney Model

Model Nomenclature	
Variable	Description
A_i	cross sectional area of air channel inlet (m ²)
A_o	cross sectional area of air channel outlet (m ²)
C_d	discharge coefficient
C_p	specific heat of air (J/kg-°C)
E_n	room air specific enthalpy corresponding to nth inlet (J/kg)
g	acceleration due to gravity (9.8 m/s ²)

Table 19.18: Nomenclature of Thermal Chimney Model

Model Nomenclature	
h_{gam}	convective heat transfer coefficients between the glass and ambient air ($W/m^2\cdot^{\circ}C$)
h_{gf}	convective heat transfer coefficients between the glass and the fluid ($W/m^2\cdot^{\circ}C$)
h_{iw}	convective heat transfer coefficients between absorber wall inner surface and the room air ($W/m^2\cdot^{\circ}C$)
h_{wf}	convective heat transfer coefficients between the absorber wall and the fluid ($W/m^2\cdot^{\circ}C$)
h_{wind}	The convective heat transfer coefficient due to the wind ($W/m^2\cdot^{\circ}C$)
H_{sr}	incident solar radiation on vertical surface (W/m^2)
k_{air}	thermal conductivity of air ($W/m\cdot^{\circ}C$)
L	total length of the thermal chimney (m)
M	mass flow rate of the air (kg/s)
r_n	relative ratio of air flow rate passing through nth inlet
S_g	solar radiation absorbed by the glass cover (W/m^2)
S_w	solar radiation absorbed by the absorber wall (W/m^2)
T_{am}	ambient air temperature (K)
T_f	fluid temperature averaged over the entire length of the thermal chimney (K)
T_{fi}	inlet air temperature of the thermal chimney (K)
T_{fo}	outlet air temperature of the thermal chimney (K)
T_g	glass cover temperature (K)
T_r	room air temperature (K)
T_s	surface temperature (K)
T_w	absorber wall temperature (K)
T_{∞}	fluid temperature (K)
u	wind speed (m/s)
U_w	Overall heat transfer coefficient from the room air and the absorber wall ($W/m^2\cdot^{\circ}C$)
w	width of the absorber wall (m)
x	elemental length of the absorber wall (m)
α_g	absorptance of glass cover
α_w	absorptance of absorber wall
β	air volumetric coefficient of expansion (K^{-1})
ε_g	emissivity of the glass cover

Table 19.18: Nomenclature of Thermal Chimney Model

Model Nomenclature	
σ	Stefan-Boltzmann constant ($5.67 \times 10^{-8} \text{ W/m}^2\text{K}^4$)
τ	transmittance of the glass cover
ν	kinematic viscosity of air (m^2/s)

19.6.20 Zone Outdoor Air Unit

The zone outdoor air unit (object ZoneHVAC:OutdoorAirUnit) is intended to model systems such as zone make-up air units and dedicated outside air systems. These components are “zone equipment” meaning that they do not require an air loop but serve a zone directly. The system is comprised of a supply fan (in either draw through or blow through configuration), an optional exhaust fan, and a variety of components such as heating coils, cooling coils, heat recovery, etc. The object of the zone outdoor air unit is to bring in additional ventilation air into a zone. These might be used for high ventilation spaces such as kitchens or laboratories where another system is primarily responsible for space conditioning while the zone outside air unit is primarily responsible for fresh air delivery to the zone. Most of the information necessary to configure a zone outdoor air unit is contained in the EnergyPlus Input/Output Reference. A diagram of the zone outdoor air unit is shown in Figure 19.36. As this system is relatively simple and does not contain any unique operating algorithm or equations, the discussion here is limited to the application of the user defined controls and how it relates to the operation of the device.

19.6.21 Controls

Three input parameters control the operation of the zone outdoor air unit. The unit control type has two options: neutral or temperature. If the temperature control type is selected, the user must also provide a high and low air temperature control schedule. The algorithm for controlling the zone outdoor air unit is dependent on these parameters which are used as described below.

Neutral Control. If the user selects neutral control, the intent is to provide additional outside air to the zone without imposing any additional thermal load on the zone or any other

Figure 19.36: Zone Outdoor Air Unit Schematic

systems serving the zone. In other words, the unit will attempt to provide air to the zone at the zone mean air temperature. Mathematically, this means:

$$T_{out} = T_{MAT} \quad (19.395)$$

where:

T_{out} is the outlet temperature of the zone outdoor air unit

T_{MAT} is the mean air temperature of the zone being served by the unit.

It should be noted that to avoid excessive iteration that the zone mean air temperature that is used is the mean air temperature from the previous time step. This will result in a slight lagging that may introduce a slight thermal load, but this should be minimal.

Temperature Control. If the user selects temperature control, the intent is to limit the outlet temperature of the unit for either heating or cooling or both or perhaps to provide unconditioned air to the space. The algorithm used to determine the outlet temperature of the unit is as follows. When the outdoor air temperature is at or below the low air temperature control schedule value, the outlet temperature is set to the low air temperature control schedule value and any heating equipment included in the unit description and available will attempt to provide enough heating to produce an outlet temperature equal to the low temperature schedule value. When the outdoor air temperature is at or above the high air temperature control schedule value, the outlet temperature of the unit is set to the high air temperature control schedule value and any cooling equipment included in the unit description and available will attempt to provide enough cooling to produce an outlet air temperature equal to the high temperature schedule value. When the outdoor air temperature is between the high and low temperature values, the unit will not provide any conditioning of outdoor air and will simply deliver it to the zone. Mathematically, this can be summarized as:

$$T_{out} = \begin{cases} T_{high} & \text{if } T_{oa} \geq T_{high} \\ T_{oa} & \text{if } T_{low} < T_{oa} < T_{high} \\ T_{low} & \text{if } T_{oa} \leq T_{low} \end{cases} \quad (19.396)$$

where:

T_{out} is the outlet temperature of the zone outdoor air unit

T_{oa} is the outside air temperature

T_{high} is the high control air temperature schedule value

T_{low} is the low control air temperature schedule value.

If the user wishes to provide “unconditioned” air all of the time, the high and low control temperature values can be set very high and very low, respectively, to always force the unit to provide unconditioned air. The same effect can also be realized by not specifying any conditioning components (such as coils) in the unit. The user can also limit the device to cooling only by specifying a low control temperature schedule with extremely low values. Conversely, the user can limit the device to heating only by specifying a high control temperature schedule with extremely high values. The user can also limit the equipment specified as part of the device to either cooling or heating components to get similar effects. In essence, the temperature control provides a variety of options in a single control type through the use of the high and low control temperature schedules.

19.6.22 Zone Exhaust Fan

The zone exhaust fan (Fan:ZoneExhaust) is a simple model to account for the fan electric energy use and impact on central air handlers from bathroom and hood exhaust. Because the fan only extracts air from the zone, it doesn’t directly impact the zone itself.

The fan flow rate is either constant or variable depending on if the user input a flow fraction modifier schedule. The value entered for maximum volume flow rate is converted to a design mass flow rate using standard (altitude-adjusted) density and used as the design flow rate. If a flow fraction schedule is used, then its values, f_{Fract} , are multiplied by the design flow rate to obtain the current mass flow.

$$\dot{m}_{Des} = \dot{V}_{Max} \rho_{air,std} \quad (19.397)$$

$$\dot{m} = f_{Fract} \dot{m}_{Des} \quad (19.398)$$

The exhaust fan model is similar to, but simpler than, the models used for air system fans. The electric power calculation is simplified and uses a constant overall efficiency. All of the fan power is added to the air stream.

$$\dot{Q}_{fan} = \frac{\dot{m} \Delta P}{e_{tot} \rho_{air}} \quad (19.399)$$

$$h_{out} = h_{in} + \frac{\dot{Q}_{fan}}{\dot{m}} \quad (19.400)$$

$$w_{out} = w_{in} \quad (19.401)$$

$$T_{out} = P_{sy} T_{dbFnHW}(h_{out}, w_{out}) \quad (19.402)$$

The controls for determining if the the exhaust fan will operate can be based on a number of factors including: an on/off availability schedule, interaction with system availability managers, minimum zone air temperature control limits and a variable flow fraction schedule. When the fan is coupled to the system availability managers then it will operate if either the local availability schedule or the system availability manager's indicate that the fan should run. When the fan is not coupled to the system availability manager, then it only uses the local availability schedule and ignores availability managers. If using the flow fraction schedule and the resulting flow is zero, then fan will not run. If using the minimum zone temperature limit schedule then the fan will only run if the fan inlet temperature is warmer than the limit.

The exhaust fan's interaction with the air system depends on the value, f_{Bal} , of the schedule for the fraction of the exhaust that is balanced. The model tracks the exhaust flows in two ways, balanced and unbalanced. Balanced exhaust air flow is considered to have been made up from simple airflow from infiltration, ventilation or zone mixing. Unbalanced exhaust air flow is considered to not be balanced by simple air flows and needs to be balanced by the air system operation. Both of these types of flow are summed at the zone and whole air system level. In a zone, the return air node flow rate is reduced from what it would be with no exhaust by the portion of the zone's exhaust flow that is unbalanced. In an air handler with an outdoor air system, the outdoor air flow rate may be increased so as to be sufficient to provide all the unbalanced exhaust air for all the zones on the air handler (when possible).

Chapter 20

On-Site Generation, Power Conversion, and Storage

This section discusses on-site generation, electric storage, and power conversion models related to serving the facility with electric power. EnergyPlus is usually predicting the electric energy consumed in a building and its HVAC equipment over time. If this electric power all comes directly from the grid and the building has no power conversion devices (such as a transformer, inverter, battery, generators, solar panels etc.) then only some basic accounting is needed and none of the additional models described here are really needed. The device models in this section are for when the electric power service system supplying the facility has some added equipment that is considered part of the building being modeled. The purpose of electric power service modeling in EnergyPlus is to account for the energy performance of such equipment at each timestep of the building and HVAC simulation. The building and HVAC simulation provides a current prediction of the electric load required by the facility and the electric power service simulation uses that information. This is simplified power system model with the only goal being to account for power losses (in Watts) and energy consumed (in Joules) by key devices in the balance of system including:

Transformer : a building may have transformers and they are not 100% efficient. A facility may own its own transformer and have high voltage utility grid connection. An on-site generation system might have an isolation transformer. The EnergyPlus model meters electric losses as a function of the power going through each transformer.

Fuel-fired generators : a building may have generators that consume one type of energy resource (natural gas, diesel, etc.) and generate electricity. These generators need supervisory control to determine when and how hard to run the engine. The generators may be used for cogeneration and include connections to a hot water plant in the HVAC models. The generator models determine the efficiency as fuels are converted to electric power and heat.

Renewable generators : a building may have wind turbines or solar photovoltaic panels. The generator models determine the efficiency as wind and sun are converted to electricity.

Inverters : the direct current generated by solar photovoltaic or discharged from storage may need to be converted from DC to AC by an inverter. The EnergyPlus models meter electric losses as a function of the power going through each inverter.

Storage : a building may have on-site electric storage and it is not 100% efficient. Storage can be used to adjust utility demand profile or store on-site renewables.

There is no explicit modeling of voltage and current between devices, just basic power and energy exchanges. There is no modeling of power loss in conductors and distribution panels throughout the building. There is no modeling of short term power draws as for a motor start – power levels are modeled as single-valued averages for the entire system timestep (1 minute or longer).

20.1 Whole-Facility Electric Service

Whenever an EnergyPlus model includes anything that consumes electricity the program will do some basic modeling of what can be thought of as the main panel where utility grid connects to the building and HVAC loads. The following output variables and meters are created and filled to report on the overall, whole-facility power flows at the main panel:

P_{purch}	Facility Total Purchased Electric Power	(W)
Q_{purch}	Facility Total Purchased Electric Energy	(J)
$P_{net,purch}$	Facility Net Purchased Electric Power	(W)
$Q_{net,purch}$	Facility Net Purchased Electric Energy	(J)
P_{surp}	Facility Total Surplus Electric Power	(W)
Q_{surp}	Facility Total Surplus Electric Energy	(J)
$P_{bldg,dmd}$	Facility Total Building Electric Demand Power	(W)
$P_{HVAC,dmd}$	Facility Total HVAC Electric Demand Power	(W)
P_{dmd}	Facility Total Electric Demand Power	(W)
P_{prod}	Facility Total Produced Electric Power	(W)
Q_{prod}	Facility Total Produced Electric Energy	(J)

The models for electric power service use the meter reporting system inside EnergyPlus to obtain data from all the other models in EnergyPlus for the electric power demand (and maybe power production). The ElectricPowerServiceManager uses a query routine called "GetInstantMeterValue" which returns the sum for all the metered equipment for the specified meter. Values for $P_{bldg,dmd}$ and $P_{HVAC,dmd}$ are both filled from the "Electricity:Facility" meter. $P_{bldg,dmd}$ is filled by passing an argument that triggers to return the "Building" electric load, which is at the zone timestep, while $P_{HVAC,dmd}$ is filled by passing an argument that returns the "HVAC" electric load, which is at the system timestep. The modeling is based on average power levels for the duration of the timestep. The return values are converted from energy in Joules to power in Watts by dividing by the number of seconds in the zone timestep for building loads and by the system timestep for the HVAC loads. Then the total facility power demand is the sum of the building loads and the HVAC loads.

$$P_{dmd} = P_{bldg,dmd} + P_{HVAC,dmd} \quad (20.1)$$

When the electric power service device models described below are being used, they also make use of the meter reporting system using the components of the ElectricityProduced:Facility (ResourceType=ElectricityProduced) meter to determine aggregate on-site electricity production rate, P_{prod} . This value rolls up all the power generated and consumed by the on-site generators, storage, and power conversion equipment:

- $P_{prod,cogen}$ is the power from fuel-fired generators, from meter Cogeneration:ElectricityProduced.
- $P_{prod,pv}$ is the power from solar photovoltaics, from meter Photovoltaic:ElectricityProduced.
- $P_{prod,wind}$ is the power from wind generators, from meter WindTurbine:ElectricityProduced.
- $P_{prod,storage}$ is the power from electric storage, from meter ElectricStorage:ElectricityProduced, with storage charging negative and storage discharging positive.
- $P_{prod,conversion}$ is the power loss by converting between different voltages or AC and DC, from meter PowerConversion:ElectricityProduced which are metered as negative values that decrease the amount of electricity produced.

$$P_{prod} = P_{prod,cogen} + P_{prod,pv} + P_{prod,wind} + P_{prod,storage} + P_{prod,conversion} \quad (20.2)$$

Then the net purchased electricity, which can be either positive or negative (for export), is calculated using,

$$P_{net,purch} = P_{dmd} - P_{prod} \quad (20.3)$$

Only the positive portion of the net purchased power is the purchased power.

$$P_{purch} = \max(P_{net,purch}, 0.0) \quad (20.4)$$

The surplus electric power is exported out to the grid and is only positive.

$$P_{surp} = \max((P_{prod} - P_{dmd}), 0.0) \quad (20.5)$$

The energy versions of the power variables are calculated by multiplying the power level by the number of seconds in the system timestep.

20.2 Electric Load Center Distribution Manager

20.2.1 Overview

The electric load center distribution manager (object name: ElectricLoadCenter:Distribution) is used to organize power conversion devices and provides supervisory control over generators and storage. Electric load centers can be thought of as subpanels connected to the facility's main electric panel. Except for two applications for transformers that are located between the main panel and the utility grid connection, all other devices are associated with a specific load center. The load center connects the "load" to the generators and "supply" power to the main panel serving the rest of the building. A load center can have any number of generators but only one storage, (DC to AC) inverter, (AC to DC) converter or (isolation) transformer. There are two separate operation schemes, one for generators and one for storage. The generator operation scheme controls the on-site generators connected to a particular load center. The storage operation scheme controls charging and discharging of electrical storage. The generator operation is managed before the storage operation. The internal meters used by EnergyPlus for reporting do all of the tracking. For more details on the individual inputs required see the Input Output Reference document.

The electric load center manager sums all of the building and system electric loads and provides operating schemes for the generators. The electric load center objects are operated in the order they are defined in the input data file (IDF), and generators are dispatched sequentially in the order they are specified within the list referenced by each load center object. The electricity produced from photovoltaic arrays and wind turbines is handled somewhat separately and is always run rather than being dispatched by supervisory control. What is not provided by the on-site generation equipment, and electric storage units, is met by (purchasing) off-site electricity. It is possible to prescribe a set of ElectricLoadCenter:Distribution objects with inconsistent or conflicting operating schemes, so users need to be careful.

20.2.2 Generator Operation Schemes

The available generator operating schemes are “Baseload”, “DemandLimit”, “TrackElectrical”, “TrackSchedule”, “TrackMeter”, “FollowThermal” and “FollowThermalLimitElectrical.” These operating schemes affect how loads are dispatched to the generators, in effect telling the generators whether or not to run and requesting power levels.

The **Baseload** scheme operates the generators at their rated (requested) electric power output when the generator is scheduled ON (ref. ElectricLoadCenter:Generators in the Input Output Reference). The Baseload scheme requests all generators scheduled ON (available) to operate, even if the amount of electric power generated exceeds the total facility electric power demand.

The **DemandLimit** scheme limits the amount of purchased electricity from the utility to the amount specified in the input. The Demand Limit scheme tries to have the generators meet all of the demand above the purchased electric limit defined by the user.

The **TrackElectrical** scheme tries to have the generators meet all of the electrical demand for the building.

The **TrackMeter** scheme tries to have the generators meet all the electrical demand from a meter chosen by the user rather than the usual meter for the entire facility. The meter can be a custom meter so that generators are tied to only certain loads in the building.

The **TrackSchedule** scheme tries to have the generators meet all of the electrical demand determined by a user-defined schedule.

The **FollowThermal** and **FollowThermalLimitElectrical** schemes run the generators to meet thermal demand. The thermal demand is determined from the plant modeling and depends on the flow requested by other components on the demand side of the plant loop, the loop temperatures, and the loop temperature setpoint. The electric load center distribution manager converts the thermal load to an electrical load using a nominal ratio of the thermal to electrical power production for each generator. For these schemes, the generator needs to be connected to the supply side of a plant loop and serve components that use hot water on the demand side of the plant loop. The thermal load request is obtained from the plant data structure (structure location in code is PlantLoop%LoopSide%Branch%Comp%MyLoad). The distribution manager converts the thermal load, $q_{thermal}$, to an electrical load using:

$$q_{Elect} = \frac{q_{thermal}}{ThermElectRatio} \quad (20.6)$$

where,

$ThermElectRatio$ is a nominal, constant, user-defined value for the ratio of thermal production to electrical production for a cogenerator. This ratio is used for supervisory control and dispatch

of the electric power request to the generator; however, the cogenerator model may determine that actual performance varies from this nominal value at different times in the simulation when operating conditions differ from those used for the nominal ratio.

For all generator operating schemes except Baseload, a total electric load reduction target (or thermal load converted to electrical equivalent) is established for the load center based on the specific operating scheme. The load center then requests that its generators operate, one-by-one in the order specified in the generator list, until the target is met or exceeded. Generators that are not scheduled as ‘available’ for the simulation time step are not called to operate. The requested power demand to be met by each generator is the **smaller** of the nominal ‘rated’ electric power output (as specified in the `ElectricLoadCenter:Generators` object) or the remaining total electric load reduction target for the load center. After each electric generator is requested to operate, the *actual* electric power delivered by the generator, which may be greater than or less than the requested amount due to inputs specified in the generator performance model (e.g., `Generator:CombustionTurbine`, `Generator:MicroTurbine`, etc.), is used to update the remaining total electric power target for the other generators associated with this load center.

Most of the operating schemes will sequentially load the available electric load centers and generators. EnergyPlus can accept multiple “`ElectricLoadCenter:Distribution`” objects with different operating schemes. Because of this, there are two levels of reporting, one for the whole building and a second for each load center. The whole-building results are managed with the internal meters for the entire model. The individual load-center results are summed for those generators connected to a particular load center. The total electricity purchased is reported both in power and energy units. This value is positive when the amount of energy is purchased from the utility. This value can be negative when the total electricity produced is greater than the facility electrical needs. The excess will either be available for storage or to sell back to the electric utility company.

The order of input objects (`ElectricLoadCenter:Distribution`) in the input file is significant and used to structure how generators are dispatched with the first load centers and generators managed before the later ones. Therefore, load centers listed earlier in the file effectively have a higher priority.

20.2.3 Load Center Buss Types

Electric load centers can have one of five different configurations. Load centers can get fairly complicated and include power conditioning and storage. Separate inverter models are used to condition DC power from photovoltaics into AC power for the building and utility. The other generators may have inverters inside the devices but these are already embedded in the generator models. The load center can also supervise electrical storage controls and depend on the buss configuration. The transformer is optional for all buss types but if included in the load center it can be used to model an isolation or voltage matching transformer acting on the load center.

The most basic configuration is selected with the keyword “`AlternatingCurrent`” for the `Electrical Buss Type`, shown in Figure 20.1.

The *AlternatingCurrent* load centers have AC generators with no storage and behave in the following way. All electric demand not met by the sum of the electrical power produced by the available generators will be met by purchased electricity. If a generator is needed in the simulation for a small load and the load is less than the generator’s minimum part load ratio, the generator will operate at the minimum part load ratio and the excess will either reduce demand or the excess energy will be exported back to the electric utility company.

Figure 20.1: Basic Alternating Current Schematic

A configuration with AC generators with on-site electrical storage is selected with the keyword “AlternatingCurrentWithStorage” and is shown in Figure 20.2.

Figure 20.2: AC Generators with On-site Electrical Storage Schematic

The *AlternatingCurrentWithStorage* load centers attempt to augment the generator electricity production so that the power requests are met. Storage control logic is discussed below under Storage Operation Scheme.

The basic configuration for photovoltaic generators is selected using the “DirectCurrentWith-Inverter” keyword and is shown in Figure 20.3.

The *DirectCurrentWithInverter* load centers collect DC power from various generators, usually PV arrays, run the DC power through an inverter and produce AC power. The PV arrays produce DC power based on the availability of sunshine and do not respond to load requests made by the electric load center.

If the PV-based load center is equipped with DC electrical storage that is connected before the inverter, then the buss type should be “DirectCurrentWithInverterDCStorage” and is shown Figure 20.4.

The *DirectCurrentWithInverterDCStorage* load centers charge or draw DC power to meet the requested electrical load depending on the storage operation scheme.

If the PV-based load center is equipped with AC electrical storage that is connected after the

Figure 20.3: Direct Current With Inverter Photovoltaic Generators Schematic

Figure 20.4: PV based Load Center with DC Electrical Storage Schematic

inverter, then the buss type should be “DirectCurrentWithInverterACStorage” and is shown in Figure 20.5.

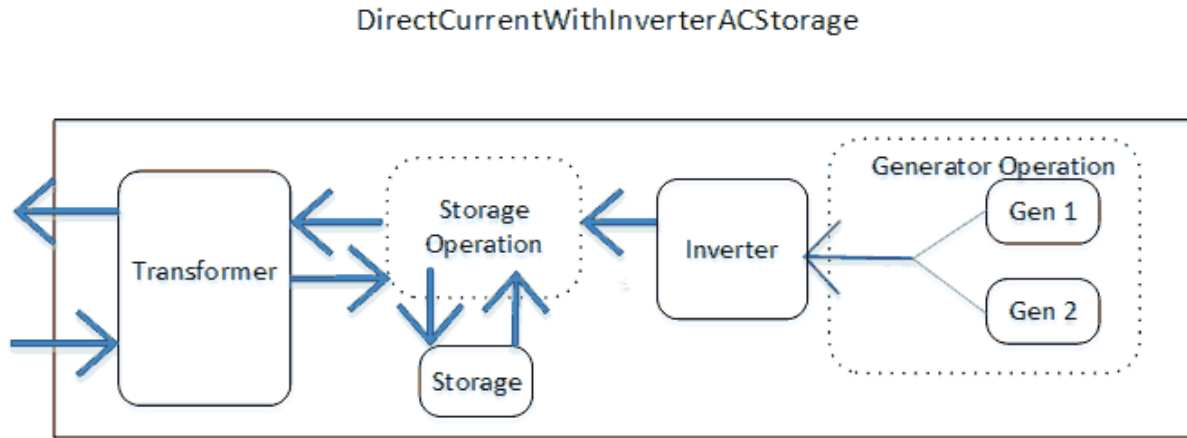

Figure 20.5: PV Based Load Center with AC Electrical Storage Schematic

The *DirectCurrentWithInverterACStorage* load centers charge or draw AC power to meet the requested electrical load. They can also draw power from the main panel into the load center to charge storage from grid-supplied electric power.

20.2.4 Electric Load Center Generators

The electric load center generators (object name: *ElectricLoadCenter:Generators*) provide a set of scheduled electric generators for supervisory control over electric power generation. Here is where the user lists what generators and PVs are available at any given time. For more details on the individual inputs required see the *EnergyPlus Input Output Reference*.

20.2.5 Inverters

EnergyPlus includes three models for converting Direct Current (DC) electrical power into Alternating Current (AC) electrical power. The DC power into the inverter, P_{DC-in} , is converted to AC power out, P_{AC-out} , of the inverter using:

$$P_{AC-out} = P_{DC-in} \cdot \epsilon_{inverter} \quad (20.7)$$

The inverter efficiency is determined using one of the three models. For the “Simple” inveter model, efficiency is constant and input by the user. For the “Look Up Table” model, the efficiency is calculated using linear interpolation. For the “Function of Power” model, the efficiency is calculating using a single-variable curve object. For both the Look Up Table and Function of Power models, the power production is normalized by P_{DC-in} .

The conversion power losses are calculated from the difference between $P_{DC,in}$ and $P_{AC,out}$ and are metered as negative values on *PowerConversion:ElectricityProduced*. The thermal losses include the conversion power losses plus any ancillary power consumed during standby. The ancillary electric power consumption occurs when the inverter is scheduled to be available but it is not conditioning any power flows at the time.

20.2.6 Converter

EnergyPlus includes a model for converting Alternating Current (AC) electric power into Direct Current (DC) electric power. This device is used to charge DC electric storage devices with AC drawn from the main panel. Although the physical device may be a two-way inverter, the modeling is separated so that the converter appears on its own in the modeling. The AC power into the converter, $P_{AC,in}$, is converted to DC power out, $P_{DC,out}$, of the converter using:

$$P_{DC,out} = P_{AC,in} \cdot \varepsilon_{converter} \quad (20.8)$$

The converter efficiency is determined using one of two method. For the "SimpleFixed" method the efficiency is constant and input by the user. For the "FunctionOfPower" method the user defined performance curve or lookup table is evaluated using the normalized power into the converter.

The conversion power losses are calculated from the difference between $P_{AC,in}$ and $P_{DC,out}$ and are metered as negative values on PowerConversion:ElectricityProduced. The thermal losses include the conversion power losses plus any ancillary power consumed during standby. The ancillary electric power consumption occurs when the converter is scheduled to be available but it is not conditioning any power flows at the time.

20.2.7 Storage Operation Schemes

The available storage operation schemes are "TrackFacilityElectricDemandStoreExcessOnSite", "TrackMeterDemandStoreExcessOnSite", "TrackChargeDischargeSchedules", and "FacilityDemandLeveling".

Figure 20.6 shows the control volume and electrical power flows that are used to model all of the storage operation schemes. Conservation of energy is used to formulate the calculations based on this control volume and the five terms shown in the diagram. This control volume is inside a given load center.

P_{gen} : This is the sum of electric power produced by the generators on the load center entering the control volume. The generator operation is run before the storage operation so that this value is current at the time the storage operation control is evaluated

P_{feed} : This is the flow of electric power out of the control volume feeding toward the main panel. This is power being supplied by the generators and storage and serving the building loads or perhaps being exported. This power level might be reduced by power conversion losses before it reaches the main panel. The method used to determine P_{feed} depends on the operation scheme.

P_{draw} : This is the flow of electric power into the control volume drawing from the main panel. This is power being drawn in order to charge storage as desired by the storage operation scheme. This power level might be increased by power conversion losses once it is drawn from the main panel.

P_{charge} : This is the flow of electric power into the storage device from the control volume. This is power being supplied by the generators and/or drawn from the main panel and then directed into storage to charge the device.

$P_{discharge}$: This is the flow of electric power out of the storage device into the control volume. This power is being pulled from storage and added to the power from generators to feed toward the main panel.

The *TrackFacilityElectricDemandStoreExcessOnSite* method tries to run the storage to follow the facility electric demand while storing any excess on-site power production that is above what

Figure 20.6: Storage operation control volume

is needed to run the facility. This is mainly appropriate for island operation. This is the intended legacy behavior before version 8.5. This scheme does not draw from the main panel to charge, so we have $P_{draw} = 0.0$. The value for P_{feed} is determined from the whole-facility total electric power demand. (When there is more than one load center in the model, it is actually the portion of the total that remains after previous load centers have been simulated.) This requested feed in rate is adjusted to be increased by any power conversion losses that may occur in an inverter or a transformer. This adjusted feed in request is used for P_{feed} .

If $P_{gen} > P_{feed}$, then we have charging:

$$\begin{aligned} P_{charge} &= P_{gen} - P_{feed} \\ P_{discharge} &= 0.0 \end{aligned} \tag{20.9}$$

If $P_{gen} < P_{feed}$, then we have discharging:

$$\begin{aligned} P_{discharge} &= P_{feed} - P_{gen} \\ P_{charge} &= 0.0 \end{aligned} \tag{20.10}$$

The *TrackMeterDemandStoreExcessOnSite* method is very similar to the *TrackFacilityElectricDemandStoreExcessOnSite* method except that instead of using the whole-facility total electric demand, the value for P_{feed} is determined from a user-specified meter. The same charge and discharge logic is used.

The *TrackChargeDischargeSchedules* method tries to run the storage to follow user-defined schedules and design power levels for charging and discharging. The user inputs a design charge rate

$P_{charge,design}$, a charge modification schedule $f_{sched,charge}$, a design discharge rate $P_{discharge,design}$, and a discharge modification schedule $f_{sched,discharge}$. The scheduled power flows will be used to determine charging and discharging as long as other limits on rates or state of charge are not triggered. The schedules should be arranged to only charge or only discharge at a given time.

If charging, we have:

$$\begin{aligned} P_{charge} &= P_{charge,design} * f_{sched,charge} \\ P_{discharge} &= 0.0 \end{aligned} \quad (20.11)$$

If $P_{gen} > P_{charge}$, then we have excess to feed toward main panel:

$$\begin{aligned} P_{feed} &= P_{gen} - P_{charge} \\ P_{draw} &= 0.0 \end{aligned} \quad (20.12)$$

If $P_{gen} < P_{charge}$, then we have a shortfall and we draw from main panel:

$$\begin{aligned} P_{draw} &= P_{charge} - P_{gen} \\ P_{feed} &= 0.0 \end{aligned} \quad (20.13)$$

If discharging, we have:

$$\begin{aligned} P_{discharge} &= P_{discharge,design} * f_{sched,discharge} \\ P_{charge} &= 0.0 \\ P_{feed} &= P_{discharge} + P_{gen} \\ P_{draw} &= 0.0 \end{aligned} \quad (20.14)$$

The *FacilityDemandLeveling* method tries to run the storage to follow a user-defined schedule for the net purchased power, $P_{net,purch}$. This is similar to demand limit operation but instead of just attempting to cap the facility demand, it will also manipulate storage to increase utility grid supply electric to meet the target for net purchased power. The user inputs a design demand target for net purchase power rate, $P_{net,purch,design}$, and a demand level modification schedule $f_{sched,dmd,target}$.

$$P_{net,purch,target} = P_{net,purch,design} * f_{sched,dmd,target} \quad (20.15)$$

This target is compared to an adjusted feed in request, $P_{feed,request}$, from the (remaining, adjusted) whole-facility total electric power demand.

$$P_{feed} = P_{feed,request} - P_{net,purch,target} \quad (20.16)$$

If $P_{feed} > 0.0$, then we have a situation where the facility needs more power than the target demand. We therefore feed that power toward the main panel, but it is not necessarily the full power request that could be served. If $P_{gen} < P_{feed}$, then we still have some power supply to make up by discharging:

$$\begin{aligned} P_{discharge} &= P_{feed} - P_{gen} \\ P_{charge} &= 0.0 \end{aligned} \quad (20.17)$$

Or if $P_{gen} > P_{feed}$, then we have excess power we can use for charging.

$$\begin{aligned} P_{charge} &= P_{gen} - P_{feed} \\ P_{discharge} &= 0.0 \end{aligned} \quad (20.18)$$

However, if $P_{feed} < 0.0$, then the facility needs less power than the target demand. We therefore draw power from the main panel to increase power purchased to meet target demand level.

$$\begin{aligned} P_{draw} &= \text{abs}(P_{feed}) \\ P_{feed} &= 0.0 \\ P_{charge} &= P_{draw} + P_{gen} \end{aligned} \quad (20.19)$$

20.2.8 Electrical Storage - Simple Energy Balance Model

EnergyPlus includes two models for storing electrical energy: a simple model that is not intended to represent any specific type of storage technology and a battery model that represents the kinetic battery model originally developed by Manwell and McGowan which discussed in the next section.

The simple model treats the battery as a black box, counting energy added and removed, with losses due to charge/discharge inefficiencies. The model is a reasonable starting point for simulation of Li-ion and other battery technologies without significant rate limitations. The simple model might be called constrained bucket with energy losses. The bucket holds a quantity of Joules of electrical energy, referred to as the state of charge. There are losses and limits to storing and drawing power but otherwise the bucket just holds electricity. The user sets constraints on the rates of charging, $P_{stor-charge-max}$, and drawing, $P_{stor-draw-max}$. The user defines efficiency values for charging, ε_{charge} , and drawing, ε_{draw} .

The user defines an initial state of charge and a maximum state of charge. The storage operation scheme makes supervisory control decisions and determines a value for the charging power, $P_{stor-charge}$, or the discharging power, $P_{stor-draw}$ and passes in control limits for the minimum and maximum state of charge fraction. The maximum state of charge is the physical capacity of the storage device, however the storage control applies a separate layer of minimum and maximum state of charge used to model controller behavior designed to protect the battery from abuse.

The control requests are constrained by the device's physical limits for how fast it can be charged or discharged, $P_{stor-charge-max}$ and $P_{stor-draw-max}$ are applied.

If charging, the new state of charge, $Q_{stor}^{t+\Delta t}$, is determined using:

$$Q_{stor}^{t+\Delta t} = Q_{stor}^t + P_{stor-charge} \cdot \varepsilon_{charge} \cdot \Delta t \quad (20.20)$$

If drawing, the new state of charge is:

$$Q_{stor}^{t+\Delta t} = Q_{stor}^t - \frac{P_{stor-draw} \cdot \Delta t}{\varepsilon_{draw}} \quad (20.21)$$

where Δt is the length of the system time step in seconds.

The storage device has an availability schedule. If it is not available then no power can be drawn or stored. The state of charge minimum and maximum that are passed into the storage model are used to decide if the device can be further charged or discharged. The separate control limits allow modeling battery preservation strategies where the full capacity of the storage device is not really used.

The gross electric power drawn and stored includes losses in the form of heat. These thermal losses are calculated from the user-specified efficiencies for charging and drawing and gross electric power stored and drawn. The thermal (heat) losses are included in a zone heat balance if the user specifies a thermal zone. A user-defined radiative split is used to divide thermal losses into radiation and convection portions. If no zone is specified, then the thermal losses are simply disregarded (e.g., rejected to outdoors and do not impact the zone air heat balance).

20.2.9 Electrical Storage – Kinetic Battery Model with Cycle Life Estimation

The Kinetic Battery Model (KiBaM) (object: ElectricLoadCenter:Storage:Battery) was originally developed by Manwell and McGowan (1993) for use in time series performance models of hybrid energy systems. The model is called kinetic because it is based on a chemical kinetics process to simulate the battery charging and discharging behavior. The model, with different improvements and modifications, has been incorporated into the software Hybrid2 and HOMER as the electrical storage module of hybrid and distributed power systems. In 2005, KiBaM was implemented as a stand-alone application in support of the European Union Benchmarking research project (Bindner et al. 2005). The model is intended to represent technologies such as Pb-acid that encounter significant rate or kinetic limitations.

The Kinetic Battery Model assumes that the battery charge is distributed over two tanks: an available-charge tank and a bound-charge tank. The tank for available charges can supply electrons directly to the load, whereas the tank for chemically bound charges can only supply electrons to the available-charge tank. At any time, the total charge q in the battery is the sum of the available charge (q_1) and bound charge (q_2). That is:

$$q = q_1 + q_2 \quad (20.22)$$

Based on the governing equations on the change of charge in both tanks (Manwell and McGowan 1993), the battery capacity can be related to a constant charge/discharge current (I) as the following equation:

$$q_{\max}(I) = \frac{q_{\max} k \cdot c \cdot t}{1 - e^{-kt} + c(kt - 1 + e^{-kt})} \quad (20.23)$$

where:

$q_{\max}(I)$ is the maximum capacity (Ah) at charge or discharge current I

q_{\max} is the maximum capacity (Ah) at infinitesimal current

t is the charge or discharge time (hr), defined by $t = \frac{q_{\max}(I)}{I}$

k is a constant coefficient (hr^{-1})

c is the parameter indicating the ratio of available charge capacity to total capacity.

Assuming that a constant current is used in any time step for charging and discharging, the available charge (q_1) and bound charge (q_2) at any time step are given by:

$$q_1 = q_{1,0} e^{-k\Delta t} + \frac{(q_0 k c - I)(1 - e^{-k\Delta t})}{k} - \frac{I c(k\Delta t - 1 + e^{-k\Delta t})}{k} \quad (20.24)$$

$$q_2 = q_{2,0} e^{-k\Delta t} + q_0(1 - c)(1 - e^{-k\Delta t}) - \frac{I(1 - c)(k\Delta t - 1 + e^{-k\Delta t})}{k} \quad (20.25)$$

where:

$q_{1,0}$ is the available charge at the beginning of time step (Ah)

$q_{2,0}$ is the bound charge at the beginning of time step (Ah)

q_0 is the total charge at the beginning of time step (Ah) or $q_0 = q_{1,0} + q_{2,0}$

Δt is the length of time step (hr).

KiBaM views the battery as a voltage source in series with an electric resistance (Figure 20.7). The internal resistance is assumed to be constant and the open circuit voltage varies with current and state of charge.

Figure 20.7: Electrical equivalent model for KiBaM

The battery's open circuit voltage is modeled in the same form for charging and discharging, but with different coefficients. The open circuit voltage in charging (E_c) and in discharging (E_d) can be respectively expressed as:

$$E_c = E_{0,d} + A_c X_c + \frac{C_c X_c}{D_c - X_c} \quad (20.26)$$

$$E_d = E_{0,c} + A_d X_d + \frac{C_d X_d}{D_d - X_d} \quad (20.27)$$

where:

$E_{0,c}$ is the open circuit voltage for a fully charged battery

$E_{0,d}$ is the open circuit voltage for a fully discharged battery

A_c, C_c, D_c are the constant parameters for charging

A_d, C_d, D_d are the constant parameters for discharging

X_c , X_d is the normalized maximum capacity at a given charging or discharging current, calculated as:

$$X = \begin{cases} q_0/q_{max}(I) & (charging) \\ (q_{max} - q_0)/q_{max}(I) & (discharging) \end{cases} \quad (20.28)$$

It needs to be noted that the performance curve (Curve:RectangularHyperbola2) used in the model input covers the 2nd and the 3rd item of the open circuit voltage equation. Due to the reformatting of performance curve, the voltage function regression coefficients can map to the curve coefficients as follows: $C_1 = -C$; $C_2 = -D$; $C_3 = A$.

With open circuit voltage, the battery terminal voltage (V) can be calculated as:

$$V = E - IR \quad (20.29)$$

where R is the battery internal resistance in Ohms; the current is positive for discharging and negative for charging.

Given desired power in/out of the battery, the desired charge or discharge current can be calculated from the basic power equation: $P = VI$. In this calculation, iteration is needed to ensure the electric current has converged and the battery operation satisfies all specified technical constraints such as maximum discharge current and charge rate limit.

KiBaM assumes that battery life is a primary function of charge/discharge cycles. One cycle is defined as the process of starting from a certain state of charge (SOC), the battery is discharged to a lower SOC and then recharged back to the starting SOC. It is regarded that the magnitude of cycle plays more important than the average of SOC during the cycle. This means that in terms of the impact on battery life, the cycle from 90% to 70% and then recharge back to 90% of SOC is equivalent to another cycle from 50% to 30% and then recharge back to 50% of SOC. Battery life in terms of the number of cycles is predicted as a function of the cycle range measured by the fractional depth of discharge. A double exponential equation is used to capture the damage to batteries due to cycling. The equation takes the following form where the coefficients need to be derived from battery test data via curve fitting.

$$C_F = C_1 + C_2 e^{C_3 R} + C_4 e^{C_5 R} \quad (20.30)$$

where:

C_F is the cycles to failure

C_1 - C_5 are the regression coefficients

R is the cycle range in terms of fractional SOC.

Following Hybrid2, the rainflow counting method (Downing and Socie 1982) is used to count battery cycles within a state of charge time series. Based on the number of cycles for each fractional SOC range, the battery damage is estimated as:

$$D = \sum_{i=1} \left(N_i \frac{1}{C_{F,i}} \right) \quad (20.31)$$

where:

D is the fractional battery damage. For example, a value of 0.5 at the end of simulation means that half of the battery life is used up after the length of the simulation period.

$C_{F,i}$ is the number of cycles to failure for the i-th cycle range

N_i is the total number of cycles over the simulation with the i -th cycle range

It needs to be noted that the temperature effects on battery performance and battery self-discharge are not supported in the current model.

20.2.10 Electrical Storage – Lithium-Ion NMC Model with Capacity Degradation Estimation

The Lithium-Ion NMC Model (object: ElectricLoadCenter:Storage:LithiumIonNMC) comprises a performance model and a capacity degradation model. The performance model captures the dynamics of the voltage, charging and discharging power of the battery, and battery temperature, and the capacity degradation model estimates the loss in maximum available capacity with calendar age, and use. The performance and capacity degradation models are imported from the shared library of the System Advisory Model (SAM). The models are intended to represent Lithium-ion batteries with NMC chemistry. A detailed description of the performance model can be obtained from (DiOrio, 2015), and the capacity degradation model from (Smith 2017). A brief description of the performance, and capacity degradation models are provided below.

20.2.10.1 Voltage Model

The SAM model strikes a balance between complexity and the computational requirements that would enable real-time control. The battery terminal voltage V is expressed as a function of the open circuit voltage V_o , the internal resistance R_{int} , the current I , the state of charge, and the battery capacity (q_{max}) as shown in the equation below.

$$V = V_o - I \cdot R_{int} - K \left(\frac{q_{max}}{q_{max} - \int I \cdot dt} \right) + a \cdot e^{(-B \cdot I \cdot dt)} \quad (20.32)$$

The expression $\int I dt$ is the amount of capacity removed and can be calculated from the following equation.

$$\int I dt = q_{max} - q \quad (20.33)$$

The parameters V_o , K , a , and B are dependent on battery chemistry and can be obtained from the manufacturer's voltage vs charge-removed curves. Default values are included in the Lithium-Ion NMC model with the parameter values obtained from (Tremblay 2007). The voltage model does not incorporate temperature effects, but the impact of temperature is indirectly implemented through battery capacity which is coupled with the thermal model.

20.2.10.2 Thermal Model

The thermal effects of the battery are important to model since they impact both the instantaneous available capacity, and also the rate of lifetime capacity degradation. An energy balance equation is used to model the battery temperature. The heat transfer between the battery and the room is depends on the temperature difference between them $T_{room} - T_{batt}$. In addition to the heat transfer between the room and battery, the battery generates its own heat due to internal resistance. The differential equation used to model the battery temperature is shown below.

$$f(T_{batt}) = \frac{dT_{batt}}{dt} = \frac{hA(T_{room} - T_{batt}) + I^2R}{mC_p} \quad (20.34)$$

The SAM model uses the trapezoidal method to numerically step the temperature forward in time as described in the equation below.

$$T_{batt,n+1} = T_{batt,n} + \frac{\Delta t}{2} [f(T_{batt,n+1}) + f(T_{batt,n})] \quad (20.35)$$

The model outputs the bulk average temperature of the battery which is used in the computation of the maximum available capacity and lifetime capacity degradation.

20.2.10.3 Capacity Model

The lithium ion capacity model updates the charge of the battery depending on the charging and discharging current. A positive value indicates charging and negative value of current indicates discharging. The updated capacity at each time-step is computed using the following equation.

$$q = q - I\Delta t \quad (20.36)$$

The battery is only allowed to charge and discharge to the user defined maximum and minimum state of charge. Capacity relates to the battery energy through voltage as shown below.

$$E = qV \quad (20.37)$$

The power is related to battery energy and voltage as follows.

$$P = IV = \frac{\Delta E}{\Delta t} = \frac{V\Delta q}{\Delta t} \quad (20.38)$$

20.2.10.4 Capacity degradation

The model developed by Smith et.al in (Smith 2017) for the LithiumIon NMC battery is used to estimate capacity degradation. The charge capacity degradation is modeled by taking into consideration two mechanisms: 1) the loss of cyclable Lithium due to formation of solid electrolyte interface (SEI) represented by (Q_{max}^{Li}), and 2) the mechanical damage of the negative electrode due to the charge/discharge cycles (Q_{max}^{neg}). The battery capacity degradation due to each of the mechanisms is briefly described below.

The primary factor driving the formation of SEI is the calendar time t , but formation is accelerated by factors such as state of charge at which the battery is stored, the depth of discharge during cycling and the number of charge and discharge cycles. The battery charge capacity (q_{max}^{Li}) and its degradation due to the formation of SEI is shown in Equation 20.39.

$$Q_{max}^{Li} = d_0 \left[b_0 - b_1 t^{1/2} - b_2 N - b_3 \left(1 - \exp\left(\frac{-t}{\tau_{b_3}}\right) \right) \right] \quad (20.39)$$

where t is the calendar time in days, N is the total number of charge/discharge cycles over the battery's lifetime, and τ_{b_3} is an experimentally determined constant. Battery temperature affects the available maximum capacity at the current time instant as well as the rate of charge degradation. The parameter d_0 captures the effect of the former as shown in Equation 20.40.

Equation 20.40.

$$d_0 = d_{0,ref} \cdot \exp \left[\frac{E_{a,d_0,1}}{R_{ug}} \left(\frac{1}{T_{bat}} - \frac{1}{T_{ref}} \right) - \left(\frac{E_{a,d_0,2}}{R_{ug}} \right)^2 \left(\frac{1}{T_{bat}} - \frac{1}{T_{ref}} \right)^2 \right] \quad (20.40)$$

The other parameters b_1 , b_2 , and b_3 model the capacity degradation and are functions of battery temperature, state of charge, open circuit voltage, negative electrode voltage, and maximum depth of discharge. For example, the equation used to compute the parameter b_1 is in Equation 20.41.

$$b_1 = b_{1,ref} \cdot \exp \left(-\frac{E_{ab1}}{R_{ug}} \cdot \left(\frac{1}{T_{batt}} - \frac{1}{T_{ref}} \right) \right) \cdot \exp \left(-\frac{\alpha_{ab1} \cdot F}{R_{ug}} \cdot \left(\frac{U_{neg}}{T_{batt}} - \frac{U_{ref}}{T_{ref}} \right) \right) \cdot \exp \left(\gamma \cdot (DoD_{max})^{\beta_{b1}} \right) \quad (20.41)$$

$$b_2 = b_{2,ref} \cdot \exp \left(-\frac{E_{ab2}}{R_{ug}} \cdot \left(\frac{1}{T_{batt}} - \frac{1}{T_{ref}} \right) \right) \quad (20.42)$$

$$b_3 = b_{3,ref} \cdot \exp \left(-\frac{E_{ab3}}{R_{ug}} \cdot \left(\frac{1}{T_{batt}} - \frac{1}{T_{ref}} \right) \right) \cdot \exp \left(-\frac{\alpha_{ab3} \cdot F}{R_{ug}} \cdot \left(\frac{V_{oc}}{T_{batt}} - \frac{V_{ref}}{T_{ref}} \right) \right) \cdot \exp(1 + \theta \cdot (DoD_{max})) \quad (20.43)$$

During the second half of the battery life cycle degradation is dominated by the charge discharge cycles. The battery capacity during this period is expressed as shown below.

$$Q_{max}^{neg} = \sqrt{(c_0^2 - 2c_2 c_0 N)} \quad (20.44)$$

As in the case with the calendar life degradation, the parameters c_0 and c_2 were determined experimentally.

The description of the model parameters, and constants can be found in (Smith, 2017), and the corresponding values can be found in (Mishra, 2020).

20.2.11 Electric Load Center Transformers

Transformers (object name: ElectricLoadCenter:Transformer) are an integral part of the electric distribution system. They have two broad applications closely related to building energy simulation. First, transformers are used to lower the voltage of electricity from utility primary circuits to customer secondary circuits, and in this case they are called distribution transformers. Second, transformers are used to output the surplus power from onsite generators to the electricity grid.

Distribution transformers reduce the voltage on utility distribution lines (34.5 kV or less) to a lower secondary voltage (600 V or less) suitable for customer equipment. Distribution transformers are usually categorized according to the medium used for cooling and insulation (liquid or air), the voltage class that they serve (low or medium), and the number of phases (single phase or three phase).

Liquid-immersed transformers rely on oil or other fire resistant liquid around the coils for cooling. In contrast, dry type transformers rely only on the natural convection of air for insulation and cooling. Medium-voltage transformers step from utility line voltage down to a lower secondary voltage, depending on the application. The secondary voltage from a medium-voltage transformer is usually at 277 V for single phase and 480 V for three phase. This secondary voltage can be directly used as 480 V three-phase power for large motors or as 277 V single-phase power for some fluorescent lighting. However, for most industrial and commercial facilities, low-voltage transformers are needed to reduce the above voltages further to 208/120 V. Common 120 V loads are wall plugs and incandescent lighting.

Most liquid-immersed transformers are owned by utilities and they are of the medium-voltage type. Virtually all dry type transformers are owned by commercial and industrial customers (Barnes et al. 1996). Of the dry type transformers, those of the medium-voltage type are generally special-order items while those of the low-voltage type are commodity items. The efficiency requirement of distribution transformers is covered by the NEMA (National Electrical Manufacturers Association) Standard TP 1. ASHRAE 90.1-2010 will cite the NEMA Standard TP 1 to stipulate the efficiency requirement for the low-voltage dry type distribution transformers.

There are two main types of energy losses in transformers: no load loss and load loss. The no load loss comes primarily from the switching of the magnetic fields in the core material. Hence, it is also called the core loss. The no load (core) loss is roughly constant and exists continuously in the core material as long as the transformer is energized. The load loss comes from the electrical resistance in the windings when there is a load on the transformer. Hence, the load loss is also called the winding loss. The load (winding) loss is proportional to the load squared with a small temperature correction.

Given the no load loss (NL) and the load loss (LL) at rated load and conditions, the total energy losses in a transformer at time t is calculated as:

$$TL(t) = NL + LL(t) = NL + LL * P(t)^2 * f_T(t) \quad (20.45)$$

where:

$TL(t)$ is the total energy loss at time t (W)

$LL(t)$ is the load loss at time t (W)

$P(t)$ is the per unit load at time t

$f_T(t)$ is the temperature correction factor for the load loss at time t .

The per unit load at time t is calculated as:

$$P(t) = \frac{Load(t)}{S_B} \quad (20.46)$$

where:

$Load(t)$ is the transformer load at time t (W)

S_B is the transformer nameplate rating (VA).

The temperature correction factor at time t is calculated as (NEMA 2002):

$$f_T(t) = L_{dc} * \frac{R(t)}{R_{ref}} + L_{eddy} * \frac{R_{ref}}{R(t)} \quad (20.47)$$

where:

L_{dc} is the per unit load loss due to electrical resistance

L_{eddy} is the per unit load loss due to eddy currents

$R(t)$ is the winding electrical resistance at time t

R_{ref} is the winding electrical resistance at the full load reference conditions.

The ratio of winding electrical resistance is calculated as:

$$\frac{R(t)}{R_{ref}} = \frac{F + T_{winding}(t) + T_{amb}(t)}{F + T_{winding,ref} + T_{amb,ref}} \quad (20.48)$$

where:

F is the thermal coefficient of resistance for the winding material (= 225 for aluminum and 234.5 for copper)

$T_{winding,ref}$ is the winding temperature rise at the full load reference conditions ($^{\circ}\text{C}$)

$T_{winding}(t)$ is the winding temperature rise at time t ($^{\circ}\text{C}$)

$T_{amb,ref}$ is the ambient temperature at the reference condition (= 20°C)

$T_{amb}(t)$ is the ambient temperature at time t ($^{\circ}\text{C}$)

The Ambient temperature $T_{amb}(t)$ is equal to the zone temperature if a thermal zone is specified in the input; otherwise, it is assumed equal to 20°C . The winding temperature rise at time t is calculated as (Barnes et al. 1997):

$$T_{winding}(t) = P(t)^{1.6} * T_{winding,ref} \quad (20.49)$$

Based on the derived total energy losses in a transformer, the transformer efficiency at time t can be calculated according to the following equation:

$$\eta(t) = \frac{Load(t)}{Load(t) + NL + LL(t)} \quad (20.50)$$

The above procedure describes how to calculate the total transformer energy losses based on the no load loss and load loss at rated conditions. The transformer model also supports the case when the nominal transformer efficiency is given. In this case, the user needs to provide the nameplate efficiency and the corresponding per unit load, the maximum efficiency and the corresponding per unit load, and the reference conductor temperature at which the nameplate efficiency is measured. Given these information, both no load loss and load loss at rated conditions can be derived as below.

The nameplate efficiency can be expressed as:

$$\eta_{np} = \frac{S_B * P_{np}}{S_B * P_{np} + NL + LL * P_{np}^2 * f_{T,np}} \quad (20.51)$$

where:

η_{np} is the nameplate efficiency

S_B is the nameplate rating (VA)

P_{np} is the per unit load at which the nameplate efficiency is measured

$f_{T,np}$ is the applied temperature correction factor for the nameplate efficiency.

Maximum efficiency generally occurs when the load loss is equal to the no-load loss. Because the no-load loss does not vary with the load on the transformer, the following relationship can be established:

$$NL = LL_{max,\eta} = LL * P_{max,\eta}^2 * f_{T,max-\eta} \quad (20.52)$$

where:

$P_{max,\eta}$ is the per unit load at which the maximum efficiency is obtained

$f_{T,max-\eta}$ is the applied temperature correction factor for the maximum efficiency.

Transformers typically have close per unit loads for the nameplate efficiency and the maximum efficiency. Therefore, it is reasonable to assume that the applied temperature correction factors are equal at those two efficiencies. This implies that:

$$\frac{LL_{np}}{LL_{max,\eta}} = \frac{LL * P_{np}^2 * f_{T,np}}{LL * P_{max,\eta}^2 * f_{T,max-\eta}} = \left(\frac{P_{np}}{P_{max,\eta}} \right)^2 \quad (20.53)$$

Rearranging Equation 20.53 and combining it with Equation 20.52 leads to:

$$LL_{np} = LL_{max,\eta} * \left(\frac{P_{np}}{P_{max,\eta}} \right)^2 = NL * \left(\frac{P_{np}}{P_{max,\eta}} \right)^2 \quad (20.54)$$

Combining Equations 20.51 and 20.54, we can obtain the no load loss as:

$$NL = \frac{S_B * P_{np} * (1 - \eta_{np})}{\eta_{np} * \left[1 + \left(\frac{P_{ref}}{P_{max,\eta}} \right)^2 \right]} \quad (20.55)$$

Substitute NL into Equation 20.52, we can calculate the load loss at rated conditions as:

$$LL = \frac{NL}{f_{T,max-\eta} * P_{max,\eta}^2} = \frac{NL}{f_{T,np} * P_{max,\eta}^2} \quad (20.56)$$

Since both no load and load losses at rated conditions are known, the total energy losses in a transformer at time t can then be calculated according to Equation 20.45.

20.3 Photovoltaic Arrays

The Photovoltaics module includes three different models referred to as “Simple”, “Equivalent One-Diode” and “Sandia” and the choice will determine the mathematical models (and input data) used to determine the energy produced by solar/electric conversion panels. There is also a PVWatts generator which abstracts away specifying PV modules and array properties for a simpler input structure. The EnergyPlus photovoltaic array models are called one at a time at the HVAC system timestep along with other electrical generation components such as gas turbines and diesel engines.

All of the photovoltaic models with the exception of the PVWatts model share the same models for predicting incident solar radiation that are also used for the solar thermal calculations and are described in the section Climate, Sky and Solar/Shading Calculations. The PVWatts generator uses the same solar calculations as the SAM software or PVWatts web API.

Note that some of the terminology used to discussed photovoltaics overlaps with terminology in software development and both may apply in these descriptions. The word *module* may refer to a PV panel or to a C++ programming entity. *Model* may refer to a manufacturers production model for a specific type of PV module or to a mathematical model used for engineering analysis. *Array* may refer to a collection of PV modules wired together or to a mathematical variable with multiple elements.

The PV modules are assumed to always run when the total incident solar is greater than 0.3 Watts. If the incident solar is less than 0.3, then the modules produce no power.

PV arrays are managed by an electric load center. The load center is a “load” with respect to generating equipment but is a “supply center” for the rest of the building. PV arrays need to be connected to ElectricLoadCenter:Distribution objects that have a DC buss type.

20.3.1 Simple Model

The Generator:PV:Simple object describes about the simplest model for predicting photovoltaic energy production. In this model the user specifies the efficiency with which surfaces convert incident solar radiation to electricity. (In the other models this efficiency is determined as part of the model.) The full geometric model for solar radiation is used, including sky models, shading, and reflections, to determine the incident solar resource. The model accepts arbitrary conversion efficiencies and does not require actual production units be tested to obtain empirical performance coefficients. (The Energy+.idd sets the range of conversion efficiencies to be within [0..1], but the user could alter the Energy+.idd to extend this range if desired.)

Table 20.1: Nomenclature for Simple Photovoltaic model

Mathematical Variable	Description
G_T	Total solar radiation incident on PV array (W/m ²)
η_{cell}	Module conversion efficiency
η_{invert}	DC to AC conversion efficiency

The usable electrical power produced by a PV surface are calculated using:

$$P = A_{surf} \cdot f_{activ} \cdot G_T \cdot \eta_{cell} \cdot \eta_{invert} \quad (20.57)$$

On the right hand side of this equation, only G_T is calculated by EnergyPlus and the rest are user inputs. Power levels are assumed constant over the timestep to arrive at energy production.

There are two modes that can be selected by the user that govern how the PV system is coupled to the building surfaces. If the integration mode is selected as ‘DECOUPLED’ then no adjustments are made to account for energy extracted in the form of electricity. If the integration mode is selected as ‘INTEGRATED’ then the energy extracted in the form of electricity is removed from surface heat transfer calculations using a sink term. This sink term is lagged from the previous timestep.

20.3.2 Equivalent One-Diode Model

This model predicts the electrical performance of a photovoltaic (PV) array. This model is also known as the “TRNSYS PV” model.

Mathematically speaking, the EnergyPlus PV module employs equations for an empirical equivalent circuit model to predict the current-voltage characteristics of a single module. This circuit consists of a DC current source, diode, and either one or two resistors. The strength of the current source is dependent on solar radiation and the IV characteristics of the diode are temperature-dependent. The results for a single module equivalent circuit are extrapolated to predict the performance of a multi-module array.

The module employs a “four-parameter” equivalent circuit to model crystalline (both mono and poly) PV modules developed at the University of Wisconsin – Madison. The values of these parameters cannot normally be obtained directly from manufacturers’ catalogs. However, the PV module will automatically calculate them from commonly available data. The PV module also includes an optional incidence angle modifier correlation to calculate how the reflectance of the PV module surface varies with the angle of incidence of solar radiation.

The module determines PV current as a function of load voltage. Other OUTPUTS include current and voltage at the maximum power point along the IV curve, open-circuit voltage, short circuit current as well as electrical load met and unmet.

Table 20.2: General Nomenclature for the PV model

Mathematical variable	Description
β	Slope of PV array (degrees)
γ	Empirical PV curve-fitting parameter
ε_γ	Semiconductor bandgap (eV)
η_c	Module conversion efficiency
μ_{isc}	Temperature coefficient of short-circuit current (A/K)
μ_{voc}	Temperature coefficient of open-circuit voltage (V/K)
θ	Angle of incidence for solar radiation (degrees)
$\tau\alpha$	Module transmittance-absorptance product
$\tau\alpha_{normal}$	Module transmittance-absorptance product at normal incidence
G_T	Total radiation incident on PV array
$G_{T,beam}$	Beam component of incident radiation
$G_{T,diff}$	Diffuse component of incident radiation
$G_{T,gnd}$	Ground-reflected component of incident radiation
$G_{T,NOCT}$	Incident radiation at NOCT conditions
$G_{T,ref}$	Incident radiation at reference conditions
I	Current
I_L	Module photocurrent
$I_{L,ref}$	Module photocurrent at reference conditions
I_o	Diode reverse saturation current
$I_{o,ref}$	Diode reverse saturation current at reference conditions
I_{sc}	Short-circuit current
$I_{sc,ref}$	Short-circuit current at reference conditions
I_{mp}	Current at maximum power point along IV curve
$I_{mp,ref}$	Current at maximum power point along IV curve, reference conditions
IAM	Dimensionless incidence angle modifier
K	Boltzmann constant (J/K)
NP	Number of modules in parallel in array
NS	Number of modules in series in array
N_s	Number of individual cells in module
P	PV output power
P_{max}	PV output power at maximum power point along IV curve
Q	Electron charge constant
R_s	Module series resistance (Ω)

Table 20.2: General Nomenclature for the PV model

Mathematical variable	Description
R_{sh}	Module shunt resistance (Ω)
T_c	Module temperature (K)
$T_{c,NOCT}$	Module temperature at NOCT conditions (K)
$T_{c,ref}$	Module temperature at reference conditions (K)
U_L	Array thermal loss coefficient
V	Voltage
V_{mp}	Voltage at maximum power point along IV curve
$V_{mp,ref}$	Voltage at maximum power point along IV curve, reference conditions
V_{oc}	Open-circuit voltage
$V_{oc,ref}$	Open-circuit voltage at reference conditions (V)

20.3.2.1 Mathematical Description

20.3.2.1.1 PV Section 1: Four-Parameter Model

The four-parameter equivalent circuit model was developed largely by Townsend [1989] and is detailed by Duffie and Beckman [1991]. The model was first incorporated into a component for the TRNSYS simulation package by Eckstein [1990]. The EnergyPlus module employs the Eckstein model for crystalline PV modules, using it whenever the short-circuit IV slope is set to zero or a positive value as modified by Ulleberg [2000]. The four parameter model assumes that the slope of the IV curve is zero at the short-circuit condition:

$$\left(\frac{dI}{dV} \right)_{v=0} = 0 \quad (20.58)$$

This is a reasonable approximation for crystalline modules. The “four parameters” in the model are $I_{L,ref}$, $I_{o,ref}$, γ , and R_s . These are empirical values that cannot be determined directly through physical measurement. The EnergyPlus model calculates these values from manufactures’ catalog data as discussed in the following section on calculating these parameters.

The four-parameter equivalent circuit is shown in Figure 20.8.

V is the load voltage and I is the current flowing through the load and PV.

Determining Performance under Operating Conditions

The IV characteristics of a PV change with both insolation and temperature. The PV model employs these environmental conditions along with the four module constants $I_{L,ref}$, $I_{o,ref}$, γ , and R_s to generate an IV curve at each timestep.

The current-voltage equation of circuit shown in Figure 20.8 is as follows:

$$I = I_L - I_o \left[\exp \left(\frac{q}{\gamma k T_c} (V + I R_s) \right) - 1 \right] \quad (20.59)$$

where R_s and γ are constants. The photocurrent I_L depends linearly on incident radiation:

Figure 20.8: Equivalent circuit in the four parameter model

$$I_L = I_{L,ref} \frac{G_T}{G_{T,ref}} \quad (20.60)$$

The reference insolation G_{ref} is nearly always defined as 1000 W/m^2 . The diode reverse saturation current I_o is a temperature dependent quantity:

$$\frac{I_o}{I_{o,ref}} = \left(\frac{T_c}{T_{c,ref}} \right)^3 \quad (20.61)$$

Equation 20.59 gives the current implicitly as a function of voltage. Once I_o and I_L are found from Equations 20.60 and 20.61, Newton's method is employed to calculate the PV current. In addition, an iterative search routine finds the current (I_{mp}) and voltage (V_{mp}) at the point of maximum power along the IV curve.

Calculating $I_{L,ref}$, $I_{o,ref}$, γ , and R_s

The Idf specification for the PV model include several values which must be read from manufacturers' PV module catalogs. The manufactures' values are used to determine the equivalent circuit characteristics $I_{L,ref}$, $I_{o,ref}$, γ , and R_s . These characteristics define an equivalent circuit that is employed to find the PV performance at each timestep, as described previously. This section describes the algebra and calculation algorithms used to solve for the four equivalent circuit characteristics.

Three of these values, $I_{L,ref}$, $I_{o,ref}$, and γ may be isolated algebraically. The first step is to substitute the current and voltage into Equation 20.59 at the open-circuit, short circuit, and maximum power conditions:

$$0 = I_{L,ref} - I_{o,ref} \left[\exp \left(\frac{q}{\gamma k T_{c,ref}} V_{oc,ref} \right) - 1 \right] - \frac{V_{oc,ref}}{R_{sh}} \quad (20.62)$$

$$I_{sc,ref} = I_{L,ref} - I_{o,ref} \left[\exp \left(\frac{q I_{sc,ref} R_s}{\gamma k T_{c,ref}} \right) - 1 \right] - \frac{I_{sc,ref} R_s}{R_{sh}} \quad (20.63)$$

$$I_{mp,ref} = I_{L,ref} - I_{o,ref} \left[\exp \left(\frac{q}{\gamma k T_{c,ref}} (V_{mp,ref} + I_{mp,ref} R_s) \right) - 1 \right] - \frac{V_{mp,ref} + I_{mp,ref} R_s}{R_{sh}} \quad (20.64)$$

In each case the “-1” term is/may be dropped to simplify the algebra. This approximation has little influence on the right side of the equations since because the magnitude of I_o is very small, generally on the order of 10^{-6} A. Some rearrangement then yields the following three expressions which isolate $I_{L,ref}$, $I_{o,ref}$, and γ :

$$I_{L,ref} \approx I_{sc,ref} \quad (20.65)$$

$$\gamma = \frac{q (V_{mp,ref} - V_{oc,ref} + I_{mp,ref} R_s)}{k T_{c,ref} \ln \left(1 - \frac{I_{mp,ref}}{I_{sc,ref}} \right)} \quad (20.66)$$

$$I_{o,ref} = \frac{I_{sc,ref}}{\exp \left(\frac{q V_{oc,ref}}{\gamma k T_{c,ref}} \right)} \quad (20.67)$$

At this point an additional equation is needed in order to determine the last unknown parameter. Taking the analytical derivative of voltage with respect to temperature at the reference open-circuit condition derives the fourth equation. This analytical value is matched to the open-circuit temperature coefficient, a catalog specification:

$$\frac{\partial V_{oc}}{\partial T_c} = \mu_{voc} = \frac{\gamma k}{q} \left[\ln \left(\frac{I_{sc,ref}}{I_{o,ref}} \right) + \frac{T_c \mu_{isc}}{I_{sc,ref}} - \left(3 + \frac{q \varepsilon}{A k T_{c,ref}} \right) \right] \quad (20.68)$$

where:

$$A = \frac{\gamma}{N_s} \quad (20.69)$$

The “TRNSYS PV model” uses an iterative search routine in these four equations to calculate the equivalent circuit characteristics. The first step is to set upper and lower bounds for the series resistance parameter R_s : physical constraints require the R_s value to lie between 0 and the value such that $\gamma = N_s$. The initial guess for R_s is midway between these bounds. γ and $I_{o,ref}$ are found from Equations 20.66 and 20.67, while Equation 20.65 gives a trivial solution for $I_{L,ref}$. The model then employs Equation 20.68 to compare the analytical and catalog values for m_{voc} . When all other variables are held constant, the analytical value for m_{voc} increases monotonically with series resistance (Townsend 1989). If the analytical voltage coefficient is less than the catalog value, the lower bound for R_s is reset to the present guess value. Likewise, the upper bound is set to the current value if the calculated m_{voc} is too large. After resetting the upper or lower bound for R_s , a new guess value is found by averaging the bounds. This procedure repeats until R_s and γ converge. Note that for $I_{L,ref}$, $I_{o,ref}$, γ , and R_s are assumed to be constant and are calculated only on the first call in the simulation. Alternatively, the user may enter a known series resistance by entering a **positive** value in the IDF. In this case the iterative routine described above is skipped and Equations 20.65, 20.66, and 20.67 find $I_{L,ref}$, $I_{o,ref}$, and γ directly from the given value of R_s .

20.3.2.1.2 PV Section 2 : Module Operating Temperature

The PV model uses one of five methods for determining cell temperature data. The cell temperature of a PV module is important because the hotter the temperature of the panel, the lower its electrical output. The cell temperature calculation method is chosen by the user in the EnergyPlus IDF file through a parameter choice in the IDD entry called Integration and Cell Temperature Mode.

If the value of this parameter is “**Decoupled NOCT Conditions**” then the cell temperature of the PV is modeled using the method from the Duffie and Beckman (1991) for estimating cell temperature. This is based upon the standard NOCT (Nominal Operating Cell Temperature) measurements to compute the module temperature T_c at each timestep. The NOCT temperature ($T_{c,NOCT}$) is the operating temperature of the module with a wind speed of 1 m/s, no electrical load, and a certain specified insolation and ambient temperature [Beckman and Duffie, 1991]. The values for insolation $G_{T,NOCT}$ and ambient temperature $T_{a,NOCT}$ are usually 800 W/m² and 20°C. η_c is the conversion efficiency of the module, which varies with ambient conditions. $\tau\alpha$ is a user-defined constant.

The equation is:

$$T_c = T_a + \frac{1 - \frac{\eta_c}{\tau\alpha}}{G_T \tau\alpha / U_L} \quad (20.70)$$

If the user specifies the “**Decoupled Ulleberg Dynamic**” mode for calculating cell temperature, then a method developed by Ulleberg is used:

$$T_{cell}|_t = T_{ambient} + (T_{cell}|_{t-1} - T_{ambient}) * e^{\frac{-U_L}{C_{ap}} \Delta t} \quad (20.71)$$

In other words, the cell temperature is a function of the previous cell temperature and the thermal capacity of the PV module material.

If the user specifies “**Integrated Surface Outside Face**” for this parameter, then the temperature result from EnergyPlus’s modeling of surfaces is used for the cell temperature. Also the energy exported from the surface as electricity becomes a sink in the internal source modeling for the heat transfer surface.

If the user specifies “**Integrated Transpired Collector**” for this parameter, then the temperature result for the unglazed transpired collector surfaces is used for the cell temperature. Also the energy exported from the collector surface as electricity is deprecated using a source term in the collector’s temperature modeling.

If the user specifies “**Integrated Exterior Vented Cavity**” for this parameter, then the temperature result for the exterior cavity is used for the cell temperature. Also the energy exported from the baffle surface as electricity is deprecated using a source term in the baffle’s temperature modeling.

20.3.2.1.3 PV Section 3 : Multi-Array Modules

The electrical calculations discussed in the sections above deal only with a single module. The EnergyPlus PV component may be used to simulate arrays with any number of modules. The IDF defines the number of modules in series (NS) and modules in parallel (NP) for the entire array. The total number of modules in the array is the product of NS and NP. When simulating a single module only, both NS and NP are set to 1. The single-module values for all currents and voltages

discussed in PV Section 1 are multiplied by NP or NS to find values for the entire array. This approach neglects module mismatch losses.

With the above equations, and the assumption that the panels operate at the maximum power point, it is a direct calculation to determine DC power production. The performance of an array of identical modules is assumed to be linear with the number of modules in series and parallel. The inverter efficiency is applied linearly to derate the energy production. The inverter capacity forms a limit for power production from a PV generator. A ‘load’ is passed the PV array acting as a generator and various trivial calculations compare PV production to this load. If the PV array is associated with a surface that is associated with a zone, then if the zone has any multipliers associated with it, electricity production will be multiplied accordingly.

20.3.3 Sandia Photovoltaic Performance Model

The third model available in EnergyPlus for predicting the electricity generated by photovoltaics is referred to as the Sandia model. This model is based on work done at Sandia National Lab, Albuquerque, NM by David King – with the help of many others. The model consists of a series of empirical relationships with coefficients that are derived from actual testing. Once the coefficients for a particular module are available, it is straightforward matter to use the model equations to calculate five select points on the current-voltage curve.

The C++ implementation in EnergyPlus is also based on work done by Greg Barker (2003) for the National Renewable Energy Lab who implemented the Sandia model in FORTRAN77 as a custom type (Type101) for the TRNSYS computer program.

There are several climate and solar orientation inputs to the model that are managed elsewhere in EnergyPlus including: incident beam solar, incident diffuse solar, incidence angle of beam solar, solar zenith Angle, outdoor drybulb, wind speed, and elevation.

20.3.3.1 Mathematical Description

This section presents the mathematical description of the Sandia model from a draft report by King et. al. (2003). The core of the model predicts the performance of a single PV module. The following nomenclature and equations summarize the Sandia model.

Table 20.3: Nomenclature for Sandia PV model

Mathematical variable	Description
I_{sc}	Short-circuit current (A)
I_{mp}	Current at the maximum-power point (A)
I_x	Current at module $V = 0.5 V_{oc}$, defines 4th point on I-V curve
I_{xx}	Current at module $V = 0.5 (V_{oc} + V_{mp})$, defines a 5th point on the I-V curve
V_{oc}	Open-circuit voltage (V)
V_{mp}	Voltage at maximum-power point (V)
P_{mp}	Power at maximum-power point (W)
fd	Fraction of diffuse irradiance used by module
N_s	Number of cells in series in a module's cell-string
N_p	Number of cell-strings in parallel in module
k	Boltzmann's constant, 1.38066E-23 (J/K)
q	Elementary charge, 1.60218E-19 (coulomb)
T_c	Cell temperature inside module ($^{\circ}\text{C}$)
$\delta(T_c)$	'Thermal voltage' per cell at temperature T_c , approximately 1 volt for a typical 26-cell crystalline silicon module
E_e	'Effective' solar irradiance
E_b	Beam solar irradiance
E_{diff}	Diffuse solar irradiance
C_0, C_1	Empirical coefficients relating I_{mp} to E_e , $C_0 + C_1 = 1$ (both dimensionless)
C_2, C_3	Empirical coefficients relating V_{mp} to E_e (C_2 dimensionless, C_3 is 1/V)
C_4, C_5	Empirical coefficients relating I_x to E_e , $C_4 + C_5 = 1$ (both dimensionless)
C_6, C_7	Empirical coefficients relating I_{xx} to E_e , $C_6 + C_7 = 1$ (both dimensionless)
n	Empirically determined 'diode factor' for individual cells
AMa	Absolute Air Mas
AOI	Solar angle-of-incidence (degrees) from normal
$f_1(\text{AM}_a)$	Empirical polynomial function used to relate short-circuit current to the solar spectrum via air mass
$f_2(\text{AOI})$	Empirical polynomial function used to relate short-circuit current to the solar angle-of-incidence
a_0, a_1, a_2, a_3, a_4	Empirical coefficients for $f_1(\text{AM}_a)$ polynomial

Table 20.3: Nomenclature for Sandia PV model

Mathematical variable	Description
$b_0, b_1, b_2, b_3, b_4, b_5, b_6$	Empirical coefficients for $f_2(\text{AOI})$ polynomial
T_o	Reference cell temperature for rating, typically fixed at 25°C
I_{sco}	Short circuit current at reference conditions
I_{mpo}	Max power point current at reference conditions
V_{mpo}	Voltage at max power at reference conditions
V_{oco}	Open circuit voltage at reference conditions
I_{xo}	Current at $V = 0.5 V_{oc}$ and at reference conditions
$I_{x xo}$	Current at $V = 0.5 (V_{mp} + V_{oc})$ and at reference conditions
α_{Isc}	Normalized temperature coefficient for I_{sc} (1/°C)
α_{Imp}	Normalized temperature coefficient for I_{mp} (1/°C)
$\beta_{V_{oc}}(E_e)$	Temperature coefficient for module open-circuit-voltage as function of E_e
$\beta_{V_{oco}}$	Temperature coefficient for module open-circuit-voltage at reference conditions
$m\beta_{V_{oco}}$	Coefficient for irradiance dependence of open-circuit-voltage-temperature coefficient, often zero (V/°C)
$\beta_{V_{mp}}(E_e)$	Temperature coefficient for module maximum-power-voltage as a function of E
$\beta_{V_{mpo}}$	Temperature coefficient for module maximum-power-voltage at reference conditions
$m\beta_{V_{oco}}$	Coefficient for irradiance dependence of maximum-power-voltage-temperature coefficient, often zero (V/°C)
T_m	PV module temperature at back surface (°C)
T_a	Ambient outdoor drybulb temperature (°C)
E	Solar irradiance incident on module surface (W/m ²)
WS	Wind speed at standard 10-m height (m/s)
a	Empirical coefficient relating module temperature at low wind and high solar irradiance
b	Empirical coefficient relating module temperature decrease with increasing wind speed
T_c	Temperature of solar cell inside module (°C)
E_o	Reference solar irradiance (1000 W/m ²)
ΔT	Temperature difference between T_c and T_m at E_o (°C), (This is $d(T_c)$ in the Sandia database)

The current implementation in EnergyPlus focuses on determining performance at the maximum power-point but also calculates, and reports, four other points on the I-V curve so that the data are available for analyses outside of EnergyPlus. The equations below use the module performance parameters that are available in a database provided by Sandia National Laboratory (see www.sandia.gov/pv). The following equations form the basis of the Sandia model implemented in EnergyPlus:

$$I_{sc} = I_{sco} \cdot f_1(AM_a) \cdot \{(E_b \cdot f_2(AOI) + f_d \cdot E_{diff}) / E_o\} \cdot \{1 + \alpha_{Isc} \cdot (T_c - T_o)\} \quad (20.72)$$

$$I_{mp} = I_{mpo} \cdot \{C_o \cdot E_e + C_1 \cdot E_e^2\} \cdot \{1 + \alpha_{Imp} \cdot (T_c - T_o)\} \quad (20.73)$$

$$V_{oc} = V_{oco} + N_s \cdot \delta(T_c) \cdot \ln(E_e) + \beta_{Voc}(E_e) \cdot (T_c - T_o) \quad (20.74)$$

$$V_{mp} = V_{mpo} + C_2 \cdot N_s \cdot \delta(T_c) \cdot \ln(E_e) + C_3 \cdot N_3 \cdot \{\delta(T_c) \cdot \ln(E_e)\}^2 + \beta_{Vmp}(E_e) \cdot (T_c - T_o) \quad (20.75)$$

$$P_{mp} = I_{mp} \cdot V_{mp} \quad (20.76)$$

$$I_x = I_{xo} \cdot \{C_4 \cdot E_e + C_5 \cdot E_e^2\} \cdot \{1 + (\alpha_{Isc}) \cdot (T_c - T_o)\} \quad (20.77)$$

$$I_{xx} = I_{xxo} \cdot \{C_6 \cdot E_e + C_7 \cdot E_e^2\} \cdot \{1 + (\alpha_{Imp}) \cdot (T_c - T_o)\} \quad (20.78)$$

where:

$$E_e = I_{sc} / [I_{sco} \cdot \{1 + \alpha_{Isc} \cdot (T_c - T_o)\}] \quad (20.79)$$

$$\delta(T_c) = n \cdot k \cdot (T_c + 273.15) / q \quad (20.80)$$

$$f_1(AM_a) = a_0 + a_1 AM_a + a_2 (AM_a)^2 + a_3 (AM_a)^3 + a_4 (AM_a)^4 \quad (20.81)$$

$$f_2(AOI) = b_0 + b_1 \cdot AOI + b_2 (AOI)^2 + b_3 (AOI)^3 + b_4 (AOI)^4 + b_5 (AOI)^5 \quad (20.82)$$

$$\beta_{Voc}(E_e) = \beta_{Voco} + m_{\beta Voc} \cdot (1 - E_e) \quad (20.83)$$

$$\beta_{Vmp}(E_e) = \beta_{Vmpo} + m_{\beta Vmp} \cdot (1 - E_e) \quad (20.84)$$

$$T_m = E \cdot \{e^{a+b \cdot WS}\} + T_a \quad (20.85)$$

$$T_c = T_m + \frac{E}{E_o} \cdot \Delta T \quad (20.86)$$

With the above equations, and the assumption that the panels operate at the maximum power point, it is a direct calculation to determine DC power production. The performance of an array of identical modules is assumed to be linear with the number of modules in series and parallel. The inverter efficiency is applied linearly to derate the energy production. The inverter capacity forms a limit for power production from a PV generator. A ‘load’ is passed the PV array acting as a generator and various trivial calculations compare PV production to this load. If the PV array is associated with a surface that is associated with a zone, then if the zone has any multipliers associated with it, electricity production will be multiplied accordingly.

The equation above for T_m is used to predict back-of-module temperature when the mode ‘SANDIA RACK’ is selected. This would be appropriate for most rack mounted PV installations. If the user selects ‘EPLUS INTEGRATED’ then the back-of-module temperature is obtained from the outside face surface temperature calculated by the full complement of Heat Balance models using Conduction Transfer Functions that is native to EnergyPlus. And energy exported from the surface is accounted for using a source/sink term that is lagged from the previous timestep (pingpong).

20.3.4 PVWatts

The PVWatts model was developed by NREL to calculate the energy production of a grid-connected PV system based on a few simple inputs. It was originally developed and maintained for the System Advisor Model software and is also available as a stand-alone web API. It is implemented as Generator and Inverter objects in EnergyPlus rather than as a photovoltaic performance object because the inputs are more high-level than Generator:Photovoltaic. Full details of the PVWatts model are explained in [PVWatts Version 5 Manual](#).

20.4 Generators

20.4.1 Internal Cumbustion Engine

The engine-driven generator model was originally developed for the BLAST program and was subsequently adapted for use in EnergyPlus. The model uses the following set of equations all of which are quadratic fits to the PLR (Part Load Ratio) of the generator. The coefficients must be derived from manufacturers data.

$$\frac{\text{electric energy output}}{\text{fuel energy input}} = \frac{\text{electric energy output}}{(\dot{m}_{fuel} \{kg/s\} \cdot LHV \{J/kg\})} = a_1 + a_2 PLR + a_3 PLR^2 \quad (20.87)$$

The electrical load and engine generator nominal load capacity are used to compute the part load ratio.

$$PLR = \frac{\text{Electric energy output}}{\text{nominal generating capacity}} \quad (20.88)$$

The exhaust gas temp and flow rate are used if a stack heat exchanger is used to recover waste heat from the exhaust. This temperature is the inlet temperature to the heat exchanger which is modeled in a UA-effectiveness form:

$$\frac{\text{Total Exhaust heat}}{\text{fuel energy input}} = \frac{\text{Total Exhaust heat}}{(\dot{m}_{fuel} \{kg/s\} \cdot LHV \{J/kg\})} = d_1 + d_2 PLR + d_3 PLR^2 \quad (20.89)$$

$$\frac{\text{Exhaust Gas Temp } \{K\}}{\text{fuel energy input}} = \frac{\text{Exhaust Gas Temp } \{K\}}{(\dot{m}_{fuel} \{kg/s\} \cdot LHV \{J/kg\})} = e_1 + e_2 PLR + e_3 PLR^2 \quad (20.90)$$

The exhaust flow rate is then calculated as:

$$\dot{m}_{exhaust} = \frac{\text{Total Exhaust heat}}{C_{p_{exhaust}} \cdot (T_{exhaust} - T_{reference})} \quad (20.91)$$

where $T_{reference}$ is the reference temperature for the fuel lower heating value (given as 25°C in manufacturer's data) and:

$$T_{stack} = T_{DesignMinExhaust} + \frac{(T_{exhaust} - T_{DesignMinExhaust})^2}{\exp\left(\frac{UA}{\dot{m}_{exhaust} C_{p_{exhaust}}}\right)} \quad (20.92)$$

Finally heat recovered from the lube oil and the water jacket are accounted for as follows:

$$\frac{\text{Recoverable jacket heat}}{\text{fuel energy input}} = \frac{\text{Recoverable jacket heat}}{(\dot{m}_{fuel} \{kg/s\} \cdot LHV \{J/kg\})} = b_1 + b_2 PLR + b_3 PLR^2 \quad (20.93)$$

$$\frac{\text{Recoverable lube oil heat}}{\text{fuel energy input}} = \frac{\text{Recoverable lube oil heat}}{(\dot{m}_{fuel} \{kg/s\} \cdot LHV \{J/kg\})} = c_1 + c_2 PLR + c_3 PLR^2 \quad (20.94)$$

The manufacturer must supply the recoverable water jacket heat, lube oil heat and exhaust heat and associated fuel consumption for a range of load conditions. This data is then fit to the PLR to obtain the fifteen a,b,c,d, and e coefficients.

20.4.2 Turbine Generator

The combustion turbine generator model was originally developed for the BLAST program and was subsequently adapted for use in EnergyPlus. The model uses the following set of equations all of which are equation fits to the PLR (Part Load Ratio) of the generator and the entering air temperature. The coefficients must be derived from manufacturers data. For electric power generated in Watts, the fuel input rate is calculated in J/s.

$$\frac{\text{fuel energy input rate}}{\text{electric power output}} = [a_1 + a_2PLR + a_3PLR^2] * [b_1 + b_2\Delta T + b_3\Delta T^2] \quad (20.95)$$

The electrical load and engine generator nominal load capacity are used to compute the part load ratio.

$$PLR = \frac{\text{Electric energy output}}{\text{nominal generating capacity}} \quad (20.96)$$

The temperature difference shows the deviation of ambient air temperature from the manufacturers design air temperature.

$$\Delta T = T_{air} - T_{design} \quad (20.97)$$

A second curve fit calculates the exhaust temperature (C) by multiplying the exhaust temperature (C) for a particular part load by a correction factor based on the deviation from design temperature.

$$T_{exhaust} = [c_1 + c_2PLR + c_3PLR^2] * [d_1 + d_2\Delta T + d_3\Delta T^2] \quad (20.98)$$

The exhaust gas temp is used if a stack heat exchanger is used to recover waste heat from the exhaust. This temperature is the inlet temperature to the heat exchanger which is modeled in a UA-effectiveness form:

$$T_{stack} = T_{DesignMinExhaust} + \frac{(T_{exhaust} - T_{DesignMinExhaust})^2}{\exp\left(\frac{UA}{\dot{m}_{exhaust}C_{p_{exhaust}}}\right)} \quad (20.99)$$

Where the design minimum exhaust temperature is a user input to the model and the exhaust mass flow rate and the UA are fit from manufacturers data as follows:

$$UA = e_3(Nominal\ Generating\ Capacity)^{e_4} \quad (20.100)$$

$$\frac{\text{exhaust gas flow rate}}{\text{Nominal Generating Capacity}} = [f_1 + f_2\Delta T + f_3\Delta T^2] \quad (20.101)$$

Finally, heat recovered from the lube oil is accounted for as follows:

$$\frac{\text{Recoverable lube oil heat}}{\text{electric power generated}} = g_1 + g_2PLR + g_3PLR^2 \quad (20.102)$$

20.4.3 Microturbine Generator

Microturbine generators are small combustion turbines that produce electricity on a relatively small scale (e.g., 25kW to 500kW). This model uses nominal performance at reference conditions along with several modifier curves to determine electrical power output and fuel use at non-reference conditions. The modifier curve coefficients must be derived from manufacturers data. Standby and ancillary power can also be taken into account.

Exhaust air energy recovery for heating water can be also be modeled. Similar to electrical power output, thermal power (heat recovery to water) output is calculated using nominal performance at reference conditions with modifier curves to account for variations at non-reference conditions. The `ElectricLoadCenter:Generators` and `ElectricLoadCenter:Distribution` objects are used to define the availability and control of the electric generators included in the simulation (ref. `ElectricLoadCenter:Generators` and `ElectricLoadCenter:Distribution`).

For each simulation time step that the generator is being asked to operate (i.e., produce electrical power as determined by the `ElectricLoadCenter`), the full load electrical output of the generator is determined using the user-defined reference electrical power output along with a bi-quadratic modifier curve to account for differences in the combustion air inlet temperature and elevation for the current simulation time step compared to the reference temperature and elevation (i.e., the modifier curve should evaluate to 1.0 at the reference combustion air inlet temperature and reference elevation).

$$P_{Elec,Full\ Load} = P_{Elec,Ref} (PowerFTempElev) \quad (20.103)$$

$$PowerFTempElev = a_1 + a_2 (T_{a,i}) + a_3 (T_{a,i})^2 + a_4 (Elev) + a_5 (Elev)^2 + a_6 (T_{a,i}) (Elev) \quad (20.104)$$

where:

$P_{Elec,Full\ Load}$ is the full load electrical power output (W)

$P_{Elec,Ref}$ is the reference electrical power output, user input (W)

$PowerFTempElev$ is the user-defined Electric Power Modifier Curve (function of temperature and elevation) evaluated at the current combustion air inlet temperature and elevation

$T_{a,i}$ is the combustion air inlet temperature (°C)

$Elev$ is the elevation (m). This value obtained from the `Location` object or the weather file.

The full load electrical power output of the generator is then checked against the minimum and maximum full load electrical power outputs specified by the user:

$$P_{Elec,Full\ Load} = MIN (P_{Elec,Full\ Load}, P_{FL,Max}) \quad (20.105)$$

$$P_{Elec,Full\ Load} = MAX (P_{Elec,Full\ Load}, P_{FL,Min}) \quad (20.106)$$

where:

$P_{FL,Max}$ is the maximum Full Load Electrical Power Output, user input (W)

$P_{FL,Min}$ is the minimum Full Load Electrical Power Output, user input (W).

The actual (operating) electrical power output from the generator is determined next based on the load requested by the Electric Load Center, the generator's minimum and maximum part-load ratios, and the ancillary power.

$$P_{Elec,Operating} = MAX(0.0, (Load + P_{Ancillary})) \quad (20.107)$$

$$P_{Elec,Operating} = MIN(P_{Elec,Operating}, P_{Elec,Full Load}) \quad (20.108)$$

$$\begin{aligned} &IF (P_{Elec,Full Load} > 0) THEN \\ &\quad PLR = P_{Elec,Operating} / P_{Elec,Full Load} \\ &\quad PLR = MIN(PLR, PLR_{max}) \\ &\quad PLR = MAX(PLR, PLR_{min}) \\ &ELSE \\ &\quad PLR = 0 \\ &ENDIF \end{aligned} \quad (20.109)$$

$$P_{Elec,Operating} = P_{Elec,Full Load} * PLR \quad (20.110)$$

where:

$P_{Elec,Operating}$ is the actual (operating) electrical power output (W)

$Load$ is the electrical power output being requested by the Electric Load Center (W)

$P_{Ancillary}$ is the ancillary power, user input (W)

PLR is the part-load ratio of the electric generator

PLR_{max} is the maximum part-load ratio of the electric generator (i.e., the maximum value for the independent variable [PLR] defined in the Curve:Quadratic or Curve:Cubic object for the Electrical Efficiency Modifier Curve [function of part-load ratio])

PLR_{min} is the minimum part-load ratio of the electric generator (i.e., the minimum value for the independent variable [PLR] defined in the Curve:Quadratic or Curve:Cubic object for the Electrical Efficiency Modifier Curve [function of part-load ratio]).

The generator's electrical efficiency is then calculated based on the user-specified reference electrical efficiency (lower heating value [LHV] basis) and two electrical efficiency modifier curves.

$$ElecEfficiencyFTemp = b_1 + b_2(T_{a,i}) + b_3(T_{a,i})^2 \quad or \quad b_1 + b_2(T_{a,i}) + b_3(T_{a,i})^2 + b_4(T_{a,i})^3 \quad (20.111)$$

$$ElecEfficiencyFPLR = c_1 + c_2(PLR) + c_3(PLR)^2 \quad or \quad c_1 + c_2(PLR) + c_3(PLR)^2 + c_4(PLR)^3 \quad (20.112)$$

$$ElecEff_{Operating} = ElecEff_{Ref,LHV}(ElecEfficiencyFTemp)(ElecEfficiencyFPLR) \quad (20.113)$$

where:

$ElecEfficiencyFTemp$ is the user-defined Electrical Efficiency Modifier Curve (function of temperature) evaluated at the current combustion air inlet temperature

$ElecEfficiencyFPLR$ is the user-defined Electrical Efficiency Modifier Curve (function of part-load ratio) evaluated at the current operating part-load ratio

$ElecEff_{Operating}$ is the electrical efficiency at the current operating conditions

$ElecEff_{Ref,LHV}$ is the reference electrical efficiency (LHV [lower heating value] Basis), user input.

The fuel energy consumption rate (LHV Basis) is then calculated as follows:

$$\dot{Q}_{Fuel,LHV} = \frac{P_{Elec,Operating}}{ElecEff_{Operating}} \quad (20.114)$$

where $\dot{Q}_{Fuel,LHV}$ is the fuel energy consumption rate, LHV basis (W).

If $ElecEff_{Operating}$ is equal to zero, then $P_{Operating}$ and $\dot{Q}_{Fuel,LHV}$ are set to zero. The fuel mass flow rate is then calculated:

$$\dot{m}_{fuel} = \frac{\dot{Q}_{Fuel,LHV}}{LHV * 1000} \quad (20.115)$$

where:

\dot{m}_{fuel} is the mass flow rate of fuel being consumed by the generator (kg/s), report variable “Generator <FuelType> Mass Flow Rate [kg/s]”

LHV = Fuel Lower Heating Value, user input (kJ/kg).

The ancillary power is calculated next using the user-specified ancillary power and ancillary power modifier curve. The ancillary power modifier curve is a quadratic function with the generator’s fuel mass flow rate as the independent variable. If an ancillary power modifier curve is not specified in the input file, the modifier is assumed to be 1.0 and the ancillary power will be constant throughout the simulation.

$$AnciPowFMdotFuel = d_1 + d_2 (\dot{m}_{fuel}) + d_3 (\dot{m}_{fuel})^2 \quad (20.116)$$

$$P_{Ancillary,Operating} = P_{Ancillary} (AnciPowFMdotFuel) \quad (20.117)$$

where:

$AnciPowFMdotFuel$ is the user-defined Ancillary Power Modifier Curve (function of fuel input) evaluated at the actual fuel mass flow rate. This multiplier is assumed to be 1.0 if an ancillary power modifier curve name is not specified in the input.

$P_{Ancillary}$ is the ancillary power, user input (W)

$P_{Ancillary,Operating}$ is the ancillary electric power at the current fuel mass flow rate (W), report variable “Generator Ancillary Electric Power [W]”.

If ancillary power is constant for the simulation (e.g., no modifier curve defined), then the calculations continue as described below. However, if an ancillary power modifier curve has been defined, then the calculations described above for $P_{ElecOperating}$, $ElecEff_{Operating}$, $\dot{Q}_{Fuel,LHV}$ and $P_{Ancillary,Operating}$ are recalculated in sequence until the solution converges.

The generator’s “net” electrical power output is calculated as the difference between the generator’s actual power output and the ancillary electric power as follows.

$$P_{Elec,Produced} = P_{Elec,Operating} - P_{Ancillary,Operating} \quad (20.118)$$

where:

$P_{Elec,Produced}$ is the generator net electric power output (W), report variable “Generator Produced Electric Power [W]”

The fuel energy consumption rate (higher heating value basis) for the generator is then calculated as follows:

$$\dot{Q}_{Fuel,HHV} = \dot{m}_{fuel} (HHV) (1000) \quad (20.119)$$

where:

$\dot{Q}_{Fuel,HHV}$ is the fuel energy consumption rate (W), report variables “Generator <FuelType> HHV Basis Rate [W]” and “Generator Fuel HHV Basis Rate [W]”

HHV is the fuel Higher Heating Value, user input (kJ/kg).

Standby electrical power may also be modeled to simulate controls or other parasitics used by the generator. The standby power is calculated only when the generator is not operating (i.e., $Load$ from the Electric Load Center is zero). If the generator operates for a given timestep (i.e., $Load > 0.0$), the standby power is set equal to 0.

$$P_{Standby} = \begin{cases} P_{Standby,User\ Input} & \text{if } Load \leq 0 \\ 0 & \text{otherwise} \end{cases} \quad (20.120)$$

where:

$P_{Standby,User\ Input}$ is the standby power, user input (W)

$P_{Standby}$ is the report variable “Generator Standby Electric Power” (W).

Report variables for electric energy produced, electric efficiency (LHV basis), fuel consumption (HHV basis), standby electric consumption and ancillary electric consumption are calculated as follows:

$$E_{Elec,Produced} = P_{Elec,Produced} (TimeStepSys) (3600) \quad (20.121)$$

$$ElecEff_{Operating,LHV} = \frac{P_{Elec,Produced}}{\dot{Q}_{Fuel,LHV}} \quad (20.122)$$

$$Q_{Fuel,HHV} = \dot{Q}_{Fuel,HHV} (TimeStepSys) (3600) \quad (20.123)$$

$$E_{Standby} = P_{Standby} (TimeStepSys) (3600) \quad (20.124)$$

$$E_{Ancillary} = P_{Ancillary,Operating} (TimeStepSys) (3600) \quad (20.125)$$

where:

$E_{Elec,Produced}$ is the report variable “Generator Produced Electric Energy” (J)

$ElecEff_{Operating,LHV}$ is the report variable “Generator LHV Basis Electric Efficiency”

$Q_{Fuel,HHV}$ can be represented as either report variable “Generator <FuelType> HHV Basis Energy” or “Generator Fuel HHV Basis Energy” (J)

$E_{Standby}$ is the report variable “Generator Standby Electric Energy” (J)

$E_{Ancillary}$ is the report variable “Generator Ancillary Electric Energy” (J)

$TimeStepSys$ is the HVAC system simulation time step (hr).

In addition to calculating electric power production and fuel usage, the model is able to determine thermal power (heat recovery) output for heating water. For this case, the water flow rate through the heat recovery heat exchanger is established first. If the Heat Recovery Water Flow Operating Mode (user input) is set to Plant Control, then the Reference Heat Recovery Water Flow Rate (user input) is requested whenever the generator operates (constant value), but the actual flow rate may

be restricted by other plant components (e.g., pump). If the Heat Recovery Water Flow Operating Mode is set to Internal Control, then the requested water flow when the generator operates is determined by the Reference Heat Recovery Water Flow Rate and a flow rate modifier curve.

If *PlantControl*:

$$\dot{m}_w = \dot{V}_{w,ref} \rho_w \quad (20.126)$$

If *InternalControl*:

$$\text{HeatRecFlowFTempPow} = e_1 + e_2 T_{w,i} + e_3 T_{w,i}^2 + e_4 P_{net} + e_5 P_{net}^2 + e_6 T_{w,i} P_{net} \quad (20.127)$$

$$\dot{m}_w = \dot{V}_{w,Ref} \rho_w (\text{HeatRecFlowFTempPow}) \quad (20.128)$$

where:

\dot{m}_w is the report variable “Generator Heat Recovery Water Mass Flow Rate” (kg/s)

$\dot{V}_{w,Ref}$ is the reference heat recovery water flow rate, user input (m³/s)

ρ_w is the density of water (kg/m³) at 5.05°C

HeatRecFlowFTempPow is the user-defined Heat Recovery Water Flow Rate Modifier Curve (function of temperature and power) evaluated at the current inlet water temperature and net electrical power output. This multiplier is assumed to be 1.0 if a water flow rate modifier curve name is not specified in the input.

$T_{w,i}$ is the heat recovery inlet water temperature (°C), report variable “Generator Heat Recovery Inlet Temperature [C]”

P_{net} is the net electrical power output from the generator (W).

The methodology for determining thermal power (heat recovery to water) is similar to that used for calculating electric power production. The generator’s steady-state thermal efficiency is calculated based on the user-specified reference thermal efficiency (LHV basis) and a thermal efficiency modifier curve.

$$\text{ThermalEff}_{SS} = \text{ThermalEff}_{Ref,LHV} (\text{ThermalEffFTempElev}) \quad (20.129)$$

$$\text{ThermalEffFTempElev} = f_1 + f_2 (T_{a,i}) + f_3 (T_{a,i})^2 + f_4 (Elev) + f_5 (Elev)^2 + f_6 (T_{a,i}) (Elev) \quad (20.130)$$

where:

ThermalEff_{SS} is the steady-state thermal efficiency at current conditions

$\text{ThermalEff}_{Ref,LHV}$ is the reference thermal efficiency (LHV Basis), user input

ThermalEffFTempElev is the user-defined Thermal Efficiency Modifier Curve (function of temperature and elevation) evaluated at the current combustion air inlet temperature and elevation. This multiplier is assumed to be 1.0 if a thermal efficiency modifier curve name is not specified in the input.

The steady-state thermal power produced (heat recovery rate) is then calculated:

$$P_{Thermal,SS} = \text{ThermalEff}_{SS} (\dot{Q}_{Fuel,LHV}) \quad (20.131)$$

The actual (operating) thermal power is then calculated using the steady-state thermal power and three modifier curves:

$$P_{Thermal,Operating} = P_{Thermal,SS} (HeatRecRateFPLR) (HeatRecRateFTemp) (HeatRecRateFFlow) \quad (20.132)$$

$$HeatRecRateFPLR = \begin{cases} = g_1 + g_2 (PLR) + g_3 (PLR)^2 \\ or \\ = g_1 + g_2 (PLR) + g_3 (PLR)^2 + g_4 (PLR)^3 \end{cases} \quad (20.133)$$

$$HeatRecRateFTemp = h_1 + h_2 (T_{w,i}) + h_3 (T_{w,i})^2 \quad (20.134)$$

$$HeatRecRateFFlow = i_1 + i_2 (\dot{m}_w) + i_3 (\dot{m}_w)^2 \quad (20.135)$$

where:

$P_{Thermal,Operating}$ is the report variable “Generator Produced Thermal Rate” (W)

$HeatRecRateFPLR$ is the user-defined Heat Recovery Rate Modifier Curve (function of part-load ratio) evaluated at the current operating part-load ratio. This multiplier is assumed to be 1.0 if a modifier curve name is not specified in the input.

$HeatRecRateFTemp$ is the user-defined Heat Recovery Rate Modifier Curve (function of inlet water temperature) evaluated at the current inlet water temperature. This multiplier is assumed to be 1.0 if a modifier curve name is not specified in the input.

$HeatRecRateFFlow$ is the user-defined Heat Recovery Rate Modifier Curve (function of water flow rate) evaluated at the current heat recovery water flow rate. This multiplier is assumed to be 1.0 if a modifier curve name is not specified in the input.

The heat recovery output water temperature is then calculated.

$$T_{w,o} = T_{w,i} + \frac{P_{Thermal,Operating}}{\dot{m}_w C p_w} \quad (20.136)$$

where:

$T_{w,o}$ is the heat recovery outlet water temperature (°C), report variable “Generator Heat Recovery Outlet Temperature [C]”

$C p_w$ is the heat capacity of water (J/kg-K).

If the calculated heat recovery outlet water temperature exceeds to Maximum Heat Recovery Water Temperature (user input), then the outlet water temperature is reset to the maximum temperature (user input) and the thermal power is recalculated.

If combustion air inlet and outlet node names are specified in the input, along with exhaust air flow rate and exhaust air temperature information, then the model calculates the exhaust air conditions for each simulation time step. The exhaust air mass flow rate is first calculated based on the Reference Exhaust Air Mass Flow Rate, two modifier curves and an air density adjustment. Since fans are volumetric flow devices, the ratio of the air density at actual inlet air conditions to air density at reference inlet air conditions is used as an adjustment factor.

$$\dot{m}_{ExhAir} = \dot{m}_{ExhAir,ref} (ExhFlowFTemp) (ExhFlowFPLR) \frac{\rho_{a,i}}{\rho_{a,ref}} \quad (20.137)$$

$$ExhFlowFTemp = \begin{cases} = j_1 + j_2 T_{a,i} + j_3 T_{a,i}^2 \\ or \\ = j_1 + j_2 T_{a,i} + j_3 T_{a,i}^2 + j_4 T_{a,i}^3 \end{cases} \quad (20.138)$$

$$ExhFlowFPLR = \begin{cases} = k_1 + k_2 T_{PLR} + k_3 T_{PLR}^2 \\ or \\ = k_1 + k_2 T_{PLR} + k_3 T_{PLR}^2 + k_4 T_{PLR}^3 \end{cases} \quad (20.139)$$

where:

\dot{m}_{ExhAir} is the exhaust air mass flow rate (kg/s)

$\dot{m}_{ExhAir,Ref}$ is the reference Exhaust Air Mass Flow Rate, user input (kg/s)

$ExhFlowFTemp$ is the user-defined Exhaust Air Flow Rate Modifier Curve (function of temperature) evaluated at the current combustion air inlet temperature. This multiplier is assumed to be 1.0 if a modifier curve name is not specified in the input.

$ExhFlowFPLR$ is the user-defined Exhaust Air Flow Rate Rate Modifier Curve (function of part-load ratio) evaluated at the current operating part-load ratio. This multiplier is assumed to be 1.0 if a modifier curve name is not specified in the input.

$\rho_{a,i}$ is the density of the combustion inlet air (kg/m³)

$\rho_{a,Ref}$ is the density of combustion inlet air at reference conditions (kg/m³).

In an analogous fashion, the exhaust air temperature is calculated using the Nominal (reference) Exhaust Air Outlet Temperature and two modifier curves.

$$T_{a,o} = T_{a,o,Nom} (ExhAirTempFTemp) (ExhAirTempFPLR) \quad (20.140)$$

$$ExhAirTempFTemp = \begin{cases} = l_1 + l_2 T_{a,i} + l_3 T_{a,i}^2 \\ or \\ = l_1 + l_2 T_{a,i} + l_3 T_{a,i}^2 + l_4 T_{a,i}^3 \end{cases} \quad (20.141)$$

$$ExhAirTempFPLR = \begin{cases} = m_1 + m_2 T_{PLR} + m_3 T_{PLR}^2 \\ or \\ = m_1 + m_2 T_{PLR} + m_3 T_{PLR}^2 + m_4 T_{PLR}^3 \end{cases} \quad (20.142)$$

where:

$T_{a,o}$ is the exhaust air outlet temperature (°C)

$T_{a,o,Nom}$ is the nominal exhaust air outlet temperature, user input (°C)

$ExhAirTempFTemp$ is the user-defined Exhaust Air Temperature Modifier Curve (function of temperature) evaluated at the current combustion air inlet temperature. This multiplier is assumed to be 1.0 if a modifier curve name is not specified in the input.

$ExhAirTempFPLR$ is the user-defined Exhaust Air Flow Rate Rate Modifier Curve (function of part-load ratio) evaluated at the current operating part-load ratio. This multiplier is assumed to be 1.0 if a modifier curve name is not specified in the input.

The above calculations for exhaust air outlet temperature assume no heat recovery to water is being done. If thermal power (water heating) is being produced, then the exhaust air outlet temperature is recalculated as follows:

$$T_{a,o} = T_{a,i} - \frac{P_{Thermal,Operating}}{\dot{m}_{ExhAir} C_{p,air}} \quad (20.143)$$

where $C_{p,air}$ = Heat capacity of air at the actual combustion air inlet conditions (J/kg-K).

The exhaust air outlet humidity ratio is also calculated.

$$w_{a,o} = w_{a,i} + \frac{\dot{m}_{fuel} (HHV - LHV) (1000)}{h_{fg,16} \dot{m}_{ExhAir}} \quad (20.144)$$

where:

$w_{a,o}$ is the exhaust air outlet humidity ratio (kg/kg)

$w_{a,i}$ is the exhaust air inlet humidity ratio (kg/kg)

$h_{fg,16}$ is the enthalpy of vaporization of moisture at 16°C (J/kg)

The remaining report variables are calculated as follows.

$$E_{Thermal,Produced} = P_{Thermal,Operating} (TimeStepSys) (3600) \quad (20.145)$$

$$ThermalEff_{Operating,LHV} = \frac{P_{Thermal,Operating}}{\dot{Q}_{Fuel,LHV}} \quad (20.146)$$

where:

$E_{Thermal,Produced}$ is the report variable “Generator Produced Thermal Energy” (J)

$ThermalEff_{Operating,LHV}$ is the report variable “Generator Thermal Efficiency LHV Basis”.

20.4.4 Micro-Cogenerator

The input object Generator:MicroCHP provides a model that is a direct implementation of a model developed by IEA Annex 42 – The Simulation of Building-Integrated Fuel Cell and Other Cogeneration Systems (FC+COGEN-SIM). Annex 42 was formed as a working group within the International Energy Agency (IEA) program on Energy Conservation in Buildings and Community Systems (ECBCS). A full description of the model specification can be found in the report by Subtask B of FC+COGEN-SIM with the title “Specifications for Modelling Fuel Cell and Combustion-Based Residential Cogeneration Device within Whole-Building Simulation Programs.” The “Micro CHP” model in EnergyPlus is the one referred to as “A Generic Model for Combustion-based Residential Cogeneration Devices.”

The Micro CHP model is a straightforward empirical model with the exception that it is dynamic with respect to thermal heat recovery where performance is cast as a function of engine temperature. It is also dynamic with respect to possible warm up and cool down periods that may affect the ability of the generator to deliver the requested power. The relevant model equations are:

$$\eta_e = f(\dot{m}_{cw}, T_{cw,i}, P_{net,ss}) \quad (20.147)$$

$$\eta_q = f(\dot{m}_{cw}, T_{cw,i}, P_{net,ss}) \quad (20.148)$$

$$q_{gross} = P_{net,ss} / \eta_e \quad (20.149)$$

$$q_{gen,ss} = \eta_q q_{gross} \quad (20.150)$$

$$\dot{N}_{fuel} = q_{gross} / LHV_{fuel} \quad (20.151)$$

$$\dot{m}_{fuel}^{t+\Delta t} = \begin{cases} \dot{m}_{fuel,demand}^{t+\Delta t} & \text{if } d\dot{m}_{fuel}/dt \leq (d\dot{m}_{fuel}/dt)_{max} \\ \dot{m}_{fuel,demand}^t \pm (d\dot{m}_{fuel}/dt)_{max} & \text{if } d\dot{m}_{fuel}/dt > (d\dot{m}_{fuel}/dt)_{max} \end{cases} \quad (20.152)$$

$$\dot{m}_{air} = f(P_{net,ss}) \quad (20.153)$$

$$P_{net}^{t+\Delta t} = \begin{cases} P_{net,ss}^{t+\Delta t} & \text{if } dP_{net}/dt \leq (dP_{net}/dt)_{max} \\ P_{net,ss}^t \pm (dP_{net}/dt)_{max} & \text{if } dP_{net}/dt > (dP_{net}/dt)_{max} \end{cases} \quad (20.154)$$

$$[MC]_{eng} \frac{dT_{eng}}{dt} = UA_{HX} (T_{cw,p} - T_{eng}) + UA_{loss} (T_{room} - T_{eng}) + q_{gen,ss} \quad (20.155)$$

$$[MC]_{cw} \frac{dT_{cw,o}}{dt} = [\dot{m}c_p]_{cw} (T_{cw,i} - T_{cw,o}) + UA_{HX} (T_{eng} - T_{cw,o}) \quad (20.156)$$

where:

η_e is the steady-state, part load, electrical conversion efficiency of the engine

η_q is the steady-state part load, thermal conversion efficiency of the engine

\dot{m}_{cw} is the mass flow rate of plant fluid through the heat recovery section (kg/s)

$T_{cw,i}$ is the bulk temperature of the plant fluid entering the heat recovery section (°C)

$T_{cw,o}$ is the bulk temperature of the plant fluid leaving the heat recovery section (°C)

$P_{net,ss}$ is the steady-state electrical output of the system (W)

q_{gross} is the gross heat input into the engine (W)

$q_{gen,ss}$ is the steady-state rate of heat generation within the engine (W)

LHV_{fuel} is the lower heating value of the fuel used by the system (J/kg or J/kmol)

\dot{N}_{fuel} is the molar fuel flow rate (kmol/s)

\dot{m}_{fuel} is the mass fuel flow rate (kg/s)

\dot{m}_{air} is the mass flow rate of air thru the engine (kg/s)

$[MC]_{eng}$ is the thermal capacitance of the engine control volume (W/K)

T_{eng} is the temperature of the engine control volume (°C)

UA_{HX} is the effective thermal conductance between the engine control volume and the cooling water control volume (W/K)

UA_{loss} is the effective thermal conductance between the engine control volume and the surrounding environment (W/K)

T_{room} is the air temperature of the surrounding environment (°C)

$[MC]_{cw}$ is the thermal capacitance of the encapsulated cooling water and heat exchanger shell in immediate thermal contact (J/K)

$[\dot{m}c_p]_{cw}$ is the thermal capacity flow rate associated with the cooling water (W/K).

The functional forms for η_e and η_q are 2nd order trivariate polynomials with all of the cross terms.

EnergyPlus solves these for state values for the engine mass temperature, T_{eng} , and the outlet plant node, $T_{cw,o}$, in the following manner. The last two equations are interrelated but otherwise ordinary differential equations with the general form:

$$\frac{dT}{dt} = a + bT \quad (20.157)$$

and have analytical solution:

$$T = (T_o + a/b) e^{bt} - a/b \quad (20.158)$$

The engine temperature at the current timestep is calculated using:

$$a = \frac{UA_{HX}}{[MC]_{eng}} * T_{cw,o} + \frac{UA_{loss}}{[MC]_{eng}} * T_{room} + \frac{q_{gen,ss}}{[MC]_{eng}} \quad (20.159)$$

$$b = - \left(\frac{UA_{HX}}{[MC]_{eng}} + \frac{UA_{loss}}{[MC]_{eng}} \right) \quad (20.160)$$

The plant node outlet fluid temperature (heat recovered) is solved using:

$$a = \frac{[\dot{m}c_p]_{cw}}{[MC]_{cw}} * T_{cw,i} + \frac{UA_{HX}}{[MC]_{cw}} * T_{eng} \quad (20.161)$$

$$b = - \left(\frac{[\dot{m}c_p]_{cw}}{[MC]_{cw}} + \frac{UA_{HX}}{[MC]_{cw}} \right) \quad (20.162)$$

The interrelation of these two is handled by sequential substitution using an iteration scheme that alternates between calculations of T_{eng} and $T_{cw,o}$. The iteration loop exits once the number of iterations exceeds 3 and the energy is determined to be balanced using the following criteria:

$$\frac{(q_{gen,ss})_{\max}}{10000000} > UA_{HX} (T_{cw,o} - T_{eng}) + UA_{loss} (T_{room} - T_{eng}) + q_{gen,ss} - [MC]_{eng} \frac{dT_{eng}}{dt} \quad (20.163)$$

$$\frac{(q_{gen,ss})_{\max}}{10000000} > [\dot{m}c_p]_{cw} (T_{cw,i} - T_{cw,o}) + UA_{HX} (T_{eng} - T_{cw,o}) - [MC]_{cw} \frac{dT_{cw,o}}{dt} \quad (20.164)$$

The Micro CHP model has a number of different operating modes. The operating mode for a given system timestep is determined from the mode during the previous timestep, user inputs, and high-level controls from elsewhere in EnergyPlus. The operating mode is reported for the state at the end of each timestep. The following table summarizes the various operating modes and the criteria for switching to a new mode for any given timestep. The EnergyPlus implementation adds the “Off” mode to the modes specified by Annex 42 which corresponds to the unit being scheduled to be unavailable. The difference between OFF and Standby modes determines whether or not standby power is consumed.

Operating mode	Main Criteria	Notes
Off	Availability schedule value = 0	No consumption of power or fuel.
Stand By	Availability schedule value \neq 0	Consumes stand by power but no fuel

Operating mode	Main Criteria	Notes
Warm Up	Load (thermal or electric) > 0.0 Availability schedule value $\neq 0$ Time Delay $<$ elapsed time since entering warm up mode Engine temp $<$ nominal engine temp	Two alternate sub-modes: Stirling Engines use warm up by “nominal engine temperature” while Internal Combustion Engines use “time delay” Fuel is consumed but no power is produced
Normal Operation	Load (thermal or electric) > 0.0 Availability schedule value $\neq 0$ Time Delay $>$ elapsed time since entering warm up mode Engine temp $> =$ nominal temp	Fuel is consumed and power is produced
Cool Down	Load (thermal or electric) $= 0.0$ Availability schedule value $\neq 0$	Two alternate sub-modes where engine can be forced to go thru a complete cool down cycle before allowed to go back into warm up or normal mode. No fuel is consumed and no power is produced.

For timesteps where the generator switches from warm up mode to normal mode in the middle of the timestep, part load ration values are calculated for the portion of the time step that the generator is in normal operation.

The engine and heat recovery thermal conditions are modeled for all modes so, for example, an engine that is off but still warm could provide some hot water recovery.

The engine model can use an arbitray fuel mixture that is defined by the user – see the entry for Generator:FuelSupply.

20.4.5 Fuel Cell Cogenerator

The Generator:FuelCell input objects provides a model which is a direct implementation of a model developed by IEA Annex 42 – The Simulation of Building-Integrated Fuel Cell and Other Cogeneration Systems (FC+COGEN-SIM). Annex 42 was formed as a working group within the International Energy Agency (IEA) program on Energy Conservation in Buildings and Community Systems (ECBCS). A full description of the model specification can be found in the report by Subtask B of FC+COGEN-SIM with the title “Specifications for Modelling Fuel Cell and Combustion-Based Residential Cogeneration Device within Whole-Building Simulation Programs.” The “Specifications for Modelling Fuel Cell Cogeneration Devices within Whole-Building Simulation Programs.”

The Annex 42 Fuel Cell model is characterized as a “grey box” empirical model where a mixture of thermodynamic principles and empirical performance maps are used to model the cogeneration performance of a fairly complex device with many individual subsystems. In EnergyPlus, the individual subsystems are separate into individual input objects such as Generator:FuelCell:PowerModule or Generator:FuelCell:ExhaustGasToWaterHeatExchanger. The resulting model is relatively complex requiring on the order of one hundred inputs. The model is not for the faint of heart; this model is far more involved than most component models in building simulation. This stems from the fact that fuel cell cogenerators are complicated devices that interact with the built environment in a number of ways. Fuel cells could drawn in gas/fuel, air, and water with as many as six separate streams. In addition to electricity and heated water, they also give off heat in the form of convection and radiation and exhaust air out of the zone. The devices may take a long time to start up and include storage to follow loads rather than attempt to vary the power the fuel cell. The fuel cell model allows examining system level interactions over annual timeframes that include all the important interactions with a building’s energy and comfort systems.

The Annex 42 fuel cell model is described more thoroughly in the references (see below). Here we provide a summary of the relevant model equations which are taken from the Annex 42 model specification. The first equation is the main energy balance for the fuel cell power module (includes the fuel reformation and fuel cell stacks). This energy balance is used to model the enthalpy of the product gases that leave the fuel cell power module.

$$\begin{aligned}
 & \sum_i \left(\dot{N}_i \cdot [\hat{h}_i - \Delta_f \hat{h}_i^o] \right)_{fuel} + \sum_i \left(\dot{N}_i \cdot [\hat{h}_i - \Delta_f \hat{h}_i^o] \right)_{air} + \dot{N}_{liq-water} \cdot \left([\hat{h} - \Delta_f \hat{h}^o]_{H_2O,liq} - \Delta_f \hat{h}_{H_2O,fg}^o \right) \\
 & + \dot{H}_{dilution-air-in} + \dot{N}_{fuel} \cdot LHV_{fuel} + P_{el,ancillaries-AC} \\
 & = P_{el} + \sum_i \left(\dot{N}_i \cdot [\hat{h}_i - \Delta_f \hat{h}_i^o] \right)_{FCPM-cg} + q_{s-cool} + q_{skin-loss} + \dot{H}_{dilution-air-out}
 \end{aligned} \tag{20.165}$$

The remaining equations describe various terms and the balance of systems. The electrical efficiency is modeled using:

$$\varepsilon_{el} = [\varepsilon_0 + \varepsilon_1 \cdot P_{el} + \varepsilon_2 \cdot P_{el}^2] \cdot [1 - N_{stops} \cdot D] \cdot \left[1 - (MAX(\int dt - t_{threshold}, 0.0)) \cdot L \right] \tag{20.166}$$

$$P_{blower-el} = b_0 + b_1 \cdot \dot{N}_{air} + b_2 \cdot \dot{N}_{air}^2 + b_3 \cdot \dot{N}_{air}^3 \tag{20.167}$$

In several places the model is formulated to offer different options. For example, the flow rate of process air can be described either as a function of electrical power produced or the fuel flow rate.

$$\dot{N}_{air} = [a_0 + a_1 \cdot P_{el} + a_2 \cdot P_{el}^2] \cdot [1 + a_3 \cdot T_{air}] \tag{20.168}$$

or

$$\dot{N}_{air} = [a_0 + a_1 \cdot \dot{N}_{fuel} + a_2 \cdot \dot{N}_{fuel}^2] \cdot [1 + a_3 \cdot T_{air}] \tag{20.169}$$

$$\dot{N}_{liq-water} = w_0 + w_1 \cdot \dot{N}_{fuel} + w_2 \cdot \dot{N}_{fuel}^2 \tag{20.170}$$

$$P_{pump-el} = p_0 + p_1 \cdot \dot{N}_{water} + p_2 \cdot \dot{N}_{water}^2 + p_3 \cdot \dot{N}_{water}^3 \quad (20.171)$$

$$P_{comp-el} = c_0 + c_1 \cdot \dot{N}_{fuel} + c_2 \cdot \dot{N}_{fuel}^2 + c_3 \cdot \dot{N}_{fuel}^3 \quad (20.172)$$

$$P_{el,ancillaries-AC} = anc_0 + anc_1 \cdot \dot{N}_{fuel} \quad (20.173)$$

$$P_{el,aux-ancillaries} = x_0 + x_1 \cdot \dot{N}_{aux-fuel} \quad (20.174)$$

$$q_{HX} = \varepsilon_{HX} \cdot \left(\dot{N} \hat{c}_p \right)_{\min} \cdot (T_{aux-mix} - T_{water,in}) \quad (20.175)$$

$$q_{HX} = (UA)_{eff} \cdot \frac{(T_{aux-mix} - T_{water,out}) - (T_{HX-exh} - T_{water,in})}{\ln \left(\frac{T_{aux-mix} - T_{water,out}}{T_{HX-exh} - T_{water,in}} \right)} \quad (20.176)$$

$$(UA)_{eff} = hx_{s,0} + hx_{s,1} \cdot \dot{N}_{water} + hx_{s,2} \cdot \dot{N}_{water}^2 + hx_{s,3} \cdot \dot{N}_{aux-mix} + hx_{s,4} \cdot \dot{N}_{aux-mix}^2 \quad (20.177)$$

or

$$(UA)_{eff} = \left[\frac{1}{(hA)_{gas}} + \frac{1}{(hA)_{water}} + F_{HX} \right]^{-1} \quad (20.178)$$

where F_{HX} is an adjustment factor and:

$$h_{gas} = h_{gas}^0 \left(\frac{\dot{N}_{gas}}{\dot{N}_{gas}^0} \right)^n \quad (20.179)$$

$$h_{water} = h_{water}^0 \cdot \left(\frac{\dot{N}_{water}}{\dot{N}_{water}^0} \right)^m \quad (20.180)$$

$$q_{HX} = (UA)_{eff} \cdot \frac{(T_{aux-mix} - T_{water,out}) - (T_{HX-exh} - T_{water,in})}{\ln \left(\frac{T_{aux-mix} - T_{water,out}}{T_{HX-exh} - T_{water,in}} \right)} + \dot{N}_{H_2O-cond} \cdot \hat{h}_{fg} \quad (20.181)$$

$$\dot{N}_{H_2O-cond} = (T_{cond-threshold} - T_{water,in}) \cdot \left[hx_{l,1} \cdot \left(\frac{\dot{N}_{H_2O}}{\dot{N}_{aux-mix}} \right) + hx_{l,2} \cdot \left(\frac{\dot{N}_{H_2O}}{\dot{N}_{aux-mix}} \right)^2 \right] \quad (20.182)$$

$$q_{aux-skin-losses} = (UA)_{aux} \cdot (T_{aux-mix} - T_{room}) \quad (20.183)$$

$$q_{skin-loss} = s_0 + s_1 \cdot \dot{N}_{fuel} + s_2 \cdot \dot{N}_{fuel}^2 \quad (20.184)$$

$$Q_{battery}^{t+\Delta t} = Q_{battery}^t + P_{battery-charge} \cdot \varepsilon_{charge} \cdot \Delta t \quad (20.185)$$

$$\eta_{PCU} = u_0 + u_1 \cdot P_{PCU-in} + u_2 \cdot P_{PCU-in}^2 \quad (20.186)$$

$$q_{s-cool} = [r_0 + r_1 (T_{stack} - T_{stack}^o)] \cdot [1 + r_2 P_{el} + r_3 P_{el}^2] \quad (20.187)$$

$$(UA)_{s-cogen} = \left[\frac{1}{(hA)_{s-cogen}} + F_{s-cogen} \right]^{-1} \quad (20.188)$$

$$h_{s-cogen} = h_{s-cogen}^0 \cdot \left(\frac{\dot{N}_{s-cogen}}{\dot{N}_{s-cogen}^0} \right)^{n_s} \quad (20.189)$$

$$P_{s-air-el} = f_0 + f_1 \cdot q_{s-air} + f_2 \cdot q_{s-air}^2 \quad (20.190)$$

The Annex 42 fuel cell was implemented directly in EnergyPlus. A sequential substitution method is used to handle all the interactions between the different subsystems. The main energy balance drawn for the fuel cell power module is rearranged to put all the terms on the right hand side. The enthalpy of the product gas stream is determined from this energy balance. The Shomate equation is used to evaluate the enthalpy and specific heat of the various streams. The EnergyPlus implementation evaluates fluid properties using the average temperature of inlet and outlet streams whereas the Annex 42 specification often uses just the inlet temperature. The Shomate equation is inverted using the root solver numerical method available within EnergyPlus to calculate the temperature of the product gases from their enthalpy.

20.4.6 Custom Fuel Supply for Generators

The Generator:FuelSupply input object in EnergyPlus implements a fairly comprehensive capability to calculate properties of fuel mixtures from a description of the molar composition of all the constituents. The fuel supply modeling is based on the specifications prepared by IEA Annex 42 for their generator models. This modeling capability allows taking into consideration the exact gas composition of local natural gas service. Or the user can explore the implications of an various alternative fuels such as alcohols or biogas. An unlimited number of possible mixtures can be analyzed.

Gas phase thermochemistry calculations and data are programmed into EnergyPlus to handle the set of constituents listed in the table below. The relevant properties of each fuel constituent, i , are calculated as a function of temperature using the Shomate equation:

$$\hat{h}_i - \Delta_f \hat{h}_i^o = A \cdot \left(\frac{T}{1000} \right) + \frac{B}{2} \cdot \left(\frac{T}{1000} \right)^2 + \frac{C}{3} \cdot \left(\frac{T}{1000} \right)^3 + \frac{D}{4} \cdot \left(\frac{T}{1000} \right)^4 - \frac{E}{\left(\frac{T}{1000} \right)} + F - H \quad (20.191)$$

where:

\hat{h}_i is the enthalpy (J/kmol)

$\Delta_f \hat{h}_i^o$ is the molar enthalpy at the standard state (J/kmol)

T is the temperature of the gas (K)

A, B, C, D, E, F, H are the coefficients for the Shomate equation.

The lower heating value (LHV) of a fuel mixture is calculated from the molar fractions using:

$$LHV_{fuel} = \sum_i (\chi_i \cdot LHV_i) \quad (20.192)$$

where:

$$LHV_i = \left[\Delta_f \hat{h}_{C_x H_y}^o - x \cdot \Delta_f \hat{h}_{CO_2}^o - \frac{y}{2} \cdot \Delta_f \hat{h}_{H_2O}^o \right] \quad (20.193)$$

x is the number of carbon atoms

y is the number of hydrogen atoms.

Similarly, the higher heating value (HHV) of the fuel mixture is calculated using:

$$HHV_{fuel} = \sum_i (\chi_i \cdot HHV_i) \quad (20.194)$$

where:

$$HHV_i = \left[\Delta_f \hat{h}_{C_x H_y}^o - x \cdot \Delta_f \hat{h}_{CO_2}^o - \frac{y}{2} \cdot \Delta_f \hat{h}_{H_2O}^o + \frac{y}{2} \cdot \left(\Delta_f \hat{h}_{H_2O}^o - H_{liq} \right) \right] \quad (20.195)$$

The Shomate coefficients used in EnergyPlus are listed in Table 20.5. Data source “NIST” indicates the data were directly from Chemistry WebBook. Data source “CHEMKIN” indicates the data were developed by curve fitting library data for the CHEMKIN commercial program (which uses the Gorden-McBride polynomial rather than the Shomate formulation).

20.4.7 Wind Turbine

20.4.7.1 Overview

The wind turbine (object Generator:WindTurbine) model is intended to estimate the production of electric power of both horizontal and vertical axis wind turbine systems. Due to the cubic relationship between the wind speed and the power produced by a wind turbine, the performance of these systems is highly dependent on local wind conditions. However, differences between typical meteorological year (TMY) wind data attached to the simulation and local wind data at the site where wind turbine system is installed typically appear. The model thus estimates the air density and wind speed at the particular height of the system and factors differences between the wind speed from the TMY weather data and the local wind speed. The weather data file should thus be included in the simulation. The model also requires inputs of both an annual average wind speed that represents accurate wind profile at the location and the height where this annual average wind speed was determined.

The model calculates the power production by both horizontal axis wind turbines (HAWT) and vertical axis wind turbines (VAWT) from generic mathematical equations. Currently, a variable speed control scheme is available in EnergyPlus. The model assumes constant power generation at the rated power and the rated wind speed when the ambient wind speed is between the rated wind speed and cut out wind speed. The model does not attempt to model various types of subsystems of the entire wind turbine system such as shafts, generators and inverters due to computational convergence, time, and usability. Instead, the total system efficiency includes both conversion losses occurring during the DC-AC-DC conversion processes and delivery losses.

20.4.7.2 Model Description

The wind turbine is modeled as a generation component that produces electricity and delivers it directly to buildings. Wind turbine components are executed at the beginning of each time step

called by the HVAC manager, and the electric load will be corrected with electricity from the wind turbine. The model calculates electricity production that both HAWTs and VAWTs produce from general mathematical equations. The model then passes the electricity to the electric load center in EnergyPlus at each HVAC system time step. The electric load center then determines the whole building electrical demand, deducting the power output by wind turbine along with any power production by photovoltaic components from the total electrical demand requested in the building. Excessive production of electricity greater than needed from wind turbine along with photovoltaic components is either sold or stored as the user specifies.

20.4.7.3 Input and Data

The user must input the required information according to the IO Reference Manual (ref: Generator:WindTurbine). The wind turbine model in EnergyPlus requires a unique identifying name and an availability schedule. The schedule name must refer to a valid schedule type (range 0-1) and contain values of fractional operation. Various inputs describes wind turbine configuration such as rotor type, control type, rotor diameter, overall height, and number of blades. Rated data provided in the manufacturer's literature determines overall electricity production by using generic equations. These inputs include rated power, rated wind speed, cut in wind speed, cut out wind speed, fraction system efficiency, and maximum tip speed ratio. Two inputs such as annual local average wind speed and height for local average wind speed define local wind conditions at a specific location so that the model predicts wind speed and air density at the height of the wind turbine at the location.

HAWT systems need a maximum power coefficient and empirical power coefficient parameters C_1 through C_6 . The maximum power coefficient controls overall performance of the rotor which defines the power extraction efficiency from the ambient air stream. The model predicts power generation more accurately when the user inputs the empirical power coefficients C_1 through C_6 for a specific wind turbine. Three additional inputs for VAWT system are required. The model requests blade lift and drag coefficients corresponding to the maximum tip speed ratio so that tangential and normal force coefficients are obtained. Blade chord area is also requested for calculating forces on a single blade.

20.4.7.4 Simulation and Control

Given the inputs needed, the wind turbine model analyzes local wind speed since wind speed is critical to determine the production of electricity of wind turbine systems. To minimize uncertainty involved with wind data, it factors differences between annual average wind speed from weather data and local annual average wind speed at the particular height of the local meteorological station. It reads annual average wind speed from statistical weather file that is automatically copied during the simulation. Note that the user should attach a weather data to the simulation (for a design day simulation, the wind speed data from the design day description is used). This annual average wind speed is converted into a wind speed at the height at which local annual average wind speed that the user inputs is measured and then factored as:

$$V_{LocalTMY} = V_{AnnualAvg} \left(\frac{\delta_{met}}{H_{met}} \right)^{a_{met}} \left(\frac{H}{\delta} \right)^a \quad (20.196)$$

$$F_V = \frac{V_{LocalTMY}}{V_{Local}} \quad (20.197)$$

Note that the wind speed factor F_v of 1.0 is assigned, if the user does not input the local wind conditions or the weather data file is not attached to the simulation.

The local air density can be obtained by using EnergyPlus psychrometric functions as follows:

$$T_{Local} = OutDryBulbTempAt(Z) \quad (20.198)$$

$$P_{Local} = OutBaroPressAt(Z) \quad (20.199)$$

$$\omega_{Local} = PsyWFnTdbTwbPb(T_{Local}, T_{wb}, P_{Local}) \quad (20.200)$$

$$\rho_{Local} = PsyRhoAirFnPbTdbW(P_{Local}, T_{Local}, \omega_{initial}) \quad (20.201)$$

The model converts TMY wind speed into a wind speed at the specific height of the wind turbine rotor (V_z) at the location by using EnergyPlus function as:

$$V_z = WindSpeedAt(Z) \quad (20.202)$$

The local wind speed at the rotor height (V_{Local}) at the location is thus:

$$V_{Local} = \frac{V_z}{F_v} \quad (20.203)$$

The tip speed ratio (TSR) can be obtained as:

$$\lambda = \frac{\omega R}{V_{Local}} \quad (20.204)$$

20.4.7.5 Horizontal Axis Wind Turbine

Once the local wind speed and air density are determined, the model calculates electrical power produced by a wind turbine system according to the rotor type. For HAWT systems, two different approximations are available. The model uses an analytical approximation when the user inputs all six empirical coefficient parameters C_1 through C_6 . The equations that define the analytical approximation are:

$$C_p = C_1 \left(\frac{C_2}{\lambda_i} - C_3 \theta - C_4 \theta^x - C_5 \right) e^{-\frac{C_6(\lambda, \theta)}{\lambda_i}} \quad (20.205)$$

$$\frac{1}{\lambda_i} = \frac{1}{\lambda + 0.08\theta} - \frac{0.035}{\theta^3 + 1} \quad (20.206)$$

Note that the model allows changing the rotor speed to meet the maximum tip speed ratio at each time step. That is, the tip speed ratio calculated is limited by the maximum tip speed ratio. Similarly, the power coefficient calculated is also set to the maximum if the calculated is greater than the maximum.

Assuming maximum of rotor angle, i.e. zero, the power production of the wind turbine is thus obtained by:

$$P_W = \frac{1}{2} \rho_{Local} A_R V_{Local}^3 C_p(\lambda, \theta) \quad (20.207)$$

The model assumes the simple approximation, if any of empirical power coefficient parameters is not input. The power production of wind turbine is directly obtained from the kinetic energy equation:

$$P_W = \frac{1}{2} \rho_{Local} A_R V_{Local}^3 C_{p,max}(\lambda, \theta) \quad (20.208)$$

Here, the model defines P_W as rated power output at the rated wind speed, if either the power production of wind turbine or local wind speed is greater than the rated power or rated wind speed, respectively. The power coefficient in this particular case is thus recalculated as:

$$C_p = \frac{P_W}{0.5 \rho_{Local} A V_{Local}^3} \quad (20.209)$$

The overall power production that includes conversion loss and delivery loss is thus:

$$P = \eta P_W \quad (20.210)$$

20.4.7.6 Vertical Axis Wind Turbine

Figure 20.9: Flow velocities and force diagram of a single blade airfoil (Adapted from Mazharul Islam et al., 2008)

If tip speed ratio at the time step is greater than the maximum tip speed ratio, the model estimates actual rotor speed at the time step as:

$$\omega R = \lambda V_{Local} \quad (20.211)$$

The model then employs general mathematical expressions for the aerodynamic analysis of straight-bladed Darrieus-type VAWTs to predict the power production by VAWTs. Assuming quasi-steady state, the induced wind speed (V_a) on the rotor is defined as:

$$V_a = \frac{2}{3}V_{Local} \quad (20.212)$$

The chordal velocity (V_c), normal velocity (V_n), and relative flow velocity (W) as shown in figure above can be expressed as:

$$V_c = \omega R + V_a \cos \theta \quad (20.213)$$

$$V_n = V_a \sin \theta \quad (20.214)$$

$$W = \sqrt{V_c^2 + V_n^2} \quad (20.215)$$

The expression for the non-dimensional angle of attack α with no consideration of blade pitch is:

$$\alpha = \tan^{-1} \left[\frac{\sin \theta}{(\omega R / V_{Local}) / (V_a / V_{Local}) + \cos \theta} \right] \quad (20.216)$$

The tangential and normal force coefficients, respectively, are expressed as:

$$C_t = C_l \sin \alpha + C_d \cos \alpha \quad (20.217)$$

$$C_n = C_l \cos \alpha + C_d \sin \alpha \quad (20.218)$$

The net tangential and normal forces are obtained from the following expressions:

$$F_t = C_t \frac{1}{2} \rho_{Local} A_c W^2 \quad (20.219)$$

$$F_n = C_n \frac{1}{2} \rho_{Local} A_c W^2 \quad (20.220)$$

Average tangential force on a single blade can be defined as:

$$F_{ta} = \frac{1}{2\pi} \int_0^{2\pi} F_t(\theta) d\theta \quad (20.221)$$

Substituting the value of F_t and arranging the tangential force on the azimuth angle, θ , the equation above can be written as:

$$F_{ta} = \frac{1}{4\pi} C_t \rho_{Local} A_c \left(\int_0^{2\pi} (\omega R)^2 + \int_0^{2\pi} V_a^2 \right) \quad (20.222)$$

The expression of the total torque for the number of blades is defined as:

$$Q = N F_{ta} \quad (20.223)$$

The power production of wind turbine is thus:

$$P_W = Q\omega \quad (20.224)$$

The model also defines P_W as the rated power output at the rated wind speed, if either the power production of wind turbine or local wind speed is greater than the rated power.

The overall power production delivered from a wind turbine system is thus:

$$P = \eta P_W \quad (20.225)$$

Table 20.6: Nomenclature for Wind Turbine model

Variable	Description	Units
A_R	swept area of rotor	m^2
A_C	blade chord area	m^2
a	site wind exponent, 0.22	
a_{met}	wind exponent, 0.14	
C_d	blade drag coefficient, 0.9	
C_l	blade lift coefficients, 0.05	
C_n	normal force coefficient	
C_p	power coefficient (performance coefficient)	
C_t	tangential force coefficient	
C_{1-6}	empirical power coefficient parameters	
g_o	standard gravity	m/s^2
F_n	normal force in radial direction	N-m (J)
F_t	tangential force	N-m (J)
F_{ta}	average tangential force	N-m (J)
F_v	wind speed factor	
H	height of local wind speed measurement	m
H_{met}	height of turbine, 10	m
N	number of blade	
P	overall power production delivered to building	W
P_{Local}	outdoor static air pressure at rotor height	Pa
P_W	wind turbine power produced	W
Q	overall torque	N-m
R	turbine radius	m
T_{Local}	local air temperature at rotor height	$^{\circ}\text{C}$
v	ambient wind speed	m/s
v_1	upstream wind speed	m/s
v_2	wind speed on the turbine	m/s
v_3	downstream wake velocity	m/s

Table 20.6: Nomenclature for Wind Turbine model

Variable	Description	Units
V_a	induced velocity	m/s
$V_{AnnualAvg}$	annual average wind speed from TMY weather data	m/s
V_{Local}	local wind speed at the location of the system	m/s
$V_{LocalTMY}$	annual average wind speed converted at the local station height	m/s
V_c	chordal velocity component	m/s
V_n	normal velocity component	m/s
V_Z	wind speed adjusted at rotor height	m/s
W	relative flow velocity	m/s
Z	height of wind turbine rotor	m
α	blade angle of attack	deg
θ	azimuth angle in VAWT and pitch angle in HAWT	deg
ρ_{Local}	local density of air at rotor height	kg/m ³
ω	angular velocity of turbine	rad/s
ω_{Local}	local humidity ratio at rotor height	kg-H ₂ O/kg-air
x	exponent, 1.5	
λ	tip speed ratio	
λ_i	tip speed ratio at the i^{th} pitch	
δ_{met}	wind boundary layer thickness of meteorological station, 270	m
δ	site boundary layer thickness, 370	m
η	wind turbine system efficiency

Chapter 21

Performance Curves and Lookup Tables

The following section describes the use of performance curves and lookup tables. Each of these objects may be used in any valid input field where a performance curve name is required.

Performance curves are used directly to simulate the performance of HVAC equipment. The curves are typically created by performing a regression analysis on tabular data for a particular equipment performance metric. The regression analysis determines the equation coefficients which are the primary input to all performance curve objects. Performance tables are similar to performance curves in that they are meant to replicate a particular performance curve. Input to performance tables are made up of data pairs, the same data pairs that would be used to create performance curve coefficients. Performance tables can be interpolated using up to a 4th order polynomial equation for one independent variable tables or using a 2nd order polynomial for two independent variable tables. A regression analysis can be performed on performance tables when the simulation is instructed to use the regression analysis during the simulation (i.e., ride the curve). In addition, a performance curve object is created that can be used in future simulations and can be written to the eio file. The performance curve is written to the eio file only when the diagnostics flag is set to DisplayAdvancedReportVariables (ref. Output:Diagnostics, DisplayAdvancedReportVariables;). Lookup tables are similar to performance tables in that tabular data is used for input, however, the input 1) is more compact, 2) a regression analysis may only be performed for one and two independent variable cases, and 3) the tabular data can be read from an external file.

Performance curves and data tables are created using empirical data that are derived from information gathered through observation, experience, or experimental means. Once a curve or table object is defined, these objects can be used to generically describe HVAC equipment performance. Performance curves and performance tables may be used interchangeably in Energyplus objects as required.

21.1 Performance Curves

Performance curves define a polynomial equation which represents a conditional response to a model input. A polynomial is a mathematical expression which uses a sum of powers in one or more variables. The equation below represents an nth order univariate polynomial. The highest power in the equation represents its order or degree (n).

$$y = a_0 + a_1x + a_2x^2 + a_3x^3 + \dots + a_nx^n \quad (21.1)$$

A polynomial in two independent variables (multi-variate) is given by:

$$z = a_{00} + a_{10}x + a_{01}y + a_{11}xy + a_{21}x^2y + a_{12}xy^2 + a_{22}x^2y^2 \dots + a_{nm}x^n y^m \quad (21.2)$$

In EnergyPlus, the result of an equation, the dependent variable, represents the response a system or component has given an input (the independent variable) to the system or component model. This response represents the equipment performance related to the mechanism that causes this change (e.g., the change in capacity or power based on a conditional change in temperature, part-load ratio, or other phenomenon). A variety of performance curves are available to describe the most common forms of engineering equations. The coefficients (a-z) in the following equations are entered in the associated curve object to define a specific phenomenon. Minimum and maximum limits may be applied to both the independent and the dependent variables as necessary.

21.1.1 Curves based on a single independent variable

A polynomial having only a single independent variable represents a one-dimensional relationship between a condition (the model input) and response (the model output). The previously described n^{th} order univariate polynomial is representative of the following performance curves.

21.1.1.1 Linear Curves

A performance curve having an order or degree of 1.

$$y = a + bx \quad (21.3)$$

21.1.1.2 Quadratic Curves

A performance curve having an order or degree of 2.

$$y = a + bx + cx^2 \quad (21.4)$$

21.1.1.3 Cubic Curves

A performance curve having an order or degree of 3.

$$y = a + bx + cx^2 + dx^3 \quad (21.5)$$

21.1.1.4 Quartic Curves

A performance curve having an order or degree of 4.

$$y = a + bx + cx^2 + dx^3 + ex^4 \quad (21.6)$$

21.1.1.5 Exponent Curves

A performance curve having an order or degree of c.

$$y = a + bx^c \quad (21.7)$$

21.1.2 Curves based on two independent variables

A polynomial having two independent variables represents a two-dimensional relationship between a condition (the model inputs) and response (the model output). The previously described n^{th} order multi-variate polynomial is representative of the following performance curves.

21.1.2.1 QuadraticLinear Curves

A performance curve having an order or degree of 2 in two independent variables.

$$z = a + bx + cx^2 + dy + exy + fx^2y \quad (21.8)$$

21.1.2.2 CubicLinear Curves

A performance curve having an order or degree of 3 in two independent variables.

$$z = a + bx + cx^2 + dx^3 + ey + fxy \quad (21.9)$$

21.1.2.3 BiQuadratic Curves

A performance curve having an order or degree of 2 in two independent variables.

$$z = a + bx + cx^2 + dy + ey^2 + fxy \quad (21.10)$$

21.1.2.4 BiCubic Curves

A performance curve having an order or degree of 3 in two independent variables.

$$z = a + bx + cx^2 + dy + ey^2 + fxy + gx^3 + hy^3 + ix^2y \quad (21.11)$$

Calculating performance curve coefficients in a spreadsheet is a simple matter of finding the data required to perform the regression analysis. For example, the biquadratic equation shown above is representative of the cooling capacity as a function of temperature performance curve for DX cooling coils. The fundamental equation for DX cooling coil capacity is:

$$TotCapTempModFac = a + b(T_{wb,i}) + c(T_{wb,i})^2 + d(T_{c,i}) + e(T_{c,i})^2 + f(T_{wb,i})(T_{c,i}) \quad (21.12)$$

where:

$T_{wb,i}$ is the wet-bulb temperature of the air entering the cooling coil ($^{\circ}\text{C}$)

$T_{c,i}$ (or $T_{db,i}$) is the dry-bulb temperature of the air entering an air-cooled condenser ($^{\circ}\text{C}$).

Given the data set shown in Figure 21.1, each of the independent variables would be calculated according to the fundamental equation above (i.e., the T , T^2 , and cross-product terms would be multiplied out). The data would be converted to degrees celcius and the cooling capacity would be converted to Watts. The data would also be normalized using the ARI rating point shown as highlighted in Figure 21.2.

The fundamental equation would be used to determine the number of independent variables and also the form of the equation. Given the example described here, the spreadsheet would be set up to look like the equation as shown in the following table. A regression analysis could then

Entering Wet-bulb Temp	Outdoor Dry- bulb Temp	Total Cooling Capacity	Total Cooling Capacity

Figure 21.2: Regression Analysis for Example

The regression analysis and summary statistical output is shown below. The equation coefficients are shown highlighted. In this example, the equation coefficients are: $a = 0.757382$, $b = 0.014666$, $c = 0.000459$, $d = -0.00095$, $e = -6.7E-05$, and $f = -0.00015$. These coefficients would be entered in a Curve:BiQuadratic object and used to describe the cooling capacity as a function of temperature for the DX cooling coil model. Minimum and Maximum values from the tabular data are entered as Min/Max values for the curve object. The values may be relaxed slightly with care to allow extrapolation as needed. A performance table may be used to automatically perform the regression analysis as described in the following section.

21.1.3 Curves based on three independent variables

A polynomial having three independent variables represents a three-dimensional relationship between a condition (the model inputs) and response (the model output).

21.1.3.1 TriQuadratic Curves

A performance curve having an order or degree of 2 in three independent variables.

$$\begin{aligned}
 \text{Output} = & a + bx^2 + cx + dy^2 + ey + fz^2 + gz + hx^2y^2 + ixy + jxy^2 + kx^2y \\
 & + lx^2z^2 + mxz + nxz^2 + ox^2z + py^2z^2 + qyz + ryz^2 + sy^2z + tx^2y^2z^2 \\
 & + ux^2y^2z + vx^2yz^2 + vxy^2z^2 + wx^2yz + x(xy^2z) + y(xyz^2) + z(xyz)
 \end{aligned} \tag{21.13}$$

21.1.4 Pressure drop curve

21.1.4.1 Functional Pressure Drop Curve

A performance curve representing the minor loss and/or friction calculations in plant pressure simulations.

$$\Delta P = [K + f(L/D)] (\rho V^2) / 2 \tag{21.14}$$

21.2 Lookup Tables

21.2.1 Table:Lookup

Lookup tables provide a method to evaluate a group of data that may or may not conform to a fundamental equation. Lookup tables can interpolate the actual data using a linear interpolation or piecewise cubic spline using the Btwxt library (<https://github.com/bigladder/btwxt>). As with curve objects, the lookup table can be used anywhere a valid curve object name is allowed so long as they share the same number of independent variables. Care must be taken to ensure the table data format is consistent with the associate model that is using the performance curve (e.g., DX cooling coil capacity as a function of temperature where independent variable X1 = indoor wet-bulb temperature and independent variable X2 = outdoor dry-bulb temperature).

A lookup table can be specified to use either linear or cubic interpolation independently for each dimension (input variable). For performance points outside the defined grid space, an extrapolation method—constant or linear—can be set independently for each dimension. Finally, each axis can have specified boundaries beyond which extrapolation is not permitted.

21.2.1.1 Linear Interpolation

For linear interpolation in 1 dimension, given known values of f at x_0 and x_1 , and a point x between x_0 and x_1 , the value at x is estimated by:

$$f(x) = (1 - \mu) \cdot f(x_0) + \mu \cdot f(x_1)$$

where μ is the location of x expressed as a fraction of the distance between x_0 and x_1 :

$$\mu = (x - x_0) / (x_1 - x_0)$$

21.2.1.2 Cubic Spline Interpolation

The general formula for a 1-dimensional piecewise cubic spline (for x between known values $f(x_0)$ and $f(x_1)$) is:

$$\begin{aligned} f(x) = & (2\mu^3 - 3\mu^2 + 1) \cdot f(x_0) + (-2\mu^3 + 3\mu^2) \cdot f(x_1) \\ & + (\mu^3 - 2\mu^2 + \mu) \cdot f'(x_0) + (\mu^3 - \mu^2) \cdot f'(x_1) \end{aligned}$$

The Catmull-Rom cubic spline interpolation defines the derivatives $f'(x_0)$ and $f'(x_1)$ as the slope between the previous and following grid points on the axis:

$$\begin{aligned} f'(x_0) &= (f(x_1) - f(x_{-1})) / (x_1 - x_{-1}) \\ f'(x_1) &= (f(x_2) - f(x_0)) / (x_2 - x_0) \end{aligned}$$

When the hypercube is at the edge of the grid, Catmull-Rom simply extends the slope of the final segment for defining the slope terms: i.e., if there is no x_{-1} , we substitute x_0 into the $f'(x_0)$ formula.

If a mix of interpolation methods are specified among the included dimensions, the interpolator will perform that mix as requested. If the lookup point is beyond the grid edge on any axis, the interpolator will perform the requested extrapolation method (linear or constant) on that dimension while proceeding with interpolation along any in-bounds dimension. If a “do-not-extrapolate-beyond” boundary is specified, the interpolator will perform a constant extrapolation from that boundary outward (in that dimension), and it will return the resulting numerical answer along with a warning that the request was outside the boundaries.

Chapter 22

Economics Calculations

22.1 Component Costs

EnergyPlus provides simple cost estimating capabilities as an aid to design analysis and for life cycle costs. There are three broad steps involved. The first involves determining *construction* costs by summing individual “line items.” The second involves determining *project* costs by adjusting construction costs to account for things like profit and design fees. The third involves comparing the current simulation to a reference case so that marginal increases can be calculated. The reference documentation contained in this section pertains to the following input object names.

- **ComponentCost:LineItem**
- **ComponentCost:Adjustments**
- **ComponentCost:Reference**

22.1.1 Line Item Costs

Line item cost calculations are generally trivial involving simple multiplication and summation. This section documents details of how line item costs are calculated. The program code consists mainly of a **Case** construct where the **Line Item Type** is used to control the details of how calculations are performed.

The overall philosophy is to provide methods of calculating items using either direct entry of needed data (**‘General’** using object type), or using component descriptive data entered elsewhere in the input file (e.g. **‘Lights’**), or by using quantities that are calculated by the program during the simulation (e.g. **‘Coil:DX’** and **‘Chiller:Electric’**).

The rest of this section provides details by organized by the type of line item.

22.1.1.1 General

The line item subtotal, L , is calculated by multiplying the number of units, N , by the Cost-per-Each, P_e :

$$L = N * P_e \tag{22.1}$$

22.1.1.2 Construction

This line item type is called “Construction” but is used to estimate the costs of surfaces in the model. The Construction attribute of Surface objects is useful for categorizing surfaces. The number of units, N , is determined by summing the Area, A , of Surface objects that have the type of construction specified in the **Item Name** field. Surfaces are screened to eliminate any duplicates that may exist for interior partitions creating a list of 1 to m unique surfaces. If a surface is associated with a Zone, then zone multiplier, M_Z , and list multipliers, M_G , are applied (these are usually defaulted to 1).

$$N = \sum_1^m (A * M_Z * M_G) \quad (22.2)$$

The line item subtotal, L , is calculated by multiplying the number of units (actually units of are here), N (m^2) by the Cost-per-Area, P_a , ($\$/\text{m}^2$):

$$L = N * P_a \quad (22.3)$$

22.1.1.3 Coil:DX and Coil:Cooling:DX:SingleSpeed

DX coil costs can be estimated in one of three ways: per-each, per-kW, per-kW-COP. The program determines which method to use based on there being non-zero values in appropriate input fields.

If **cost per each** is greater than 0.0 then the number of units, N , is the number of cooling coils. This will be 1 if the **Item Name** is the name of a specific coil described elsewhere. If the name is set to the wildcard (*) then this will equal the total number of DX:Coils in the model. Then the line item subtotal, L , is calculated by multiplying the number of units, N , by the Cost-per-Each, P_e :

$$L = N * P_e \quad (22.4)$$

If **cost per kilowatt** is greater than 0.0 then the number of units, N , is the number of kilowatts of total, rated, cooling capacity. This will be based on all the DX:Coils in the model if **Item Name** is set to the wildcard (*) and will be that of the named coil if set to a valid coil name. Then the line item subtotal, L , is calculated by multiplying the number of units, N , by the Cost-per-kilowatt, P_{kW} :

$$L = N * P_{kW} \quad (22.5)$$

If **Cost per kilowatt per coefficient-of-performance** is greater than 0.0 then the number of units, N , is the number of kilowatts of total, rated, cooling capacity multiplied by the nominal coefficient of performance (COP) of the DX:Coils. This will be based on all the DX:Coils in the model if **Item Name** is set to the wildcard (*) and will be that of the named coil if set to a valid coil name. Then the line item subtotal, L , is calculated by multiplying the number of units, N , by the Cost-per-kilowatt-per-COP, P_{kW-COP} :

$$L = N * P_{kW-COP} \quad (22.6)$$

22.1.1.4 Coil:Heating:Fuel

Fuel-fired heating coil costs can be estimated in one of three ways: per-each, per-kW, per-kW-COP. The program determines which method to use based on there being non-zero values in appropriate input fields.

If **cost per each** is greater than 0.0 then the number of units, N , is the number of heaters. This will be 1 if the **Item Name** is the name of a specific heater described elsewhere. If the name is set to the wildcard (*) then this will equal the total number of Coil:Heating:Fuel objects in the model. Then the line item subtotal, L , is calculated by multiplying the number of units, N , by the Cost-per-Each, P_e :

$$L = N * P_e \quad (22.7)$$

If **Cost per kilowatt** is greater than 0.0 then the number of units, N , is the number of kilowatts of total, rated, heating capacity. This will be based on all the Coil:Heating:Fuel objects in the model if **Item Name** is set to the wildcard (*) and will be that of the named coil if set to a valid coil name. Then the line item subtotal, L , is calculated by multiplying the number of units, N , by the Cost-per-kilowatt, P_{kW} :

$$L = N * P_{kW} \quad (22.8)$$

If **Cost per kilowatt per coefficient-of-performance** is greater than 0.0 then the number of units, N , is the number of kilowatts of total, rated, heating capacity multiplied by the theoretical efficiency of the heater(s). (Here we are treating gas heating efficiency as a Coefficient of Performance (COP)). This will be based on all the Coil:Heating:Fuel objects in the model if **Item Name** is set to the wildcard (*) and will be that of the named coil if set to a valid coil name. Then the line item subtotal, L , is calculated by multiplying the number of units, N , by the Cost-per-kilowatt-per-COP, P_{kW-COP} :

$$L = N * P_{kW-COP} \quad (22.9)$$

22.1.1.5 Chiller:Electric

Electric chiller costs can be estimated in one of three ways: per-each, per-kW, per-kW-COP. The program determines which method to use based on there being non-zero values in appropriate input fields.

If **cost per each** is greater than 0.0 then the number of units, N , is the number of chillers. This will be 1 if the **Item Name** is the name of a specific coil described elsewhere. Then the line item subtotal, L , is calculated by multiplying the number of units, N , by the Cost-per-Each, P_e :

$$L = N * P_e \quad (22.10)$$

If **Cost per kilowatt** is greater than 0.0 then the number of units, N , is the number of kilowatts of total, rated, cooling capacity for the specified chiller. Then the line item subtotal, L , is calculated by multiplying the number of units, N , by the Cost-per-kilowatt, P_{kW} :

$$L = N * P_{kW} \quad (22.11)$$

If **Cost per kilowatt per coefficient-of-performance** is greater than 0.0, then the number of units, N , is the number of kilowatts of total, rated, cooling capacity multiplied by the nominal coefficient of performance (COP) of the chiller. This will be based on the named chiller (if set to a valid coil name). Then the line item subtotal, L , is calculated by multiplying the number of units, N , by the Cost-per-kilowatt-per-COP, P_{kW-COP} :

$$L = N * P_{kW-COP} \quad (22.12)$$

22.1.1.6 Daylighting:Controls

The costs of controllers for harvesting daylight are determined by the number of reference points. The cost for each controller, P_e , are input. The of units, N , is determined from the number of daylight reference points in all the zones if the **Item Name** is the wildcard (*). If **Item Name** is set to a valid Zone name then N is the number of daylight reference points in just that zone (zones can have more than one daylight controllers). Then the line item subtotal, L , is calculated by multiplying the number of units, N , by the Cost-per-Each, P_e :

$$L = N * P_e \quad (22.13)$$

22.1.1.7 Shading:Zone:Detailed

Shading surfaces need to be handled separately because they do not have the **Construction** attribute. The **Item Name** must be set to a valid name for a **Shading:Zone:Detailed** object defined elsewhere in the file. The number of units, N , is determined from the area of the named surface multiplied by zone multiplier, M_Z , and list multipliers, M_G :

$$N = A * M_Z * M_g \quad (22.14)$$

The line item subtotal, L , is calculated by multiplying the number of units, N (m²) by the Cost-per-Area, P_a , (\$/m²):

$$L = N * P_a \quad (22.15)$$

22.1.1.8 Lights

The cost of electric lighting systems can be modeled in two ways: per-each and per-kW. The program determines which method to use based on there being non-zero values in appropriate input fields. The **Item Name** must be the name of a valid Zone defined elsewhere in the input.

If **cost per each** is greater than 0.0, then the number of units, N , is the number lighting systems in the zone and is assumed to be 1. Then the line item subtotal, L , is calculated by multiplying the number of units, N , by the Cost-per-Each, P_e :

$$L = N * P_e \quad (22.16)$$

If **Cost per kilowatt** is greater than 0.0 then the number of units, N , is the number of kilowatts in the design level for electric lighting systems defined in Lights objects associated with the zone. The **Item Name** must be the name of a valid Zone defined elsewhere in the input. N is

then the sum of all the Lights associated with the named Zone. Then the line item subtotal, L , is calculated by multiplying the number of units, N , by the Cost-per-kilowatt, P_{kW} :

$$L = N * P_{kW} \quad (22.17)$$

22.1.1.9 Generator:Photovoltaic

The costs of simple photovoltaic power systems can be modeled using cost per kilowatt. The number of units, N , is the nominal rated peak power of the photovoltaic panels. The photovoltaic generator must be modeled using the PhotovoltaicPerformance:Simple input object which is a very simplistic model and does not include input for the nominal rated peak power of the system. Therefore a peak power is calculated using the usual 1000 W/m² of incident solar radiation, G_p , multiplied by the active solar cell area, A and the efficiency, E , and converted to units of kilowatts.

$$N = \frac{G_p * A * E}{1000.0} \quad (22.18)$$

Where, the cell area A is calculated by multiplying the area of the surface associated with the simple photovoltaic system and the active area fraction defined in the PhotovoltaicPerformance:Simple. Then the line item subtotal, L , is calculated by multiplying the number of units, N , by the Cost-per-kilowatt, P_{kW} :

$$L = N * P_{kW} \quad (22.19)$$

22.1.2 Adjustments

Various adjustments are available to model total project costs from the component costs modeled using individual line items. These adjustments are provided to allow propagating how changes in component costs are amplified by things like design fees, profit, bonding, and taxes.

The subtotal of individual line items, S_L , is obtained by summing all line item subtotals, L :

$$S_L = \sum L \quad (22.20)$$

For the reference building, S_L , is user input (typically from a prior run of baseline building model).

The subtotal for miscellaneous construction costs (typically those costs not explicitly included as line items), S_m , are calculated by multiplying the **Miscellaneous Cost Model** (per Square Meter), C_m , by the total conditioned floor area, A_c :

$$S_m = A_c * C_m \quad (22.21)$$

The subtotal for the amount that the construction costs should be altered because of regional differences in material and labor costs (e.g. when using national average data), S_r , is determined by multiplying the Regional Adjustment Factor, R_f , by the sum of S_L and S_m :

$$S_r = (S_L + S_m)R_f \quad (22.22)$$

Remaining adjustments are applied to the subtotal for construction costs, S_c , which is the sum of S_L , S_m , and S_r :

$$S_C = S_L + S_m + S_r \quad (22.23)$$

The **Design and Engineering Fee Fraction**, F_d , is the fraction of construction costs, S_c , attributable to costs associated with architectural and engineering services needed for the project. The subtotal for costs associated with these fees, S_D , are determined by multiplying S_C by F_d :

$$S_D = S_c * F_D \quad (22.24)$$

The **Contractor Fee Fraction**, F_c , is the fraction of construction costs, S_c , attributable to costs associated with the contractor's profit that should be included in the project. The subtotal for costs associated with contracting, S_P , are determined by multiplying S_C by F_d :

$$S_P = S_c * F_C \quad (22.25)$$

The **Contingency Fraction**, F_S , is the fraction of construction costs, S_c , which should be included in a cost estimate to provide for contingencies (perhaps related to errors and uncertainty in the estimate and project). The subtotal for contingency costs, S_S , are determined by multiplying S_C by F_S :

$$S_S = S_c * F_S \quad (22.26)$$

The **Permits, Bonding, Insurance Fraction**, F_B , is the fraction of construction costs, S_c , which should be included in a cost estimate to provide for things like taxes, bonding, insurance, and permits. The subtotal for these extra costs, S_B , are determined by multiplying S_C by F_B :

$$S_B = S_c * F_B \quad (22.27)$$

The **Commissioning Fee Fraction**, F_{CX} , is the fraction of construction costs, S_c , which should be included in a cost estimate to provide for commissioning the building systems. The subtotal for these extra costs, S_{CX} , are determined by multiplying S_C by F_{CX} :

$$S_{CX} = S_c * F_{CX} \quad (22.28)$$

Finally, the cost estimate total, T , is obtained by summing the various subtotals:

$$T = S_L + S_m + S_r + S_D + S_P + S_S + S_B + S_{CX} \quad (22.29)$$

The normalized total cost estimate, C , is calculated by dividing T by the total conditioned floor area, A_c :

$$C = \frac{T}{A_C} \quad (22.30)$$

22.1.3 Comparisons

The capability of comparing the current cost estimate to that of a reference building is provided because is common to consider the marginal increases in costs associated with applying different energy design measures. EnergyPlus calculates and reports the difference between the current model and a reference case for all the subtotals and totals discussed above. The reported differences are the reference values subtracted from the current value.

22.2 Tariff Computation

The EnergyPlus economic (Utility Costs) objects related to computing utility bills include:

- UtilityCost:Tariff
- UtilityCost:Qualify
- UtilityCost:Charge:Simple
- UtilityCost:Charge:Block
- UtilityCost:Ratchet
- UtilityCost:Variable
- UtilityCost:Computation

This section builds upon the discussion that appears in the Input Output Reference under the heading “EnergyPlus Economics.” The actual computation of monthly utility bills is not difficult since it is mostly consists of multiplying energy consumptions or demands by the price on a per unit basis and adding different bill components. The implementation in EnergyPlus becomes more complex since the objects were crafted to allow a great deal of flexibility in specifying a utility tariff while, at the same time, being as simple as possible.

The following discussion on variables and hierarchies is based on the text that appears in the Input Output Reference.

22.2.1 Conceptual Framework – Variables and Hierarchy

To understand how to use the utility bill calculation portion of EnergyPlus you first need to understand some important concepts of variables and hierarchy. A variable, for the purposes of this section, is simply a named holder of a series of numbers. In most cases, the variable will be a named holder of 12 numbers, one number for each monthly utility bill. A simple visualization of a variable called Electric Energy Use is shown in Table 22.1.

Table 22.1: Example of Monthly Electric Energy Use

Month	Electric Energy Use
January	12143
February	13454
March	14178
April	14876
May	15343
June	16172
July	16105
August	15762

Month	Electric Energy Use
September	14543
October	13987
November	13287
December	12403

If you have ever done any computer programming, you can think of a variable as an array. Many of the names used in the utility bill calculation portion of EnergyPlus are names of variables. In the case of the UtilityCost:Charge objects, the name of the object is also used as a name of a variable.

In many of today’s utility rates, the charges for energy or demand are broken into distribution and supply charges. To allow for this, more than one charge may to be defined for a particular category. The variables assigned to the same category are added together.

The categories are combined in the hierarchy shown in Figure 22.1.

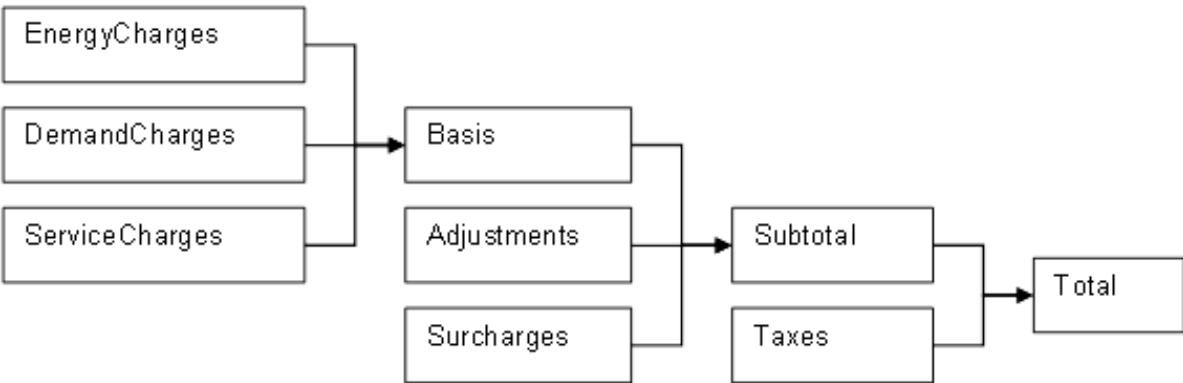

Figure 22.1: Category Hierarchy for Utility Bills

Any charges included in the EnergyCharges category are added together. The EnergyCharges, DemandCharges and ServiceCharges are added together to form the Basis. The Basis, Adjustments and Surcharges are added together to form the Subtotal. The Subtotal and Taxes are added together to be the Total. The total represents the total monthly charges on that tariff for the energy source used. The combining of categories together is performed automatically unless the user specifies the UtilityCost:Computation. In addition, each category, which is also a variable, may be used as a source. For example, a tax that is 5% of the subtotal would be shown as:

```
UtilityCost:Charge:Simple,  
  TaxOfFivePercent,      ! Charge Variable Name  
  TariffExample1,         ! Tariff Name  
  Subtotal,              ! Source Variable  
  Annual,                ! Season  
  Taxes,                 ! Category Variable Name  
  0.05;                  ! Cost Per Unit Value (or Variable)
```

As you can see, the UtilityCost:Charge:Simple and UtilityCost:Charge:Block objects do most of the “work” of computing the annual energy cost. The benefit of using this categorization is that

totals of each category are shown in the output reports and it organizes the charges in the monthly calculations in a logical way that fits almost all tariffs. If no categorization is desired, theoretically, all charges could be assigned to the Total category. The categories themselves are simply variable names. Charges may also be assigned to the “NotIncluded” category if the result of the charge is used as an intermediate calculation and should not be included in the Total.

The objects that create variables are:

- UtilityCost:Qualify
- UtilityCost:Charge:Simple
- UtilityCost:Charge:Block
- UtilityCost:Ratchet
- UtilityCost:Variable

22.2.2 Default Order of Computation

The user has the option of two different ways to determine the order of computation. If an UtilityCost:Computation object is specified for the tariff, the sequence specified in that object is used for computing the various variables. If no UtilityCost:Computation object is specified, a sequence of computational steps is automatically derived and shown as part of the report. The routine that creates this automatic sequence of computation steps is called CreateDefaultComputation as part of the EconomicTariff module.

The order in which the computation should be made is complicated by the fact that the objects can each have variables that are inputs and others that are outputs. Since any of the variables can be used as inputs, we must ensure that they are computed prior to being used. In other words, because the objects allow a great deal of flexibility, there is no simple default order that the computations should be made.

Luckily there are known algorithms for sorting through these types of interdependencies. In fact, the method that spreadsheets use for sorting through the dependencies of cell formulas referencing other cells with formula is very similar. In addition, linkers (used as part of the computer language compiling process) face similar issues of sorting through dependences. Figuring out the optimal path in a complex project represented by a PERT Chart also uses a similar algorithm.

Generically, dependency problems are usually characterized as Directed Acycle Graphs (DAGs). A DAG shows the individual formulas as circles and uses arrows between the circles to show which formula is dependent on which other formulas. One example algorithm that was used in EnergyPlus is described below:

- Calculate, for each node, the in-degree of that node (ie, how many edges end up there). Store these in array D.
- Repeat:
 - Remove (output) node such that $D[n] = 0$.
 - Decrement $D[x]$ for all nodes x that are neighbors of n (edge from n to x).

Of course in this case “node” has nothing to do with EnergyPlus nodes but is just describing one of the formulas in a DAG. This is just one of several different methods to solve a DAG. The general method for solving a DAG is called a topological sort. The algorithm used in EnergyPlus is one of the simplest methods available and is appropriate given the number of dependencies. More efficient algorithms are known but are probably only appropriate for much larger number of dependencies.

One important note, if after the algorithm is exercised, and some of the formulas still have a count on the number of dependencies, it must be the result of a circular dependency and an error condition is flagged in the ERR file.

The objects have specific variables that are used as inputs and outputs, and thus the outputs are dependent on the inputs, are shown in Table 22.2.

Table 22.2: Object Variables: Inputs and Outputs

Object	Outputs	Inputs
Qualify	Name	Source Threshold
Charge:Simple	Name Category	Source Cost Per Unit
Charge:Block	Name Category Remaining	Source Block Size Multiplier Block Size Block Cost
Ratchet	Name	Baseline Adjustment Multiplier Offset

In addition, the hierarchy shown in the first diagram in this section also represents dependencies that are included when determining the order of computation.

The resulting order of computation is shown at the bottom of the economics report.

22.2.3 Computation Steps

Once the order that the formulas should be computed is known, the actual evaluation of the formulas is based on a simple Last In First Out (LIFO) stack. This is a common method to compute expressions where values are stored on the stack and operands work off of the top of the stack.

22.3 Life-Cycle Cost Computations

The objects used for performing a life-cycle cost analysis are:

- LifeCycleCost:Parameters

- LifeCycleCost:RecurringCosts
- LifeCycleCost:NonrecurringCost
- LifeCycleCost:UsePriceEscalation
- LifeCycleCost:UseAdjustment

The computation of life-cycle costs is broken into three main routines which are described below.

22.3.1 ExpressAsCashFlows

- Step 1. If the input file has ComponentCost:* items, then create an additional instance of a nonrecurring cost to hold the total.
- Step 2. Get the costs for each resource that has non-zero utility costs.
- Step 3. Compute the inflation on a monthly basis. For cases where the inflation approach is constant dollars, the inflation is set to 1.0 for all months. For current dollar analyses, compute the inflation rate on a monthly basis. Just using 1/12 of the annual inflation is almost correct but introduces a small error so instead the inverse of the formula 4-32 from Newnan (Engineering Economic Analysis Ninth Edition by Donald Newnan, Ted Eschenbach, and Jerome Lavelle):

$$\text{Inflation Per Month} = ((\text{inflation} + 1.00)^{1.0/12.0}) - 1 \quad (22.31)$$

Then the inflation is applied for each month:

$$\text{Monthly Inflation Factor}(j\text{Month}) = (1 + \text{inflationPerMonth})^{j\text{Month} - 1} \quad (22.32)$$

- Step 4. Put the nonrecurring, recurring, and utility costs into a monthly array for the entire length of the study period.
- Step 5. Multiply the monthly costs by the monthly inflation which was set to 1.0 for constant dollar analyses.
- Step 6. Multiply the monthly costs for resources with use adjustments.
- Step 7. Sum the monthly costs by category.
- Step 8. Based on the base date, accumulate the monthly costs into yearly costs.

22.3.2 ComputePresentValue

Step 1. For each year of the study compute the discount factor (SPV) using the following formula:

$$SPV_{yr} = 1 / ((1 + curDiscountRate)^{effectiveYear}) \quad (22.33)$$

This formula is based on formula D.2.1.1 from NIST Handbook 135 Life Cycle Costing Manual for the Federal Energy Management Program by Sieglinde K. Fuller and Stephen R. Petersen.

Where the effectiveYear depends on the discount convention. If end of year discounting is used than the effectiveYear is the year. If middle of the year discounting is used than the effectiveYear is reduced by 0.5. If the beginning of year discounting is used, than the effectiveYear is reduced by 1.0.

For energy costs, the use price escalations are multiplied by the discount factors.

Step 2. Compute the present value for each month by multiply the monthly costs by the discount factor for each year.

Step 3. Sum the costs by category.

22.3.3 ComputeTaxAndDepreciation

Step 1. Depending on the depreciation method selected the depreciation factors are set to various constants. Depreciation factors are based on IRS Publication 946 for 2009 “How to Depreciate Property.” The MACRS values are based on Modified Accelerated Cost Recovery System GDS for 3, 5, 7, 10 year property are based on 200% depreciation method shown in Appendix A of IRS Publication 946 using half year. 15 and 20 are based on 150% (Chart 1 of IRS Publication 946). For Straight Line depreciation GDS is used for 27 years (actually 27.5) 31 years (actually 31.5 years) and 39 years using mid month. For 40 years ADS is used (chart 2) Table A-1 is used for 3, 4, 5, 10, 15 and 20 years. Table A-6 is for 27 years. Table A-7 for 31 years. Table A-7a for 39 years. Table A-13 for 40 years. These years are a classification of property and should not be confused with the length of the study. For 27 years, 31 years, 39 years and 40 years the June value was used. All references in this paragraph are to IRS Publication 946.

Step 2. Apply the annual depreciation factors to the capital costs.

Step 3. For each year the taxable income is the grand total of all costs minus the depreciated capital costs.

Step 4. Taxes are the taxable income times the tax rate.

Step 5. The after tax present value is:

$$AfterTaxPresentValue_{yr} = GrandTotal_{yr} - Taxes_{yr} * SPV_{yr} \quad (22.34)$$

All major results are presented on the tabular report.

Chapter 23

Special Modules/Reporting

23.1 Environmental Impacts

Typically when a new building technology is evaluated the energy performance of a baseline building is compared to the energy and life-cycle costs of alternatives to determine cost-effectiveness. But what if the lowest energy or life-cycle cost alternative is not the cleanest or lowest environmental impact? By calculating environmental impact, designers can compare alternatives not only in terms of their energy performance but also their environmental performance—working towards a more sustainable design (Liesen 1997; Stroot, Nemeth, and Fournier 1996). Environmental impacts are quantified, in part, by modeling the amount of emissions and in EnergyPlus this is done using the input objects “EnvironmentalImpactFactors,” “FuelFactors,” and “Output:EnvironmentalImpactFactors.”

Based on emissions factors entered by the user, EnergyPlus calculates the mass or volume of thirteen different pollutants: CO₂ (carbon dioxide), CO (carbon monoxide), CH₄ (methane), NO_x (nitrogen oxides), N₂O (nitrous oxide), SO₂ (sulphur dioxide), PM (particulate matter), PM₁₀ (particulate matter 10>PM₁₀>2.5 microns), PM_{2.5} (particulate matter<2.5 microns), NH₃ (ammonia), NMVOC (non-methane volatile organic compounds), Hg (mercury), and Pb (lead) as well as water consumed through evaporation in thermo- and hydro-electric generation and high- and low-level nuclear waste from nuclear electricity generation for on- and off-site energy production. Note that while these comprise the largest proportion of pollutants, more than one hundred other pollutants are emitted from fossil fuel combustion or electricity generation. Much of the information compiled here for fossil fuel combustion comes from *AP-42 Compilation of Air Pollutant Emission Factors* (EPA 1998a, 1998b, 1996). For more information on pollutants, see the U.S. Environmental Protection Agency (EPA) Clearinghouse for Inventories & Emission Factors (www.epa.gov/ttn/chief/efinformation.html).

EnergyPlus models energy performance of on-site fossil fuels and purchased electricity (generated from a variety of fuels including natural gas, oil, gasoline, diesel, coal, hydroelectric, nuclear, wind, solar power, and biomass). The energy performance calculated by EnergyPlus is converted into a mass or volume of pollutants emitted. From a baseline building, alternative energy and pollution saving technologies can be explored, and the energy savings and pollution reduction can be calculated. Figure 23.1 and Figure 23.2 illustrate a comparison of two buildings simulated using Chicago weather data in EnergyPlus and the calculated pollutant levels (based on U.S. national average pollutants) (Crawley 2003).

To calculate the mass or volume of each pollutant, consumption is multiplied by an emissions

factor for each fuel (natural gas, electricity, fuel oil, diesel, or coal). In future versions, users will be able to schedule how the emissions factors by time of day, month, season and year. For electricity, the mix of generation fuel sources—whether utility, state or regional—is used to adjust the emission factors. If a user has emissions factors specific to the building site and equipment, these can be entered directly. **There are no default emissions factors.**

23.1.1 Types of Pollutants

EPA categorizes pollutants as either Criteria Pollutants or Hazardous Pollutants. Criteria pollutants are the six substances for which EPA has set health-based standards, including carbon monoxide (CO), nitrogen oxides (NO_x), sulfur dioxide (SO₂), and particulate matter (PM10 and PM2.5), ozone (O₃), and lead (Pb). Because ozone is created in atmospheric photochemical reactions of volatile organic compounds, ammonia, and other substances rather than direct building-related energy emissions, we do not calculate ozone emissions in EnergyPlus. But we do include ozone precursors: methane (CH₄), non-methane volatile organic compounds (NMVOC), and ammonia (NH₃). Hazardous pollutants are substances that are known or suspected to cause serious health problems such as cancer. We include typical hazardous substances associated with energy production and use including lead (Pb) and mercury (Hg). We also include CO₂ (carbon dioxide) since it is largest greenhouse gas in terms of impact.

Figure 23.1: Example Annual Atmospheric Pollutants and Water Consumption

Figure 23.2: Example Annual Total Carbon Equivalent for Major Greenhouse Gases

23.1.2 Carbon Equivalent

The Intergovernmental Panel on Climate Change has studied the effects on the relative radiative forcing effects of various greenhouse gases. This effect, called Global Warming Potential (GWP), is described in terms of the Carbon Equivalent of a particular greenhouse gas. This equivalent is based on a factor of 1.0 for carbon. This group of gases includes carbon dioxide (CO₂), carbon monoxide, nitrous oxide, methane, halocarbon emission, hydrofluorocarbons (HFC), perfluorocarbons (PFC), and chlorofluorocarbons (CFC). For building energy use, the main gases of concern are carbon dioxide, carbon monoxide, methane, and nitrous oxide. Although carbon monoxide has a relatively short life, CO emissions into the atmosphere may have a significant impact on climate forcing due to chemical impact on CH₄ lifetime, and tropospheric O₃ and CO₂ photochemical production normally reacts to produce carbon dioxide, but it can't be ignored since it is produced in incomplete combustion and the carbon remains to interact as CO₂. Yet there is no agreement on its carbon equivalent (IPCC 2001). The carbon equivalent of carbon dioxide, methane, and nitrous oxide are calculated and then multiplied by their GWP on a 100 year time frame. The Carbon Equivalents of the following gases have been determined and used in the program are shown in the following table.

Table 23.1: Carbon Equivalents (IPCC 2001)

Gas	Carbon Equivalent
NO _x	80.7272
CH ₄	6.2727
CO ₂	0.2727

The resulting carbon equivalents by fuel type are shown in the output of the program along with the individual gas pollutants.

23.1.3 Fossil Fuel Emissions Factors

Emission factors for on-site fossil fuel consumption are based on Section 1.4 Natural Gas Combustion in EPA (1998a) Table 23.2 shows the greenhouse gas and precursors and criteria pollutant emissions factors for natural gas. Similar emissions factors are shown for residual fuel oil (No. 4 and No. 6 fuel oil) [Table 23.3], distillates (No. 1 and No. 2 fuel oil) [Table 23.4], residential oil furnace [Table 23.5], LPG (butane and propane) [Table 23.6], gasoline and diesel [Table 23.7], and coal [Table 23.8] in the indicated tables. Note that a zero for a pollutant in the table may mean that no data were available, not that there are no emissions of that pollutant.

Table 23.2: Emission Factors for Natural Gas

Pollutant	Emission (g/MJ)	Factor ^a
Carbon Dioxide (CO ₂)	50.23439	
Carbon Monoxide (CO)	3.51641E-02	

Table 23.2: Emission Factors for Natural Gas

Pollutant	Emission Factor ^a (g/MJ)
Methane (CH ₄)	9.62826E-04
Nitrogen Oxides (NO _x)	4.18620E-02
Nitrous Oxide (N ₂ O) ^b	9.20964E-04
Sulphur Dioxide (SO ₂) ^c	2.51172E-04
Particulate Matter (PM) ^d	3.18151E-03
Particulate Matter (PM10) ^d	2.38613E-03
Particulate Matter (PM2.5) ^d	7.95378E-04
Ammonia (NH ₃)	0 ^e
Volatile Organic Compounds (NMVOC)	2.30241E-03
Mercury (Hg)	1.08841E-07
Lead (Pb)	2.09310E-07

a: Based on data from Tables 1.4-1, 1.4.-2 and 1.4.4 in EPA (1998a), Natural gas heat value of 1027 Btu/ft³ based on data for 2003 in Table A-4 in DOE (2004).

b: Values shown are for uncontrolled burner. For controlled-low NO burner, use 0.64 lb/106 ft³, 0.000627 lb/MMBtu, 0.0002679 g/MJ.

c: Based on 100% conversion of fuel sulfur to SO. Assumes sulfur content is natural gas of 2,000 grains/106 ft³. The SO₂ emission factor can be converted to other natural gas sulfur contents by multiplying the SO emission factor by the ratio of the site-specific sulfur content (grains/106 ft³) to 2,000 grains/106 ft³.

d: PM is the sum of all particulate matter including PM10 and PM2.5. PM10 and PM2.5 stand for particles smaller than 10 and 2.5 microns, respectively.

e: No data.

Table 23.3: Emission Factors for Residual Fuel Oil (No. 4 and No. 6 Fuel Oil)

Pollutant	No. 4 Fuel Oil Emission Factor ² (g/MJ)	No. 6 Fuel Oil Emission Factor ² (g/MJ)
Carbon Dioxide (CO ₂)	76.77128	76.77128
Carbon Monoxide (CO)	1.53543E-02	1.53543E-02
Methane (CH ₄)	1.45865E-03	6.63304E-04

Table 23.3: Emission Factors for Distillates (No. 4 and No. 6 Fuel Oil)

Pollutant	No. 4 Fuel Oil Emission Factor ² (g/MJ)	No. 6 Fuel Oil Emission Factor ² (g/MJ)
Nitrogen Oxides (NO _x)	1.68897E-01	6.14170E-02
Nitrous Oxide (N ₂ O)	3.37794E-04	3.37794E-04
Sulphur Dioxide (SO ₂) ^b	4.82124E-01	4.60628E-01
Particulate Matter (PM) ^c	2.56109E-02	2.14960E-02
Particulate Matter (PM10) ^c	1.58763E-02	1.58763E-02
Particulate Matter (PM2.5) ^c	5.89603E-03	5.89603E-03
Ammonia (NH ₃)	0 ^d	0 ^d
Volatile Organic Compounds (NMVOC)	3.47006E-03	1.04409E-03
Mercury (Hg)	3.47006E-06	3.47006E-06
Lead (Pb)	4.63699E-06	4.63699E-06

a: Based on data from Tables 1.3-1, 1.3-3, 1.3-8, 1.3-10 and 1.3-12 in EPA (1998b).

b: Based on 100% conversion of fuel sulfur to SO₂. Assumes 1% sulfur content. The SO₂ emission factor in this table can be converted to other natural gas sulfur contents by multiplying the SO₂ emission factor by percentage sulfur content.

c: PM is the sum of all particulate matter including PM10 and PM2.5. PM10 and PM2.5 stand for particles smaller than 10 and 2.5 microns, respectively.

d: No data.

Table 23.4: Emission Factors for Distillates (No. 1 and No. 2 Fuel Oil)

Pollutant	No. 1 Fuel Oil Emission Factor ^a (g/MJ)	No. 2 Fuel Oil Emission Factor ^a (g/MJ)
Carbon Dioxide (CO ₂)	66.0233	68.47998
Carbon Monoxide (CO)	1.54E-002	1.54E-002
Methane (CH ₄)	6.63E-004	6.63E-004
Nitrogen Oxides (NO _x)	6.14E-002	7.37E-002
Nitrous Oxide (N ₂ O)	3.38E-004	3.38E-004
Sulphur Dioxide (SO ₂) ^b	4.36E-001	4.82E-001
Particulate Matter (PM) ^c	6.14E-003	6.14E-003
Particulate Matter (PM10) ^c	3.32E-003	3.32E-003
Particulate Matter (PM2.5) ^c	2.55E-003	2.55E-003

Table 23.4: Emission Factors for Distillates (No. 1 and No. 2 Fuel Oil)

Pollutant	No. 1 Fuel Oil Emission Factor ^a (g/MJ)	No. 2 Fuel Oil Emission Factor ^a (g/MJ)
Ammonia (NH ₃)	0 ^d	0 ^d
Volatile Organic Compounds (NMVOC)	1.04E-003	1.04E-003
Mercury (Hg)	3.47E-006	3.47E-006
Lead (Pb)	4.64E-006	4.64E-006

a: Based on data from Tables 1.3-1, 1.3-3, 1.3-8, 1.3-10 and 1.3-12 in EPA (1998b).

b: Based on 100% conversion of fuel sulfur to SO₂. Assumes 1% sulfur content.

The SO₂ emission factor in this table can be converted to other natural gas sulfur contents by multiplying the SO₂ emission factor by percentage sulfur content.

c: PM is the sum of all particulate matter including PM10 and PM2.5. PM10 and PM2.5 stand for particles smaller than 10 and 2.5 microns, respectively.

d: No data.

Table 23.5: Emission Factors for Residential Oil Furnace

Pollutant	Emission Factor ^a (g/MJ)
Carbon Dioxide (CO ₂)	68.48237
Carbon Monoxide (CO)	1.53543E-02
Methane (CH ₄)	5.46612E-02
Nitrogen Oxides (NO _x)	5.52753E-02
Nitrous Oxide (N ₂ O)	1.53543E-04
Sulphur Dioxide (SO ₂) ^b	4.36061E-01
Particulate Matter (PM) ^c	2.14960E-02
Particulate Matter (PM10) ^c	1.58763E-02
Particulate Matter (PM2.5) ^c	5.89603E-03
Ammonia (NH ₃)	0 ^d
Volatile Organic Compounds (NMVOC)	2.18952E-03
Mercury (Hg)	3.47006E-06
Lead (Pb)	4.63699E-06

a: Based on data from Tables 1.3-1, 1.3-3, 1.3-8, 1.3-10, and 1.3-12 in EPA (1998b).

b: Based on 100% conversion of fuel sulfur to SO₂. Assumes 1% sulfur content.

Table 23.5: Emission Factors for Residential Oil Furnace

Pollutant	Emission (g/MJ)	Factor ^a
The SO ₂ emission factor in this table can be converted to other natural gas sulfur contents by multiplying the SO ₂ emission factor by percentage sulfur content.		
c: PM is the sum of all particulate matter including PM10 and PM2.5. PM10 and PM2.5 stand for particles smaller than 10 and 2.5 microns, respectively.		
d: No data.		

Table 23.6: Emission Factors for LPG (butane and propane)

Pollutant	LPG (butane) Emission Factor ^a (g/MJ)	Propane Emission Factor ^a (g/MJ)
Carbon Dioxide (CO ₂)	66.0233	68.47998
Carbon Monoxide (CO)	1.54E-002	1.54E-002
Methane (CH ₄)	6.63E-004	6.63E-004
Nitrogen Oxides (NO _x)	6.14E-002	7.37E-002
Nitrous Oxide (N ₂ O)	3.38E-004	3.38E-004
Sulphur Dioxide (SO ₂) ^b	4.36E-001	4.82E-001
Particulate Matter (PM) ^c	6.14E-003	6.14E-003
Particulate Matter (PM10) ^c	3.32E-003	3.32E-003
Particulate Matter (PM2.5) ^c	2.55E-003	2.55E-003
Ammonia (NH ₃)	0 ^d	0 ^d
Volatile Organic Compounds (NMVOC)	1.04E-003	1.04E-003
Mercury (Hg)	3.47E-006	3.47E-006
Lead (Pb)	4.64E-006	4.64E-006

a: Based on data from Table # 1.5-1 in EPA (1996); Higher Heating value of 1.02 MMBtu/gal for butane and 0.915 MMBtu/gal for propane based on data in EPA (1996).

b: Based on 100% conversion of fuel sulfur to SO₂. Assumes sulphur content is 0.18 gr/100 ft³. The SO₂ emission factor can be converted to other LPG sulphur contents by multiplying the SO₂ emission factor by the ratio of the site-specific sulphur content gr/100 ft³ to 0.18 gr/100 ft³.

c: PM is the sum of all particulate matter including PM10 and PM2.5. PM10 and PM2.5 stand for particles smaller than 10 and 2.5 microns; respectively.

Table 23.6: Emission Factors for LPG (butane and propane)

Pollutant	LPG (butane) Emission Factor ^a (g/MJ)	Propane Emission Factor ^a (g/MJ)
d: No data.		

Table 23.7: Emission Factors for Gasoline and Diesel

Pollutant	Gasoline Emission Factor ^a (g/MJ)	Diesel Emission Factor ^a (g/MJ)
Carbon Dioxide (C) ₂)	66.20808	70.50731
Carbon Monoxide (CO)	2.70E+001	4.08E-001
Methane (CH ₄)	0 ^c	0 ^c
Nitrogen Oxides (NO _x)	7.01E-001	1.90E+000
Nitrous Oxide (N ₂ O)	0 ^c	0 ^c
Sulphur Dioxide (SO ₂)	3.61E-002	1.25E-001
Particulate Matter (PM) ^a	0 ^c	0 ^c
Particulate Matter (PM10) ^a	4.30E-002	1.33E-001
Particulate Matter (PM2.5) ^a	0 ^c	0 ^c
Ammonia (NH ₃)	0 ^c	0 ^c
Volatile Organic Compounds (NMVOC)	9.03E-001	1.50E-001
Mercury (Hg)	0	0
Lead (Pb)	0	0

a: Based on data from Table # 3.3-1 in EPA (1996); Diesel higher heating value of 19300 Btu/lb and gasoline higher heating value of 20300 Btu/lb based on data in EPA (1996).

b: PM is the sum of all particulate matter including PM10 and PM2.5. PM10 and PM2.5 stand for particles smaller than 10 and 2.5 microns; respectively.

c: No data.

Table 23.8: Emission Factors for Coal

Pollutant	Bituminous Emission Factor ^a (g/MJ)	Anthracite Emission Factor ^b (g/MJ)	Lignite Emission Factor ^c (g/MJ)
Carbon Dioxide (CO ₂)	91.11052	99.26669	152.12646

Table 23.8: Emission Factors for Coal

Pollutant		Bituminous Emission Factor ^a (g/MJ)	Anthracite Emission Factor ^b (g/MJ)	Lignite Emission Factor ^c (g/MJ)
Carbon Monoxide (CO)		8.27E-003	1.05E-002	8.27E-003
Methane (CH ₄)		6.61E-004	0 ^f	0 ^f
Nitrogen Oxides (NO _x)		1.98E-001	3.15E-001	2.35E-001
Nitrous Oxide (N ₂ O)		4.96E-004	0 ^f	0 ^f
Sulphur Dioxide (SO ₂) ^d		6.28E-001	6.82E-001	9.92E-001
Particulate Matter (PM) ^e		1.65E-001	1.75E-001	2.18E-001
Particulate Matter (PM10) ^e		3.80E-002	4.02E-002	7.61E-002
Particulate Matter (PM2.5) ^e		9.92E-003	1.05E-002	2.18E-002
Ammonia (NH ₃)		0 ^f	0 ^f	0 ^f
Volatile Organic Compounds (NMVOC)	Or-	9.92E-004	2.15E-002	1.32E-003
Mercury (Hg)		6.94E-006	2.27E-006	2.74E-006
Lead (Pb)		1.37E-006	1.56E-004	1.39E-005

a: Based on data on pulverized coal from Tables 1.1-3, 1.1-6, 1.1-18, 1.1-19 in EPA (1998a), Coal average higher heating value of 26.0 MMBtu/ton based on EPA (1998a).

b: Based on data on pulverized coal from Tables 1.2-1, 1.2-2, 1.2-3, 1.2-4, 1.2-7 in EPA (1996), Coal average higher heating value of 24.6 MMBtu/ton based on EPA (1996).

c: Based on data on pulverized coal from Tables 1.7-1, 1.7-3, 1.7-7, 1.7-14 in EPA (1998b), Coal average higher heating value of 13.0 MMBtu/ton based on EPA (1998b).

d: Based on 100% conversion of fuel sulfur to SO₂. Assumes 1% sulfur content. The SO₂ emission factor in this table can be converted to other natural gas sulfur contents by multiplying the SO₂ emission factor by percentage sulfur content.

e: PM is the sum of all particulate matter including PM10 and PM2.5. PM10 and PM2.5 are particles smaller than 10 and 2.5 microns, respectively. Expressed in terms of coal ash content, assumes 1% ash content. Multiply weight % ash content of coal (as fired) by the value.

f: No data.

23.1.4 Off-Site Electricity Generation Emissions

While estimating emissions from on-site fossil fuel combustion can be fairly straight-forward, emissions from off-site electricity is more challenging. How the electricity is generated, i.e., from gas, oil, coal, nuclear, renewable sources (wind, PV) or hydroelectric, and the mix of generation determines the resulting level of emissions. While data are available at utility and even power plant level (from the sources cited), data are shown here for United States national- and state-level average emissions from electricity generation. Table 23.9 provides average greenhouse gas and precursors and criteria pollutant emissions factors for the entire United States from electricity generation. Table 23.10 provides average electricity emissions factors by state, for greenhouse gas and precursors, and Table 23.11 for criteria pollutant emission factors. These two tables also include a ratio of heat input to electric output (efficiency of electricity generation) including distribution and transmission losses to allow calculation of source energy.

As mentioned in the introduction to this section, EnergyPlus also calculates water consumed through evaporation in thermo-electric and hydro-electric generation. Torcellini, Long, and Judkoff (2004) provide data on average water consumption by generator type by state. These data are summarized in units suitable for EnergyPlus in Table 23.9, for national and state average water consumption for thermal-electric, hydro-electric, and Table 23.10 for weighted total electricity generation.

Table 23.9: United States National Average Emission Factors for Electricity Generation

	Efficiency (J/J)	Ratio
Ratio of Heat Input to Electricity Output ^a	2.253	
Pollutant	Emission (g/MJ)	Factor
Carbon Dioxide (CO ₂) ^b	168.333168	
Carbon Monoxide (CO) ^c	4.20616E-02	
Methane (CH ₄) ^b	1.39858E-03	
Nitrogen Oxides (NO _x) ^a	4.10753E-01	
Nitrous Oxide (N ₂ O) ^b	2.41916E-03	
Sulphur Dioxide (SO ₂) ^a	8.65731E-01	
Particulate Matter (PM) ^{c,d}	2.95827E-02	
Particulate Matter (PM10) ^{c,d}	1.80450E-02	
Particulate Matter (PM2.5) ^{c,d}	1.15377E-02	
Ammonia (NH ₃) ^c	1.10837E-03	
Volatile Organic Compounds (NMVOC) ^a	3.72332E-03	
Mercury (Hg) ^c	3.36414E-06	

Table 23.9: United States National Average Emission Factors for Electricity Generation

	Efficiency (J/J)	Ratio
Lead (Pb)	0 ^e	
a: Data based on 1999 data from *eGRID* version 2.01 (EPA 2003a).		
b: Data based on 1998-2000 average data in DOE (2002).		
c: Data based on tier emissions report for criteria air pollutants in EPA (2003b).		
d: PM is the sum of all particulate matter including PM10 and PM2.5. PM10 and PM2.5 stand for particles smaller than 10 and 2.5 microns, respectively.		
e: No data.

a: Based on data from Torcellini, Long, and Judkoff (2004).

23.1.5 Other Energy-Related Pollutants and Sources of Other Information

EnergyPlus (with user entered-data) will also calculate high- and low-level nuclear waste from electricity generation. Few utilities now provide data on nuclear waste resulting from electricity generation and no US national or state-level data are yet available (this will be added as data become available). Two Illinois utilities regularly report nuclear waste in terms of pounds per kWh or MWh for high-level waste and cubic feet per kWh or MWh for low-level waste. For these two utilities, high level nuclear waste values range from 0.0042 to 0.01 lb/MWh (7000 to 16000 g/MJ); low-level nuclear waste ranges from 0.0001 to 0.0002 ft³/MWh (0.01 to 0.02 m³/MJ) depending on relative proportion of nuclear as compared with other electricity generation sources.

IEA (2003) contains carbon dioxide (CO₂) emissions factors for electricity generation by country and region. Carbon dioxide (CO₂) is responsible for over 60% of the anthropogenic greenhouse effect (UNEP 2002). Because only limited greenhouse gas emissions factors and data (other than CO₂) is available for other countries, an interim method for estimating emission factors would be to compare the CO₂ emission factor for the particular country from IEA (2003) and match it to the state with the closest CO₂ emission factor in Table 23.10—using the other emissions factors for that state. Since the Kyoto Protocol (UNFCCC 1997) requires each country to report emissions of the major greenhouse gases [carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O)] as well as ozone-depleting substances [hydrofluorocarbons (HFC), perfluorocarbons (PFC), and sulphur hexafluoride (SF₆)] and all energy consumption in their annual ‘national communication’, more complete emission factors for a larger number of countries should become available over the next few years. More information and other resources for calculating emissions factors are available in IPCC (2000, 1997).

23.2 Component Loads Summary

Many building energy simulation programs provide reports that breakdown the design load into component contributions from walls, roofs, floors, underground walls, windows, interior walls, infiltration, ventilation, occupancy, lighting, refrigeration cases, and internal equipment. Some of these components have both sensible and latent subcomponents. It is important to understand the difference between gains and loads. ASHRAE Handbook of Fundamentals 2009 describes the space heat gain as “...the rate at which heat enters into and/or is generated within a space” while the space cooling load is “the rate at which sensible and latent heat must be removed from the space to maintain a constant space air temperature and humidity.” The difference is that the radiant heat gains which is “absorbed by walls, floors, furniture, etc., contributed to the space cooling load only after a time lag.”

The heat balance algorithms used by EnergyPlus result in a single combined design load for a given zone and some, but not all, of the zone instantaneous heat gains. This section describes the estimation procedure for the three Component Loads Summary reports that shows an estimated breakdown of load components from each type of heat gain for each zone. The three different reports are the Zone Component Loads Summary, the AirLoop Component Loads Summary and the Facility Component Loads Summary. The procedure described below is used for each zone and then the AirLoop and Facility level reports are generated by aggregating the results for the appropriate zones.

If the time of the peak load for each Zone for cooling exactly matches the time of the peak load for the AirLoop or Facility then the Estimated Cooling Peak Load Components will represent a sum of the values from the corresponding zones. Likewise the Estimated Heating Peak Load Components will add up for the AirLoop or Facility if the times of the heating peaks exactly match. This is not necessarily the case for Peak Conditions or the Engineering Checks tables. Since the sizing of Airloops is based on the system sizing they usually will be different than the sum of the

corresponding zones.

The Estimated Cooling Peak Load Components and Estimated Heating Peak Load Components subtables of the Zone Component Loads Summary report contain values that are estimated and are not part of the normal heat balance algorithms used in the rest of EnergyPlus. In particular, the column described as Sensible-Delayed represents an estimate of the sensible load contributed at the peak time based on radiant contributions from various load components that have radiant portions in previous timesteps. The focus of this section will be on the Sensible-Delayed column.

The columns labeled Sensible-Instant, Sensible-Return Air, and Latent are directly computed for people, lights, equipment, refrigeration, water use equipment, HVAC equipment losses, power generation equipment, infiltration, zone ventilation and interzone mixing. For example, Lights objects have inputs for the fractions of the gains that are to return air, radiant, visible and the remainder is convected. In this case, the fraction to return air is reported in the Sensible Return Air column and the fraction that is convected is reported in the Sensible-Instant column.

At the time of the peak load, each surface in the zone is contributing a convective heat loss or heat gain depending on the inside surface temperature.

The radiant portion of the internal heat gains from lighting, equipment, and incident solar are radiantly transmitted to the surfaces of the zone. The heat from these radiant gains is stored in the surfaces and retransmitted back into the zone over time as convective gains to the zone. By the time the heat is retransmitted, it is impossible to know the contribution of each possible radiant gain from past time steps on that surface into the convective gain for that timestep. The temperature change of the surface includes the impact of all of these radiant gains as well as any heat transfer through the surface.

To disaggregate the delayed affect of zone radiant (delayed) portions of the peak load, a pulse of radiant internal loads is used to determine custom radiant to convective decay curves for heating and cooling, essentially replicating part of the method used for Radiant Time Series (see Chapter 18 of ASHRAE Handbook of Fundamentals 2009) to isolate the delayed impacts of internal loads. This is performed during the zone sizing routines.

The response of each surface to a pulse of radiant heat is used to estimate the peak load components for solar gains and the radiant portion of internal gains. Subtracting these for each surface then leaves the peak load component from conduction through the surfaces. The approach is described in more detail below:

- 1) When zone sizing is performed for cooling or heating, the heat convected from each opaque surface for each timestep during sizing day is saved to an array.
- 2) For each type of internal gain, HVAC equipment gain, and solar energy entering the zone, the radiant and convective portions are saved for every timestep during sizing. In addition, for each type of radiant gain, the amount that lands on each surface in the zone is saved for every timestep during sizing.
- 3) An additional “pulse sizing” run is performed for cooling and heating during zone sizing that includes an additional small, single timestep, pulse of radiant-only heat for each zone but is otherwise the same as a normal zone sizing simulation. This is equivalent to adding an ElectricEquipment object that is scheduled for a single timestep and is 100% radiant heat. The heat convected from each opaque surface for each timestep during sizing is saved to an array. This run is not used for sizing, but just to gather the impact of the pulse of radiant heat.

- 4) For each surface, a “decay curve” is developed by subtracting the results from the normal sizing (1) from the “pulse” sizing run (3). This represents the delay in converting incoming radiant heat into convected heat for each surface in the zone. The graphs below show the decay curves for an exterior wall (RIGHT-1) and an interior wall (SB23) for a test file.

Figure 23.3: Load Component - Decay Curve of Exterior Wall

- 5) Using the internal and solar gain results saved from the normal sizing period in step (2), for each timestep prior to and including the time of the peak load during the sizing day, the decay curve is applied to each radiant gain on each surface for each timestep to generate a predicted delayed load component for the internal and solar gains for each timestep that comprise the peak load (based on Timesteps in Averaging Window). Timesteps just before the peak have much larger impacts than those just a few timesteps before the peak. These results will be the radiant portion of the load for each type of internal and solar gain.
- 6) The difference between the sum of the predicted convective loads from internal and solar gains from step (5) and the total convective loads for that surface for the timesteps that comprise the peak load from step (1) is assumed to be the load from heat transfer through that surface. This is essentially subtracting out the radiant portions of the internal and solar gains on each surface for the sizing day.

Figure 23.4: Load Component - Decay Curve of Interior Wall

23.2.1 Estimated Component Load Details

In `HeatBalanceInternalHeatGains`, in the `InitInternalHeatGains` routine, the single timestep pulse is added to the thermal radiation absorbed on the inside surface. It is based on 0.01 W per square meter of the zone area. The time of the pulse and the amount received by each surface is also saved. A new routine `GatherComponentLoadsIntGain` was also added to that file that gathers the instantaneous heat gains from people, lights, equipment, refrigeration equipment, water use, hvac losses, and power generation. Latent gains from people and refrigeration are also gathered along with the radiant portion of the gains from these same sources. `EnergyPlus` tracks internal gains by type, and these are grouped as follows for the rows of the report:

The gains from “People” contain:

- `IntGainTypeOf_People`

The gains from “Lights” contain:

- `IntGainTypeOf_Lights`

The gains from “Equipment” contain:

- `IntGainTypeOf_ElectricEquipment`
- `IntGainTypeOf_ElectricEquipmentITEAirCooled`
- `IntGainTypeOf_GasEquipment`
- `IntGainTypeOf_HotWaterEquipment`
- `IntGainTypeOf_SteamEquipment`
- `IntGainTypeOf_OtherEquipment`

The gains from “Refrigeration” contain:

- `IntGainTypeOf_RefrigerationCase`
- `IntGainTypeOf_RefrigerationCompressorRack`
- `IntGainTypeOf_RefrigerationSystemAirCooledCondenser`
- `IntGainTypeOf_RefrigerationSystemSuctionPipe`
- `IntGainTypeOf_RefrigerationSecondaryReceiver`
- `IntGainTypeOf_RefrigerationSecondaryPipe`
- `IntGainTypeOf_RefrigerationWalkIn`
- `IntGainTypeOf_RefrigerationTransSysAirCooledGasCooler`
- `IntGainTypeOf_RefrigerationTransSysSuctionPipeMT`

- IntGainTypeOf_RefrigerationTransSysSuctionPipeLT

The gains from “Water Use Equipment” contain:

- IntGainTypeOf_WaterUseEquipment
- IntGainTypeOf_WaterHeaterMixed
- IntGainTypeOf_WaterHeaterStratified

The gains from “HVAC Equipment Losses” which are gains to the zone due to the location of the equipment within the zone include:

- IntGainTypeOf_ZoneBaseboardOutdoorTemperatureControlled
- IntGainTypeOf_ThermalStorageChilledWaterMixed
- IntGainTypeOf_ThermalStorageChilledWaterStratified
- IntGainTypeOf_PipeIndoor
- IntGainTypeOf_Pump_VarSpeed
- IntGainTypeOf_Pump_ConSpeed
- IntGainTypeOf_Pump_Cond
- IntGainTypeOf_PumpBank_VarSpeed
- IntGainTypeOf_PumpBank_ConSpeed
- IntGainTypeOf_PlantComponentUserDefined
- IntGainTypeOf_CoilUserDefined
- IntGainTypeOf_ZoneHVACForcedAirUserDefined
- IntGainTypeOf_AirTerminalUserDefined
- IntGainTypeOf_PackagedTESCoilTank
- IntGainTypeOf_FanSystemModel
- IntGainTypeOf_SecCoolingDXCoilSingleSpeed
- IntGainTypeOf_SecHeatingDXCoilSingleSpeed
- IntGainTypeOf_SecCoolingDXCoilTwoSpeed
- IntGainTypeOf_SecCoolingDXCoilMultiSpeed
- IntGainTypeOf_SecHeatingDXCoilMultiSpeed

The gains from “Power Generation Equipment” include:

- IntGainTypeOf_GeneratorFuelCell
- IntGainTypeOf_GeneratorMicroCHP
- IntGainTypeOf_ElectricLoadCenterTransformer
- IntGainTypeOf_ElectricLoadCenterInverterSimple
- IntGainTypeOf_ElectricLoadCenterInverterFunctionOfPower
- IntGainTypeOf_ElectricLoadCenterInverterLookUpTable
- IntGainTypeOf_ElectricLoadCenterStorageBattery

The ReportSurfaceHeatBalance routine in the HeatBalanceSurfaceManger module gathers the shortwave radiant heat gain from lighting and fenestration solar gains on each surface. In the same module, the CalcHeatBalanceInsideSurf routine gathers the surface by surface convection for both the normal and pulse zone sizing times along with the net radiation on the surface during the normal zone sizing times. In addition, a routine called GatherComponentLoadSurfAbsFact gathers the factors used in distributing the radiant heat from a zone to each surface (TMULT and ITABSF).

The SizingManager module repeats the zone sizing portion of the procedure when this report is requested. The pulse occurs at 10am during the zone sizing simulations. The 10am time was chosen after some testing that looked at pulses at different times of the day. It is important that the pulse occurs while the system is running and stable not during start up hours. In addition, the plus timing needs to be early enough that the duration of the resulting decay curve can be appropriately applied to as many timesteps as possible during the peak day.

The following subroutines in the OutputReportTabular module produce the report:

- ComputeLoadComponentDecayCurve
- GatherComponentLoadsSurface
- GatherComonentLoadsHVAC
- WriteLoadComponentSummaryTables
- GetDelaySequences
- MovingAvgAtMaxTime
- ComputeTableBodyUsingMovingAvg

The ComputeLoadComponentDecayCurve routine determines the heating and cooling decay curves using the following (for cooling but repeated also for heating):

```

TimeOfPulse = radiantPulseTimestep(ZoneNum,CoolDesSelected)
DO TimeStep = TimeOfPulse, NumOfTimeStepInHour* 24
  IF (radiantPulseReceived(surfNum,CoolDesSelected) .NE. 0.0) THEN
    diff = loadConvectedWithPulse(surfNum,TimeStep,CoolDesSelected)
          - loadConvectedNormal(surfNum,TimeStep,CoolDesSelected)
    decayCurveCool(surfNum, TimeStep - TimeOfPulse + 1) = -diff /
      radiantPulseReceived(surfNum,CoolDesSelected)
  ELSE
    decayCurveCool(surfNum, TimeStep - TimeOfPulse + 1) = 0.0
  END IF
END DO

```

The `ComputeTableBodyUsingMovingAvg` routine applies the decay curve to the load components. It does the following for the heating and cooling sizing period that was selected and for each zone and each surface in the zone

- a. Determine the heat gain on the surface of people, equipment, hvac losses, power generation and long wave light radiation.
- b. For each time step backwards from the current timestep, estimate the delayed convected heat from people, equipment, HVAC losses, power generation, lighting long wave radiation, lighting short wave radiation, and fenestration solar by multiplying the decay curve with the value determined from (a).
- c. Accumulate the values on a zone basis
- d. Determine the remaining convective heat from surfaces that are not from these gains and remove the net surface radiation (output variable `Surface Inside Face Convection Heat Gain Rate`)
- e. Store the estimated values in a sequence to be later averaged over the averaging window.

23.3 Output:Table:Annual

No special algorithms were employed to implement the `Output:Table:Annual` object.

23.4 Heat Emissions

Heat emissions from buildings are a crucial component influencing climate change and urban microclimate, e.g., urban heat island effect. The heat emissions from a building include heat releases from three levels of building systems: building envelope, zone/space, and HVAC systems. Quantifying heat emissions from buildings and its spatiotemporal distribution have significant implications on urban environment and climate studies. Knowing how much heat is released into the atmosphere can help quantify the magnitude of its impact on urban microclimate, e.g., urban heat island effect and climate change. Spatial and temporal distribution of heat emissions can serve to locate hot spots in space and time, therefore useful for prioritizing recourse to mitigate heat emissions from buildings.

This routine calculates heat emissions from buildings and the scope is restricted to report the buildings' heat directly discharged to the ambient air. As shown in the figure, the emissions include heat releases from three levels of building components: (1) building envelope - exterior surface convection and radiative heat transfer to the ambient air, (2) zone - exhaust air or exfiltration to ambient, (3) HVAC system - relief/exhaust air from AHUs, and (4) HVAC system - heat rejected by air-cooled condensers or central plants, including cooling towers of water-cooled chillers, gas-fired boilers, furnaces and water heaters. It should be noted that any under-ground zone or envelope is excluded, since heat from those spaces is rejected to ground instead of to ambient air.

The calculated heat emissions measure the heat transfer from buildings to their ambient environment, and can have both positive and negative values. The positive values indicate the building injects heat to the environment, while the negative values indicate the building extracts heat from the environment.

Figure 23.5: Building released heat compositions

For heat transfer via air flow, both the sensible and latent heat emissions are calculated and reported.

23.4.1 Heat Emission from Building Envelope

Exterior surfaces emit heat to ambient air in the form of convection and long-wave radiation, which could be absorbed by particles and gas molecules in air. The internal sources modify the outside surface temperature through envelope conduction, along with incident solar radiation, which triggers the heat exchange with the ambient air. This part does not include the long-wave radiation from surfaces to the sky or the ground. The surface outside face heat emission rate is calculated as:

$$Q_{\text{emission,surf}} = Q_{\text{conv,surf}} + Hr * A * (T_{\text{surf}} - T_{\text{out}}) \quad (23.1)$$

where $Q_{\text{conv,surf}}$ is the surface outside face convection heat gain rate, Hr is the surface outside face thermal radiation to air heat transfer coefficient, A is the surface area, T_{surf} and T_{out} are the surface and outdoor air temperature.

23.4.2 Heat Emission from Zones

Discharge air carries heat to ambient at the zone level from exfiltration and exhaust fan. Exfiltration is unintended airflow to outside through envelope cracks, as opposite to infiltration. Zones such as restroom, kitchen and laundry room may be equipped with exhaust fans for active venting. These items can be quantified by:

$$Q_{exf,zone} = m_{exf}(h_{zone} - h_{out}) \quad (23.2)$$

$$Q_{exh,zone} = m_{exh}(h_{zone} - h_{out}) \quad (23.3)$$

where m_{exf} is the exfiltration air mass flow rate, m_{exh} is the zone exhaust air mass flow rate from the zone exhaust node, h_{zone} and h_{out} are the zone and outdoor air enthalpy. Among these, the sensible parts are:

$$Q_{exf,zone,sensible} = m_{exf} * c * (T_{zone} - T_{out}) \quad (23.4)$$

$$Q_{exh,zone,sensible} = m_{exh} * c * (T_{zone} - T_{out}) \quad (23.5)$$

where c is the specific heat of air, T_{zone} and T_{out} are the zone and outdoor air temperature. And the latent parts are determined by taking the difference between the total and the sensible rate. For each zone, its exfiltration rate is calculated by solving a mass flow balance on the zone including infiltration, ventilation, outdoor air mixing, zone-to-zone mixing, and all of the zone inlet, exhaust, and return nodes.

This part of zone exhaust only includes the exhaust heat at the zone level defined by **Fan:ZoneExhaust** or **AirflowNetwork:MultiZone:Component:ZoneExhaustFan**. For each zone, we aggregated this part by searching its exhaust fans. The exhaust heat from Zone HVAC system nodes is included in the next item.

23.4.3 Heat Emission from HVAC Systems through Relief Air

HVAC systems relieve heat from system outdoor air relief nodes, and the total and sensible emission rate are calculated as:

$$Q_{exh,sys} = m_{exh}(h_{node} - h_{out}) \quad (23.6)$$

$$Q_{exh,sys,sensible} = m_{exh} * c * (T_{node} - T_{out}) \quad (23.7)$$

And the latent parts are determined by taking the difference between the total and sensible rate.

The air exchange with outdoor is represented with an **OutdoorAir:Mixer** object in the **Air-LoopHVAC:OutdoorAirSystem** object. This part is aggregated and reported by each **Controller:OutdoorAir** object.

23.4.4 Heat Rejection from HVAC System Equipment

HVAC system equipment also directly exchanges heat with ambient air via refrigeration cycle and its energy usage. For example, for gas-fired boilers/heaters, waste heat is exhausted to outside together with combustion byproduct. For space cooling, heat is removed from indoors and dumped to outdoor at the condenser side or corresponding cooling equipment, such as cooling tower. In addition, energy consumed by outdoor equipment will directly dissipate to the ambient air, such as compressors and fans in packaged DX systems. The surface outside face heat emission rate is calculated as:

- (1) Gas-powered combustion unit: Fuel generated heat - fuel heat supply
- (2) Condensing unit:
 - a. Air-cooled: cooling rate + electric power of condenser fan and compressor
 - b. Water-cooled: total heat transfer rate with outdoor air

Detailed calculation of HVAC rejected heat varies with different HVAC object groups and component types, as summarized in Table 23.14.

Table 23.14: Heat Rejection Calculation for Different HVAC Component Types

Object Group	Component	Calculation Methods
Coils	Chilled water cooling coil	Emit heat in condensing unit defined in Condenser Equipment
	Heating coil (fuel heated)	Fuel Consumed + Heating Coil Defrost Electric Consumption + Heating Coil Crankcase Heater Electric Consumption – Heating Coil Total Heating Energy
	Hot water/steam heating coil	Emit heat in plant source defined in Plant Heating and Cooling Equipment
	DX cooling coil (air-cooled)	Cooling Coil Source Side Heat Transfer Rate + Cooling Coil Electric Power + Cooling Coil Crankcase Heater Electric Energy + Fuel Waste Heat
	DX cooling coil (Evaporatively-cooled)	Evaporative Cooler Condenser Pump Electricity Consumption + Cooling Coil Basin Heater Electric Energy + Evaporative Cooler Water Volume * rho * evaporation heat of water (δH_{we})
	DX VRF cooling coil	Emit heat in condensing unit defined in Variable Refrigerant Flow Equipment
	DX heating coil (air-cooled)	Heating Coil Electric Power / Fuel Consumed + Heating Coil Defrost Electric Power + Heating Coil Crankcase Heater Electric Power – Heating Coil Total Heating Rate
	Water to air heat pump	Emit heat in condensing unit defined in Condenser Equipment
Evaporative Coolers	DX VRF cooling /heating coil	Emit heat in condensing unit defined in Variable Refrigerant Flow Equipment
	Evaporative Coolers	Evaporative Cooler Condenser Pump Electricity Consumption + Cooling Coil Basin Heater Electric Energy + Evaporative Cooler Water Volume * rho * evaporation heat of water (δH_{we})

Table 23.14: Heat Rejection Calculation for Different HVAC Component Types

Object Group	Component	Calculation Methods
Variable Re- frigerant Flow Equipment	VRF air-to-air heat pump condensing unit (air-cooled)	VRF Heat Pump Total Cooling Rate + VRF Heat Pump Total Electric Power (cooling mode) VRF Heat Pump To- tal Heating Electric Power / Fuel Rate - VRF Heat Pump Total Heating Rate (heating mode)
	VRF air-to-air heat pump condensing unit (evaporative-cooled)	Evaporative Cooler Condenser Pump Elec- tricity Consumption + Cooling Coil Basin Heater Electric Energy + Evaporative Cooler Water Volume * rho * evaporation heat of water (δH_{we})
	VRF air-to-air heat pump condensing unit (water- cooled)	VRF Heat Pump Condenser Heat Transfer Rate
Plant Heating and Cooling Equipment	Hot water/Steam boiler	Boiler <Fuel Type> Rate + Boiler Ancil- lary Electric Energy - Boiler Heating Rate
	Chiller water-cooled	Emit heat in Condenser Equipment
	Chiller air-cooled / evap- cooled	Chiller Condenser Heat Transfer Rate
Condenser Equipment	Cooling Tower	Cooling Tower Heat Transfer Rate + Cool- ing Tower Fan Electric Power
Water Heaters and Thermal Storage	Water heater	Water Heater <Fuel Type> Rate - Water Heater Heating Rate
Zone HVAC Forced Air Units	Window air conditioner / Packaged terminal air con- ditioner (PTAC) / Pack- aged terminal heat pump (PTHP); Energy recovery ventilator (ERV); Unit ven- tilator/heater; Zone outdoor air unit	<unit type> Total Cooling Rate + <unit type> Electric Energy (cooling mode) <unit type> Heating Electric Power / Fuel Rate + <unit type> Electric Power - <unit type> Total Heating Rate (heating mode)
	Water-to-air heat pump	Emit heat in condensing unit defined in Condenser Equipment
	Zone evaporative cooler	Emit heat in condensing unit defined in Evaporative Coolers

Table 23.14: Heat Rejection Calculation for Different HVAC Component Types

Object Group	Component	Calculation Methods
	Hybrid Unitary HVAC	System dependent; Calculated according to the equipment specification as above

There are several types of components for which the heat rejection is not clearly defined. The following are not included in the heat emissions report:

- User defined systems have a variety of possible sources of heat emission including outdoor air relief for exhaust or a condenser outlet for heat rejection. These parts can be counted by tracing the condensing unit linked to the air connection inlet and outlet (for user defined zone HVAC and plant component).
- For user defined coil, this part depends on how the coil is designed and equipped. We do not count this in report.
- ThermalStorage:Ice:* do not indicate where losses go, so we neglect this.

By summing up these components, the heat emissions are calculated and reported from buildings by systems and components as well as in total.

23.5 Resilience Metrics

With increasing frequency and severity of extreme weather events (e.g., heat waves), it is crucial to ensure urban buildings and infrastructure are resilient to provide critical services to preserve human life and properties during natural disasters. Building resilience has the opportunity to become an additional value proposition for technologies and systems if it can be reliably quantified, valued, and trusted by stakeholders. Metrics or an assessment of potential vulnerability, likelihood, and consequence for each risk would help to prioritize further consideration of these risk factors of building resilience [1]. Measuring the resilience of buildings help owners make better decisions and protect their assets, better assess the built environment resilience of larger geographic units such as communities and cities, and complement existing assessments of building sustainability.

The following metrics are added in EnergyPlus as optional report variables and summary tables in three aspect: thermal, visual, and CO_2 resilience. Each metric can be calculated and reported when users declare it as an input. The selected resilience metrics (e.g., thermal metrics: Heat Index, Humidex, and SET) are well defined, calculable, and have been adopted by government agency and industry.

23.5.1 Thermal Resilience

23.5.1.1 Heat Index

The heat index (HI) is an index that combines air temperature and relative humidity (Steadman 1979), in shaded areas, to posit a human-perceived equivalent temperature, as how hot it would feel

if the humidity were some other value in the shade. The HI measures the temperature feels like to the human body when relative humidity is combined with the air temperature. HI is widely used in the United States. The Occupational Safety and Health Administration (OSHA) uses HI as an indicator to assess heat stress [2]. This has important considerations for the human body's comfort. When the body gets too hot, it begins to perspire or sweat to cool itself off. If the perspiration is not able to evaporate, the body cannot regulate its temperature. When the atmospheric moisture content (i.e. relative humidity) is high, the rate of evaporation from the body decreases. In other words, the human body feels warmer in humid conditions. The opposite is true when the relative humidity decreases because the rate of perspiration increases.

Table 1 developed by U.S. National Oceanic and Atmospheric Administration (NOAA) is used to look up the heat index by temperature (°C) and relative humidity (%) [3]. The HI effects on human health are categorized at five levels: Safe, Caution, Extreme caution, Danger and Extreme danger, defined in Table 23.15 and color coded in Figure 23.6.

NOAA national weather service: heat index

Key to colors: Caution Extreme caution Danger Extreme danger

Figure 23.6: Heat Index lookup table

The computation of the heat index is a refinement of a result obtained by multiple regression analysis carried out by Lans P. Rothfus and described in a 1990 National Weather Service (NWS) Technical Attachment (SR 90-23) [4-5]. The calculation is based on degree Fahrenheit.

The regression equation of Rothfus is

$$HI = c_1 + c_2T + c_3R + c_4TR + c_5T^2 + c_6R^2 + c_7T^2R + c_8TR^2 + c_9T^2R^2 \quad (23.8)$$

where

HI = heat index (expressed as an apparent temperature in degrees Fahrenheit),

T = ambient dry-bulb temperature (in degrees Fahrenheit),

R = relative humidity (percentage value between 0 and 100),

$c_1 = -42.379$,

Table 23.15: Definition of four levels of Heat Index

Heat Index in Celsius	Heat Index in Fahrenheit	Heat Index Level
Less than 26.7 °C	Less than 80 °F	Safe: no risk of heat hazard
26.7 °C - 32.2 °C	80–90 °F	Caution: fatigue is possible with prolonged exposure and activity. Continuing activity could result in heat cramps.
32.2 °C - 39.4 °C	90–103 °F	Extreme caution: heat cramps and heat exhaustion are possible. Continuing activity could result in heat stroke.
39.4 °C - 51.7 °C	103–125 °F	Danger: heat cramps and heat exhaustion are likely; heat stroke is probable with continued activity.
over 51.7 °C	over 125 °F	Extreme danger: heat stroke is imminent.

$$\begin{aligned}
c_2 &= 2.04901523, \\
c_3 &= 10.14333127, \\
c_4 &= -0.22475541, \\
c_5 &= -0.00683783, \\
c_6 &= -0.05481717, \\
c_7 &= 0.00122874, \\
c_8 &= 0.00085282, \\
c_9 &= -0.00000199.
\end{aligned}$$

If the RH is less than 13% and the temperature is between 80 and 112 °F, then the following adjustment is subtracted from HI:

$$HI = (13 - R)/4 * ((17 - |T - 95|)/17)^{0.5} \quad (23.9)$$

Otherwise, if the RH is greater than 85% and the temperature is between 80 and 87 °F, then the following adjustment is added to HI:

$$HI = (R - 85)/10 * (87 - T)/5 \quad (23.10)$$

The Rothfusz regression is not appropriate when conditions of temperature and humidity warrant a heat index value below about 80 °F. In those cases, a simpler formula is applied to calculate values consistent with Steadman's results:

$$HI = 0.5 * (T + 61.0 + (T - 68.0) * 1.2 + (R * 0.094)) \quad (23.11)$$

In practice, the simple formula is computed first based on the temperature and humidity. If this heat index value is 80 °F or higher, the full regression equation along with any adjustment as described above is applied. The Rothfusz regression is not valid for extreme temperature and relative humidity conditions beyond the range of data considered by Steadman.

The Heat Index Hours (accumulated hours for a space) and Heat Index OccupantHours (accumulated hours for the sum of all occupants in a space) of each level for each zone and the whole building are reported under the Annual Thermal Resilience Report.

23.5.1.2 Humidex

The humidex (short for humidity index) is an index number used by Canadian meteorologists to describe how hot the weather feels to the average person, by combining the effect of heat and humidity. The term humidex was first coined in 1965 [6]. The humidex is a nominally dimensionless quantity (though generally recognized by the public as equivalent to the degree Celsius) based on the dew-point temperature [7].

The Humidex effects on human health are categorized at five levels: Little to no discomfort, Some discomfort, Great discomfort; avoid exertion, Dangerous and Heat stroke imminent, defined in Table 23.16 and color coded in Figure 23.7.

The humidex (H) formula is:

$$H = T_{air} + \frac{5}{9}(6.11 * \exp^{5417.7530 * (\frac{1}{273.16} - \frac{1}{273.15 + T_{dew}})} - 10) \quad (23.12)$$

Where,

H = the Humidex,

Figure 23.7: Humidex lookup table

Table 23.16: Definition of five levels of Humidex

Humidex Value	Humidex Level
Below 29	Little to no discomfort
29 to 40	Some discomfort
40 to 45	Great discomfort; avoid exertion
45 to 50	Dangerous
Above 50	Heat stroke imminent

T_{air} = the air temperature in °C,
 T_{dew} = the dew-point temperature in °C,
 $exp = 2.71828$.

The Humidex Hours (accumulated hours for a space) and Humidex OccupantHours (accumulated hours for the sum of all occupants in a space) of each level for each zone and the whole building are reported under the Annual Thermal Resilience Report.

23.5.1.3 Standard Effective Temperature Hours

Standard Effective Temperature (SET) is a model of human response to the thermal environment. Developed by A.P. Gagge and accepted by ASHRAE in 1986, SET is also referred to as the Pierce Two-Node model [8]. Its calculation is similar to PMV because it is a comprehensive comfort index based on heat-balance equations that incorporate personal factors of clothing and metabolic rate. Its fundamental difference is it takes a two-node method to represent human physiology in measuring skin temperature and skin wettedness. ASHRAE 55-2010 defines SET as "the temperature of an imaginary environment at 50% relative humidity, < 0.1 m/s [0.33 ft/s] average air speed, and mean radiant temperature equal to average air temperature, in which total heat loss from the skin of an imaginary occupant with an activity level of 1.0 met and a clothing level of 0.6 clo is the same as that from a person in the actual environment, with actual clothing and activity level" [9].

LEED Pilot Credit IPpc100 - Passive Survivability and Back-up Power During Disruptions - defines "Livable conditions" as SET between 54 °F and 86 °F. The credit requires buildings to maintain safe thermal conditions in the event of an extended power outage or loss of heating fuel, or provide backup power to satisfy critical loads. Accumulated SET-days and SET-hours are metrics to measure thermal safety and temperatures. The SET-days and SET-hours are degree-days and degree-hours in Celsius/Fahrenheit degrees based on the indoor SET.

LEED Passive Survivability defines the Thermal Safety Temperatures for Path 2 using the SET:

- Cooling: Not to exceed 9 °F SET-days (216 °F SET-hours) above 86 °F for residential buildings. (SI Metric: Not to exceed 5 °C SET-days (120 °C SET-hours) above 30 °C SET for residential buildings.)
- Cooling: Not to exceed 18 °F SET-days (432 °F SET-hours) above 86 °F SET for non-residential buildings. (SI Metric: Not to exceed 10 °C SET-days (240 °C SET-hours) above 30 °C SET for non-residential buildings.)
- Heating: Not to exceed 9 °F SET-days (216 °F SET-hours) for all buildings. (SI Metric: Not to exceed 5 °C SET-days (120 °C SET-hours) below 12 °C SET-hours for all buildings.)

EnergyPlus calculates and reports SET as a time-step report variable when Pierce method is chosen as the People's thermal comfort model. The aggregated the SET-Hours and the SET-OccupantHours (at zone level) for both cooling and heating are reported under the Annual Thermal Resilience Summary. The tables also include the longest continuous unmet time duration in hours and the start time of their occurrences (first occurrence if multiple time slots have the same duration).

Table 23.17: Indoor CO_2 levels required at various health conditions

Indoor CO_2 Concentration	CO_2 Level
≤ 1000 ppm	Normal
$\leq 5,000$ ppm and > 1000 ppm	Caution
$> 5,000$ ppm	Hazard

23.5.2 Indoor Air Quality - CO_2 Resilience

For indoor air quality, we chose to use CO_2 concentration at the zone level as an indicator. CO_2 at very high concentrations (e.g., greater than 5,000 ppm) can pose a health risk, referring to Appendix D Summary of Selected Air Quality Guidelines in ASHRAE Standard 62.1-2016, "Ventilation for Acceptable Indoor Air Quality". At concentrations above 15,000 ppm, some loss of mental acuity has been noted. The Occupational Safety and Health Administration (OSHA) of the US Department of Labor defined the Permissible Exposure Limits (PEL) and Short-Term Exposure Limit (STEL) of CO_2 level to be 5,000 ppm and 30,000 ppm accordingly [10].

CO_2 increases in buildings with higher occupant densities, and is diluted and removed from buildings with outdoor air ventilation. High CO_2 levels may indicate a problem with overcrowding or inadequate outdoor air ventilation. Thus, maintaining a steady-state CO_2 concentration in a space no greater than about 700 ppm above outdoor air levels will indicate that a substantial majority of visitors entering a space will be satisfied with respect to human bio-effluents (body odor). With outdoor CO_2 concentration varies from 350 to 500 ppm, we assume 1000 ppm is the safe threshold of indoor CO_2 concentration.

EnergyPlus calculates and reports the Zone Air CO_2 Concentration [ppm] as a report variable, and the thresholds of different levels defined in Table 23.17. The Annual CO_2 Resilience summary reports the Hours and OccupantHours of each level for each zone and the whole building.

To activate the CO_2 concentration calculation in EnergyPlus, the **ZoneAirContaminantBalance** object needs to be specified and with the field "**Carbon Dioxide Concentration**" set to Yes. Users can define a schedule of outdoor air CO_2 concentration in the field "**Outdoor Carbon Dioxide Schedule Name**". CO_2 generation rate at the zone level can be specified using the **ZoneContaminantSourceAndSink:CarbonDioxide** object.

23.5.3 Visual Resilience

Adequate indoor lighting level is crucial for occupant safety, health and productivity. The 10th edition of The Lighting Handbook published by IESNA recommends illuminance levels for various types of spaces in a building. The US General Services Administration provides lighting levels for US Government buildings (Table 23.18), which can be used as a guide for other types of buildings. The required light levels are indicated in a range because different tasks, even in the same space, require different amounts of light. In general, low contrast and detailed tasks require more light while high contrast and less detailed tasks require less light.

For resilience reporting purpose, we chose three thresholds: a bit dark - less than 100 lux, dim - 100 to 300 lux, adequate - 300 to 500 lux, bright - more than 500 lux.

Table 23.18: GSA recommended lighting levels

Room Type	Light Level (Foot Candles)	Light Level (Lux)
Bedroom - Dormitory	20-30 FC	200-300 lux
Cafeteria - Eating	20-30 FC	200-300 lux
Classroom - General	30-50 FC	300-500 lux
Conference Room	30-50 FC	300-500 lux
Corridor	5-10 FC	50-100 lux
Exhibit Space	30-50 FC	300-500 lux
Gymnasium - Exercise / Workout	20-30 FC	200-300 lux
Gymnasium - Sports / Games	30-50 FC	300-500 lux
Kitchen / Food Prep	30-75 FC	300-750 lux
Laboratory (Classroom)	50-75 FC	500-750 lux
Laboratory (Professional)	75-120 FC	750-1200 lux
Library - Stacks	20-50 FC	200-500 lux
Library - Reading / Study- ing	30-50 FC	300-500 lux
Loading Dock	10-30 FC	100-300 lux
Lobby - Office/General	20-30 FC	200-300 lux
Locker Room	10-30 FC	100-300 lux
Lounge / Breakroom	10-30 FC	100-300 lux
Mechanical / Electrical Room	20-50 FC	200-500 lux
Office - Open	30-50 FC	300-500 lux
Office - Private / Closed	30-50 FC	300-500 lux
Parking - Interior	5-10 FC	50-100 lux
Restroom / Toilet	10-30 FC	100-300 lux
Retail Sales	20-50 FC	200-500 lux
Stairway	5-10 FC	50-100 lux
Storage Room - General	5-20 FC	50-200 lux
Workshop	30-75 FC	300-750 lux

- 100 lux – This level of light is sufficient for lifts, corridors and stairs. Areas that are transitory for occupants and don't require any detailed work. Warehouse areas and bulk stores will also require this minimal light level.
- 300 lux – Assembly areas, like village halls require at least 300 lux.
- 500 lux – Retail spaces should have this as a minimum light level, as should general office spaces. This level should be suitable for prolonged work on computers, machinery and reading.
- More than 500 lux – If you have an area where intricate work is being carried out, then very high lux values may be needed. Where fine detailed work is being carried out, anything up to 2,000 lux can be used – this is usually only necessary in fairly unusual circumstances.

To activate the indoor illuminance calculation in EnergyPlus, users need to define the **Daylighting:Controls** and the **Daylighting:ReferencePoint** objects, even if no daylighting controls are actually implemented in the building simulation model.

The Annual Visual Resilience summary reports the Hours and OccupantHours of each illuminance level for each zone and the whole building.
